THIS paper extends the contribution on grounds of the first paper[1] in the following directions: experimentally, theoretically, and from the application standpoint.

The experimental data are from tests on twelve additional grounds driven in the field adjacent to the Sharon high-voltage laboratory. Seven of the grounds are in clay soil in a location which is naturally moist; these Meggered from 10 to 40 ohms. Two of the grounds are in naturally dry and gravelly soil, and one is in sand; the Megger resistance for these is from 60 to 220 ohms. The remaining two are in soil which consists of a mixture of clay and stones and Meggered from 25 to 190 ohms. The depth of the grounds ranges from 8 to 30 feet. Impulse and 60-cycle data are presented both for the single grounds and for parallel combinations. The impulse data extend up to 15,000 amperes and cover both positive and negative waves as well as other conditions. Tables, curves, and typical cathode-ray oscillograms present the more pertinent findings.

Analysis of the data shows that the decrease in resistance of driven grounds with increasing impulse current can be considered as the result of an increase in the effective radius and length of the rod. The agreement between experimental curves and curves calculated in this manner establishes the fact that the soil surrounding the rod breaks down at a critical voltage gradient. The two important factors associated with the soil are the resistivity and the breakdown gradient. In addition to providing a basic explanation of the physical processes involved, the analysis indicates that the impulse characteristic curve of a ground may be extrapolated with reasonable assurance to higher currents than the experimental data alone would permit. Furthermore, the methods established may be extended to study the relative characteristics of other types of grounds and arrangements, such as parallel grounds, the footing of tower structures, and so on.

This paper considers briefly the effect of lead inductance in combination with the ground proper, and it points out the practical importance of the lead or tower structure drop particularly for the rapid current discharge associated with direct strokes. Other factors affecting the impulse discharge are the conditions in the earth related to the soil and geological structure.

Physical Characteristics of Grounds

The 12 additional grounds, designated as *E, F, G, H, I, J, K, L, M, N, O*, and *P*, were driven in the spring of 1940 with the assistance of the Pennsylvania Power Company. The physical characteristics of the grounds are summarized in Table I. A view of the location and arrangement is shown in Figures 1 and 2. The one-inch-diameter rods and the rod in sand were driven with a sledge hammer; all other grounds were driven with a gasoline-operated hammer. The deeper grounds, *L* and *P*, are made up of eight-foot rods which are joined with suitable coupling.

All of the grounds except *M* are in natural soil and are located within 80 feet of the high-voltage laboratory. The grounds are well removed from fences and adjacent conducting objects with the possible exception of grounds *N* and *O*. Other details of adjacent objects and the terrain are apparent from the figures. Ground *M* consists of a six-foot diameter, ten-foot-deep hole packed with ordinary sand. The rod is driven down in the center of the sand. The sand was left to settle fully six months before the first serie sof impulse tests was made. At the time of the second series of tests a year later, the soil had gained considerable consistency and hardness.

The physical nature of the soil for grounds *E, F, G, H, I, J*, and *P* became apparent from the examination of a six-foot-diameter, ten-foot-deep hole (Figure 3) which was dug at a location some 30 feet from the grounds. While details of the strata and formation of the soil can vary considerably over this distance, nevertheless, Figure 3 indicates what to expect at the grounds. About six inches or more at the top is vegetation soil, then follows to a depth of four feet a combination of clay and gravel with a sprinkling of sand. Below this is a strata of about a foot of compact gravel and rocks. From five feet down to ten feet, the bottom of the hole, the soil is a thick blue clay. Water seeped in the hole at a depth of three feet. While this may not be the exact depth of the ground-water level, it indicates evidently that the soil for these grounds is naturally moist. It is difficult to state with certainty how far down bedrock lies. Rod *P* was driven with the gasoline hammer, straight down as far as it could be driven. Apparently it struck bedrock at 30 feet. According to the Geological Survey of Pennsylvania, bedrock in this district consists of fine-grained sandstone with alternate layers of shale.

Grounds *K* and *L* are located on the flat part of the embankment which rises

Table I. Physical Characteristics of Grounds

Ground	Date Driven	Diameter of Rod and Material	Depth Driven (Feet)	Nature of Soil	Spacing Apart and Location*

M	5-1-40	$^5/_8$-inch Copperweld	8	Ordinary sand used in construction work	6-foot diameter 10-foot deep hole filled and packed with sand

*For details on location, spacing, and terrain, see Figures 1 and 2.

Paper 42-22, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing December 10, 1941.

P. L. BELLASCHI is development engineer and R. E. ARMINGTON is an engineer, both with Westinghouse Electric and Manufacturing Company, Sharon, Pa. A. E. SNOWDEN is a student at Carnegie Institute of Technology, Pittsburgh, Pa.

The authors acknowledge the assistance in securing the test data of G. L. Candler, L. J. Besch, K. C. Kelley, and others of the Sharon high-voltage laboratory.

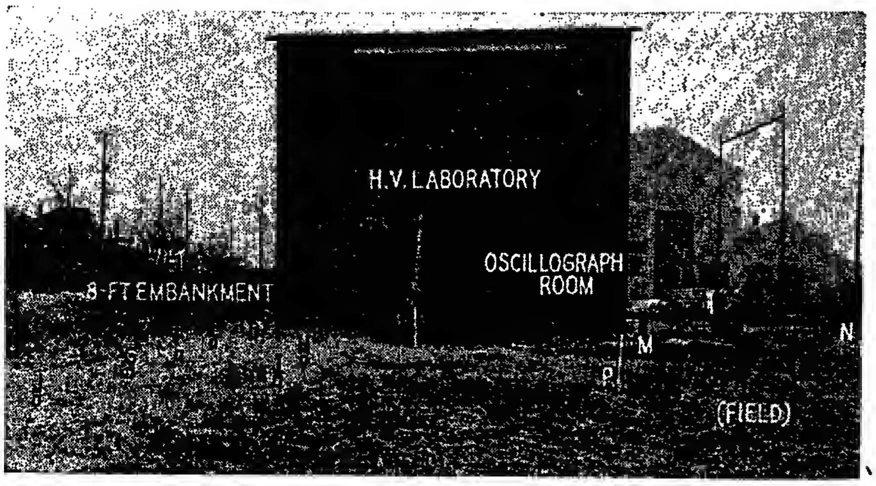

Figure 1. General view of grounds

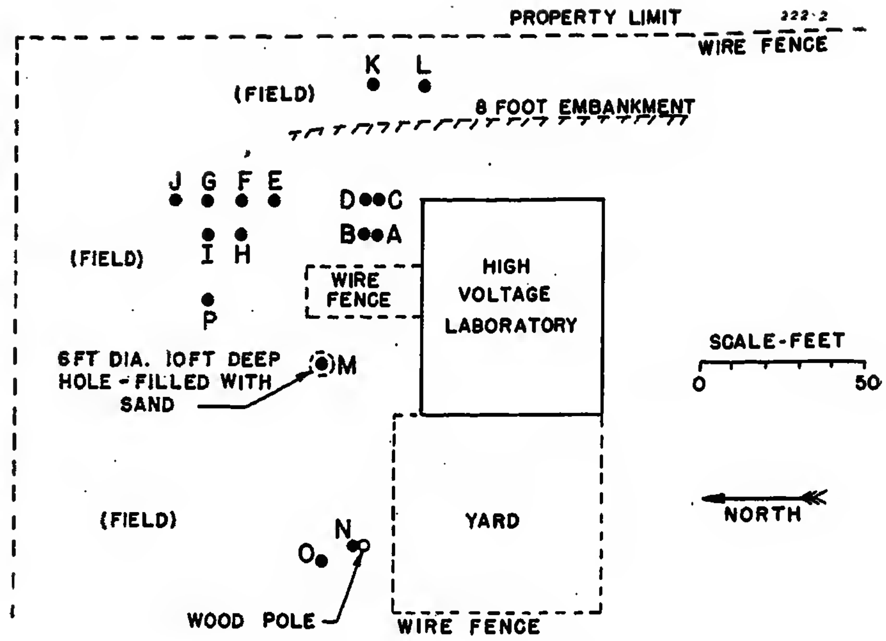

Figure 2. Arrangement of grounds

above the field where all of the other grounds are located. From *K* and *L* the land extends to the highway nearby, then up a hill rising beyond. A recent excavation of soil (October 1941) from the embankment near the grounds reveals that the top six feet are largely gravel with some clay, sand, and stones. Deeper down the soil becomes mostly clay with a mixture of sand. Due to the natural drain and the composition of the soil, grounds *K* and *L* are in naturally dry soil. This is particularly noticeable for ground *K* which in fact meggered the highest of all the grounds.

Grounds *N* and *O* are located in the flat terrain extending westward. Ground *N* is six inches from a distribution-line wood pole that was erected in 1934. Digging the hole for the pole at the time evidenced the presence of many large stones with clay, sand, and gravel. Ground *N* in particular and ground *O* to a lesser extent are embedded in soil of this nature. The terrain in which the twelve grounds are driven has a natural drain toward the Shenango River which lies a quarter mile westward at a level some 30 feet below.

The class and nature of the soil in which the twelve additional grounds are driven, as well as the physical characteristics of the grounds proper, represent a variety of typical conditions that should give rather wide scope to the investigation presented here.

Tests

The first series of impulse tests was completed late in the fall of 1940 before the ground frost started. Grounds *F*, *G*, *P*, *M*, and the parallel combination *F–G* were tested at this time. The results are summarized in Tables III and IV. For the grounds in clay (*F*, *G*, *P*) the wave is close to 20x50 microseconds, while for the ground in sand (*M*), it varies with increase in current from 8x125 to 25x65 microseconds. The currents for these tests cover a range of 400 to 15,500 amperes. Typical oscillograms are shown in Figure 5 (*AA* and *AV*) and Figure 6 (*AR*). Both positive and negative wave impulses were applied in the first series of tests.

The second series of impulse tests covers a period from August to September 1941. The results of these tests appear in Tables V, VI, VII, and VIII. The grounds tested are *F*, *H*, *I* and the parallel combination *F–G–H–I* all in clay soil; *M* in sand; and *K*, *L*, *N*, *O* in gravel and stones with a mixture of clay and sand. Some of these grounds were tested under the conditions of both fair weather and rain. In the preceding and other tests it was found that the polarity of the wave has little effect, and for this reason the second series of tests was made with negative waves, since this polarity appears to predominate in the lightning-stroke discharges to earth. In addition to the waves used in the first series, tests were

also made with an 8x25-microsecond and a longer wave. The wave form and duration of the impulse for the tests on each ground are given in the tables. Typical oscillograms for these tests are shown in Figure 5 (*AL* and *AZ*) and Figure 6 (*CI* and *BE*).

Sixty-cycle measurements of the grounds have been recorded from time to time. Most of the readings were recorded with a Megger. These were taken through the assistance of the Pennsylvania Power Company in the conventional manner. In a few of the tests, the voltmeter-ammeter method was applied. This and previous investigations show that the Megger and the voltmeter-ammeter methods give practically the same resistance value. The two methods are, therefore, considered one and the same, and the data obtained from them are designated as 60-cycle resistance. In addition to the 60-cycle resistance measurements of single grounds and parallel combinations, the voltages developed from one ground to adjacent grounds were studied. The results of these tests are reported in Table IX. Similar tests made with impulse currents will be discussed in another section.

The method of test has been described in the first paper. Briefly, the impulse generator and the instruments are grounded to the common, low-resistance ground of the laboratory, which meggered for this investigation from 0.3 ohm to 0.9 ohm, and averaged 0.5 ohm to earth. The impulse voltage is recorded at the cathode-ray oscillograph through a voltage divider, and the current is recorded by means of a suitable shunt inserted in the grounded end of the impulse generator. Three values of impulse generator capacitance have been used, as stated in the tables. The impulses corresponding to each are nominally 20x50-, 8x25-, and 20x120-microsecond waves, the specific form depending on the resistance of the ground. The superimposed oscillations appearing on the front of the wave are due primarily to the combined effect of the stray capacitance and series inductance in the test circuit. For instance, *AR* of Figure 6 is an oscillogram with more than the usual amount of superimposed oscillations. These have no major effect on the ground proper but render difficult the analysis of the oscillograms below about three to five microseconds. It is an established principle that superimposed oscillations resulting from stray capacitance C_1 and series inductance L_s in the generator circuit may be damped out by a series resistance of $2\sqrt{L_s/C_1}$ or a load resistance of $^1/_2\sqrt{L_s/C_1}$. The series resistance is impractical for it materially limits the current delivered to the ground. A calculated resistance of 150 ohms was shunted across the surge generator with the improvement in the wave generated and applied as shown in oscillogram *CI* of Figure 6. Oscillograms *AR* and *CI* are directly comparable.

60-Cycle Characteristics

Sixty-cycle measurements for the 16 single grounds and five parallel combinations, taken over a period of two years, are plotted in Figure 4. The curves for the grounds in clay soil are grouped in the upper half of the chart; those for the grounds in sand, gravel, and stone are in the lower half. It is apparent that the seasonal variation of the resistance of grounds follows a cycle essentially inverse to the temperature cycle. While temperature appears to account largely for the seasonal change, rain precipitation, long dry spells, natural moisture content, composition of soil, and other factors can affect the resistance. For the grounds in clay, the variation from the annual mean resistance ranges from 10 to 20 per cent. The grounds in sand, gravel, and stone are subject to variations of 25 per cent and even more from the annual mean resistance. Since the annual variation of the average temperature of the top ten feet of soil would be in the order of 10 to 15 degrees centigrade, the temperature coefficient of the resistance of the soil is about two to three per cent per degree centigrade. These characteristics check the results reported by other investigators.[2,3,4] The deeper the ground is, the less will be the seasonal variation. For instance, *L* is twice as deep as *K* and has half the per cent variation in resistance. The seasonal change in the resistance of ground *P* which is 30 feet deep in clay soil is about eight per cent compared to 20 per cent for the nine-foot ground *A* also in clay. Ground *N*, embedded largely in stones, suffers very wide seasonal fluctuations in the 60-cycle resistance. The instability of this ground was further evidenced by the fact that while the 60-cycle measurements of all

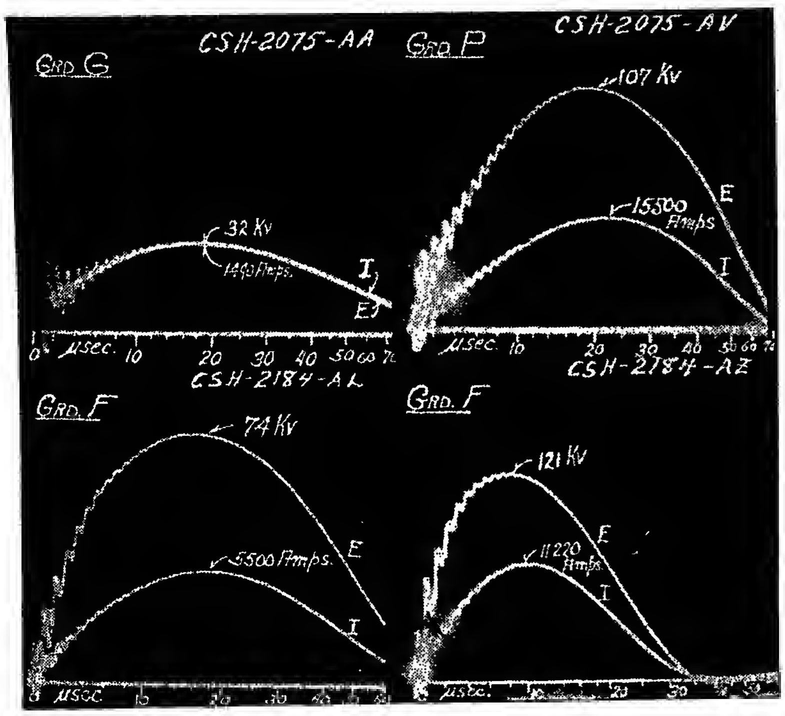

Figure 5 (left). Typical oscillograms of impulse currents and voltages (grounds in clay)

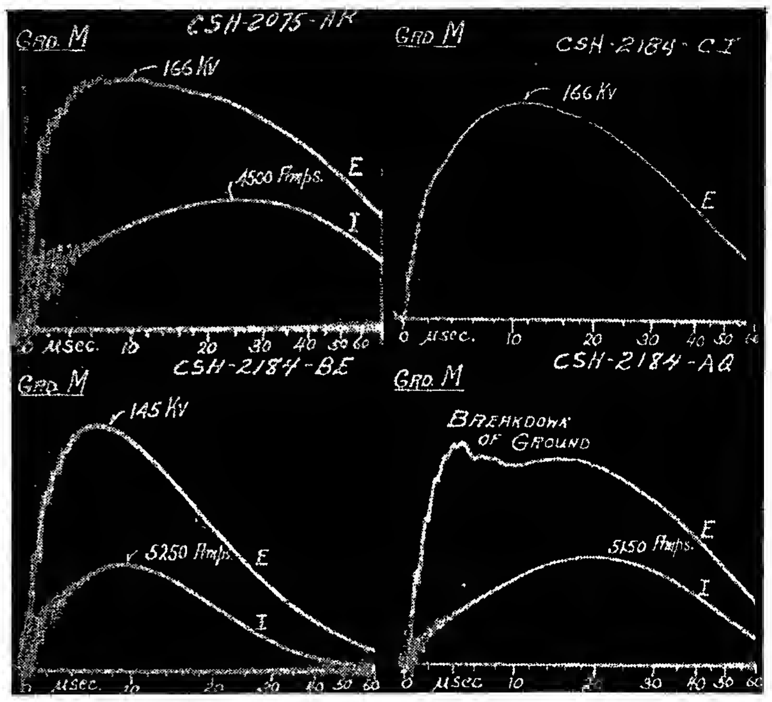

Figure 6 (right). Typical oscillograms of impulse currents and voltages (ground in sand)

the other grounds could be duplicated at a given time within the usual small experimental error, the check measurements of ground N would show wide variation.

The physical dimensions of the rod and the resistivity of the soil determine the 60-cycle resistance of a driven ground. The relationship is given in equation 1 of appendix I. While the physical dimensions are well defined, the resistivity of the soil may only be approximated, since it varies with the temperature and depends on the moisture content of the soil, the physical and chemical composition, as well as on other factors. Moreover, the soil may not be homogeneous even within the limited volume surrounding the rod, nor is the temperature constant from the surface down to the effective depth of the ground. All this is apparent from a study of the data for grounds, E, F, G, H, I, J in Figure 4. These grounds physically are identical and are in clay soil, driven within an area 10 by 30 feet. Over a period of one year, the resistivity of the soil for the individual grounds as determined from the equation ranges from 7,000 to 13,000 ohm-centimeters with an over-all average for the six grounds of 9,000-ohm-centimeters. Even when a suitable correction for the temperature is applied, the resistivity of the individual grounds for measurements taken at a given time may vary ±25 per cent from the average of the six grounds. In view of these inherent difficulties of calculation, direct measurement of the grounds remains to this day the practice.

Until more is known of the resistivity of soils, equation 1 cannot be applied with sufficient assurance to predetermine the resistance of a ground. However, certain principles are apparent and practically useful. For instance, according to equation 1 ground P (29 feet deep) should

measure 43 per cent of the resistance of a ten-foot ground driven in the same clay soil as E, F, G, H, I, J. Experimentally, ground P is 48 per cent of the average resistance of the six grounds. Equation 1 is also useful to determine the resistivity of different soils. Let us consider ground K in gravel, M in sand, and the grounds in clay. From the data we find that the average resistivities of the clay, sand, and gravel soils in this investigation are respectively 9,000, 20,800, and 41,800 ohm-centimeters or the resistivities are in the ratio of 1.0, 2.31, and 4.65.

For grounds in parallel, the 60-cycle resistance depends on the physical dimensions of the individual rods, the spacing and geometrical configuration of the rods, and the resistivity of the soil. The formulas and relationship for the parallel-ground arrangements in this investigation are discussed in appendix I. When the soil is fairly homogeneous, it is possible to determine the resistance of grounds combined in parallel, provided either the resistances of the single grounds are known experimentally, or the average resistivity of the soil has been established. Calculated and experimental data for the parallel grounds are compared in Table II. Grounds E, F, G, H, I, J in clay are in fairly homogeneous soil. The calculated resistance for the parallel pairs, F–G and H–I, is 57 per cent of the average single-ground resistance, for the four grounds F–G–H–I in a square arrangement and E–F–G–J in a row, it is respectively 35 and 33 per cent. The agreement between the calculated and experimental values for the two pairs, F–G and H–I, is within three per cent. For the two parallel groups, F–G–H–I and E–F–G–J, the agreement is within ten per cent. Part of the difference is accounted for by error in measurement, part is due to the assumptions in the calculation. Methods for determining the parallel resistance of two rods driven at different depths, as grounds K and L, have been developed. The calculated and experimental values for these two grounds which are in gravel lie within ten per cent of each other. A difference of 25 per cent is found for ground N–O in parallel. These two rods physically are identical. The large discrepancy is due likely to the instability of ground N, which is driven close to a wood pole, adjacent to a fence and possibly to other conducting objects in the soil, and is embedded in rocky soil. In summary, the resistance of parallel grounds can be calculated with good engineering approximation as a per cent of the resistance of the individual grounds, provided the conditions of the soil are fairly homogeneous, and no major extraneous effects are present.

The 60-cycle data in Table IX show that 85 per cent of the voltage applied to

a single one-inch diameter rod appears within a radius of about ten feet from the rod. In the case of four rods in parallel which correspond to the four legs of a tower structure in the earth, 75 per cent of the voltage drop is absorbed within the first ten feet from the footings. Conditions of the soil can change this distribution of voltage and gradients, but on the whole, these data are in good agreement with the findings of other investigators.[4] In fairly homogeneous soil, it is apparent that the resistance of grounds is determined largely by the mass of earth within a few feet of the rods. In this confined region relatively high gradients may be developed, particularly adjacent to the rod. Analysis of the voltage distribution has been made and the results agree with the experimental data.

Impulse Characteristics

A. Variation of Resistance With Current

This and previous investigations indicate that when impulse currents are applied to driven grounds, the resistance decreases considerably with increasing current. The nature of this decrease can be shown by plotting the apparent resistance (crest voltage divided by crest current) against the crest current, as illustrated in Figures 7 and 8. To compare kinds of soil and types of grounds, the ratio of apparent impulse resistance to 60-cycle resistance is plotted against the crest impulse current. This curve is called the "impulse characteristic" of the ground: Figures 9 and 10 are examples.

The physical processes accounting for the decrease in resistance are considered in the next section.

Briefly, according to this analysis, the soil breaks down at a critical gradient, increasing the effective radius and length of the rod. The analysis shows that the effective radius is proportional to the current above critical breakdown current which corresponds to critical gradient at the rod surface.

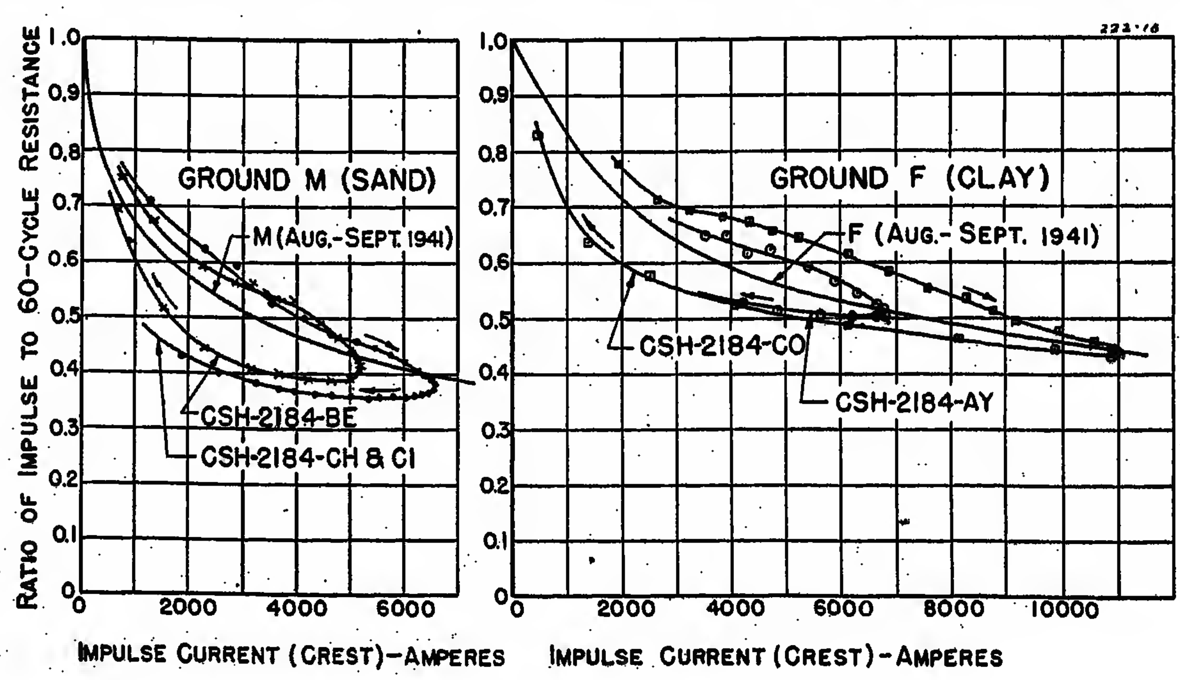
B. Factors Affecting Impulse Characteristic

The impulse resistance data of Tables III and V for ground *F* in clay and of Table VII for parallel ground *F–G–H–I* all in clay are plotted in Figure 7. Similarly the data of Tables IV and VI for ground *M* in sand are plotted in Figure 8. These figures show the effect on impulse resistance of the polarity of the wave, the wave form, the seasonal changes, and other influencing factors due to the weather such as rain.

Present data confirm that polarity has little effect on impulse resistance. Within the range of waves applied in this and the previous investigation (6x13 to 20x120), the wave of the impulse does not affect in an appreciable amount the impulse resistance characteristic.

On the other hand, a seasonal variation is clearly in evidence and is an important factor. For instance, the impulse resistances at 1,000 amperes for grounds *F* and *M* are subject to about the same per cent variation as the corresponding 60-cycle resistances. The seasonal effect is particularly marked at the

Figure 16. Variation of ratio during impulse current discharge compared with characteristic



low and medium currents but decreases at the higher currents. Tests on these grounds made within a few days of each other, both in fair weather and under or after sustained rain, indicate that rain does not affect the impulse resistance appreciably.

According to the analysis referred to previously, there are two properties of soil which determine in a large measure the impulse characteristic of a ground driven in it. These are the resistivity which determines the gradient for a given current density and the critical gradient at which the soil breaks down. The influence of soil on the impulse characteristic of grounds is illustrated in Figure 9. For comparison of results, curves for the similar grounds, *F*, *M*, *K*, and *N* are taken respectively from the data of Tables III, IV, and VIII. Considering critical gradient the same for two soils of different resistivity, the impulse characteristic of a rod driven in the high-resistivity soil will be moved to the left of the impulse characteristic of a similar rod in the low-resistivity soil by an amount approximately equal to the ratio of the lower resistivity to the higher resistivity. This relation is apparent from the curves in Figure 9 for grounds *F* in clay, *M* in sand, *K* in gravel and stones with clay, and *N* in stones with clay. As stated previously the 60-cycle soil resistivity for clay (*F*), sand (*M*), and gravel (*K*) are in the ratios of 1.0, 2.3, and 4.7. The characteristic curves for the three grounds are displaced to the left by an amount bearing an inverse relation to the corresponding resistivities of the soils. In short, grounds in very low-resistance soils approach the flat characteristic curve through unity which corresponds to a metallic conductor, while grounds in high-resistivity soil and of high resistance have a characteristic falling abruptly to low ratios. Grounds driven in high-resistivity soils such as *N*, *K*, and to a lesser extent *M*, may suffer in addition major breakdowns in the body of the soil, beginning at medium or even rather low currents, thus accentuating the characteristic still more. The voltage oscillogram of Figure 6-*AQ* illustrates a major breakdown in the body of the soil for ground *M* which occurred at a rather high current. This tendency for high-resistance grounds to break down at low currents has the effect of bringing closer together the resistance of low- and high-resistance grounds for high currents. For instance, ground *K* in gravel has a Megger value about six times as high as *F*,

yet on a 5,000-ampere impulse discharge, it has an impulse resistance only twice that of F. All things being equal, a ground inherently low in 60-cycle resistance is desirable and preferred.

The influence of the effective length of rod in the earth on the impulse characteristic of grounds is illustrated in Figures 9 and 10. For comparison of results, the curves for grounds P and F in Figure 9 are from the data in Table III, and the curves for grounds F, H, and I, and F–G–H–I in Figure 10 are from Tables V and VII. Following the analysis previously mentioned, the impulse characteristic for a long rod, compared to that for a short rod of the same diameter and in the same soil, lies displaced along the current axis in proportion to the ratio of the lengths. As an example in Figure 9 the characteristic is shown for rod P which has 2.9 times the length of F. For the same ratios of impulse to 60-cycle resistance, the curve corresponds to currents from 2.2 to 3 times the values for F. The curve for the parallel ground F–G–H–I, Figure 10, is also compared with a single ground. Ground F which is representative of the four single grounds is used for this comparison. The total length of the four rods is four times the length of a single rod, and the characteristic of F–G–H–I would, therefore, be displaced to the right of F by a factor of four except for the mutual effect. For a ten-foot spacing the mutual effect is not great. For the same ratios the characteristic of parallel ground F–G–H–I lies displaced to currents that are two to four times the

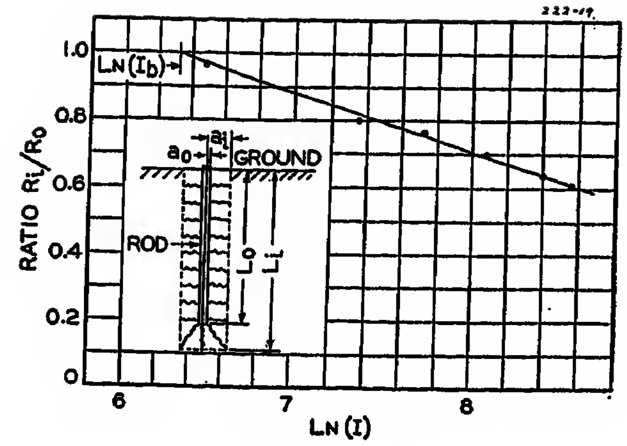

Figure 19. Method of determining the impulse characteristic of driven grounds

currents corresponding to the characteristic of *F*. There are other factors in regard to parallel grounds which will be discussed later.

The presence of metal fences, pipes, and other extraneous objects located adjacent to a driven ground can materially affect the impulse characteristics of the ground. This is the case for grounds *N* and *O*. The particular point to note here is that for the same soil, the ratio of impulse to 60-cycle resistance when referred to unit length of rod or to current density at the rod surface is a fairly typical form of curve which is a characteristic of the soil; although a departure from this characteristic may be expected even for grounds driven in presumably identical soil. This variation is due to the fact that the soil may not be altogether homogeneous and entirely the same throughout the mass of earth in which the grounds are driven, but can vary considerably from location to location as the curves for *H*, *F*, and *I* in Figure 10 clearly demonstrate. It is apparent from Figure 3 that a soil which for convenience may be classified as a kind can vary even for a single ground.

C. Analysis of Impulses

Valuable information concerning impulse characteristics can also be obtained by a direct analysis of the individual oscillograms. The method used is to plot the voltage and current from a given oscillogram to a uniform time scale and plot the resistance throughout. Typical oscillograms for grounds in clay, sand, and gravel are plotted and examined in Figures 11, 12, 13, 14, 15, and 18. Some of these oscillograms are practically free of superimposed oscillations on the front, as discussed in a preceding section with reference to oscillogram *CI* of Figure 6. In others these extraneous effects are averaged out.

In Figures 11 and 18, the resistance of ground *F* in clay is analyzed during the discharge for impulses close to 10,000 amperes crest. These results are in substantial agreement with the previous studies[1] on single grounds in clay soil. At the start of the impulse, the resistance appears to be the same as the 60-cycle value, dropping with the rising current on the front and reaching a minimum near and just beyond the crest current. As the current recedes beyond the crest, the resistance rises, apparently returning or directed toward the initial value. With this high current, the resistance does not vary more than 15 per cent from the minimum value within ten microseconds of the crest current. For lower currents the variation is less. As illustrated in *AA* of figure 5, for moderate currents the resistance varies only a small per cent over a relatively wide range of the discharge before and after crest current. For currents in the order of 5,000 amperes for a 10-foot ground (*F*) and 15,000 amperes for a 29-foot ground (*P*), as shown in *AL* and *AV* of Figure 5, the variation over some ten microseconds before and after crest is still within ten per cent of the minimum

Calculated and experimental curves compared

value. In view of this small variation, the impulse resistance can be defined adequately as the ratio of crest voltage to crest current.

For the ground in sand (*M*) due to the higher resistivity of the soil, a greater variation is naturally encountered at the currents mentioned above. Figure 12 strikingly shows that the initial drop in the resistance from 65 ohms to 31 ohms at five microseconds follows rapidly the corresponding rise of the current from zero to two-third crest. As these oscillograms and the data in Tables IV and VI show, the resistance values of ground *M* corresponding to crest voltage and to crest current for these higher currents may differ as much as 30 per cent. Practical considerations have suggested to the authors that the ratio of crest voltage to crest current be accepted as the resistance, but to avoid possible misinterpretation, it is designated as the apparent resistance. As shown in Figure 14, even greater variation in the resistance is noted for ground *K* in gravel. An abrupt change from the initial value of 150 ohms to 60 ohms occurs in the first two microseconds. This rapid drop possibly is partly due to a major breakdown in the soil.

In Figures 11 and 18 the resistance curve of the clay ground *F* is indicated as a dotted line, dropping rapidly from the 60-cycle value. Even with good smooth oscillograms, a difficulty, in determining the true resistance initially and on the steep rising front during the first few microseconds, arises from the fact that the voltage (E) in addition to the resistance drop (Ri) includes an inductive drop (Ldi/dt) due to the rapid rising current and the presence of some inductance in the ground proper and the connections. For this reason, the curves determined from the ratio of voltage to current (E/I), which closely represent resistance down to three or four microseconds, are dotted in below these values. Estimating the inductance and correcting for the inductive drop, the authors find that the curve of the true resistance still points essentially toward the 60-cycle value initially at time zero. In Figure 13 is presented a similar analysis for parallel grounds *F–G–H–I* for an impulse in the order of 12,000 amperes crest. Up to this current the variation of the resistance for this ground, as is expected, naturally is relatively small. The true resistance during the discharge is shown by the full line. The high ratio of inductance to resistance inherent in this low-resistance ground thus shows emphatically the presence of the inductive effect (dotted line is E/I) in the early part of the discharge. For the higher-resistance grounds as *M*, the initial inductive drop is less prominent than for *F*, so that the ratio E/I in Figure 12, even below three or four microseconds, practically corresponds to the true resistance of ground *M*.

From the initial abrupt rise or "kick" of the voltage and the initial rate of rise of the current, scaled from a number of oscillograms, we estimate that the inductance as measured is about 15 microhenrys. Actual calculations of the inductance based on the dimensions of the driven rods and the lead connections of

Calculated and experimental curves compared

the test confirm this value. About a third of the inductance as measured is in the rod proper, and even less in the large mass of the earth path of the discharge. The remainder, about ten microhenrys, is picked up in the leads, partly in the short segment of the discharge circuit proper from the top of the rod to the potential lead, and a greater part induced from the discharge circuit in the potential lead. The potential lead extends some 30 feet to the voltage divider, which is located adjacent to the oscillograph room.

The variation of the ratio of impulse to 60-cycle resistance during discharge for grounds F and M and currents from 5,000 to 11,000 amperes (crest) is shown in Figure 16. The ratio is plotted against current and is compared to the impulse characteristic (ratio for crest current) for each of the two grounds. The variation during discharge follows fairly close to the characteristic, intersecting it near crest current, and then returns below the characteristic, describing a considerable loop much in the same manner as found in the first investigation.[1] Since an inductive drop is present for the rapidly increasing part of the current, the true resistance curves would be even closer for the downward part than indicated. The analysis of these data and the previous curves establish that the variation of the true resistance rapidly follows the current with no appreciable time lag for wave fronts as fast as some two or three microseconds, the limit that the data can be interpreted. On the basis that the lowering of the resistance is a breakdown or sparking phenomenon consisting of small arcs, theoretically it stands to reason that little or no time lag in the change of the resistance would be expected for wave fronts longer than one or two microseconds. The exact fundamental mechanism which determines the lowering of the resistance is not well defined and established, and it is quite possible that the true resistance for a very rapid rise of current to crest in one microsecond would result in a time lag in the decrease of the resistance from high to low value.

It is apparent from the oscillograms and the figures that the effect of the high resistance of the ground in the initial stage of the discharge is to displace the voltage wave from the current and give it a more abrupt and steeper front. This is clearly shown by a comparison of Figures 11, 12, 14, and 15 in their sequence order. The higher the resistance of the ground the more accentuated is the effect. The inductance of the ground and lead connection also adds to displace the front of the voltage even further forward. Therefore, the rate of rise of the voltage for the same current is proportionately greater for grounds in high-resistivity soils and having high inductance associated with them. Due to the sustained ionization process, the low value of the resistance at and beyond crest current is sustained for a good part of the duration. The subsequent recovery of the resistance does not seem to have particular practical significance.

The question may be raised as to the resistance of a lightning-stroke discharge direct to earth. Figure 15 records a typical discharge of 8,300 amperes crest to the open field (clay soil) adjacent to the laboratory. All driven grounds and conducting objects are well removed from the spot hit. A small part of the grass at the earth's surface was scooped out and thrown up by the discharge. The resistance initially is very high, but as the discharge penetrates or pierces the earth, it drops to 60 ohms in five microseconds and still further to a minimum of 18 ohms at crest current. The stroke discharge, therefore, "drives" its own ground, for the resistance attains a value not much greater than that of a ten-foot rod driven in soil similar to that struck. On the other hand, the initial high resistance develops a very steep-front voltage wave which reaches 90 per cent of its crest in about a microsecond: long before the current reaches its crest. The resistance continues to fall rapidly so that at crest current the voltage has dropped to 75 per cent of its crest value. There are a number of ramifications to this problem. These tests indicate that the resistance characteristic of the location hit by lightning may influence the rate of current discharge and, to some extent, limit the maximum current attained. The investigation of the influence of the earth on lightning should be continued.

D. Voltage Developed in Soil

The impulse characteristics of driven grounds are further revealed from a study of the voltages induced or developed on adjacent objects. Data on impulse tests of this kind are presented in Figures 17 and 18. In these tests impulse discharges from 1,000 to 10,000 amperes crest were

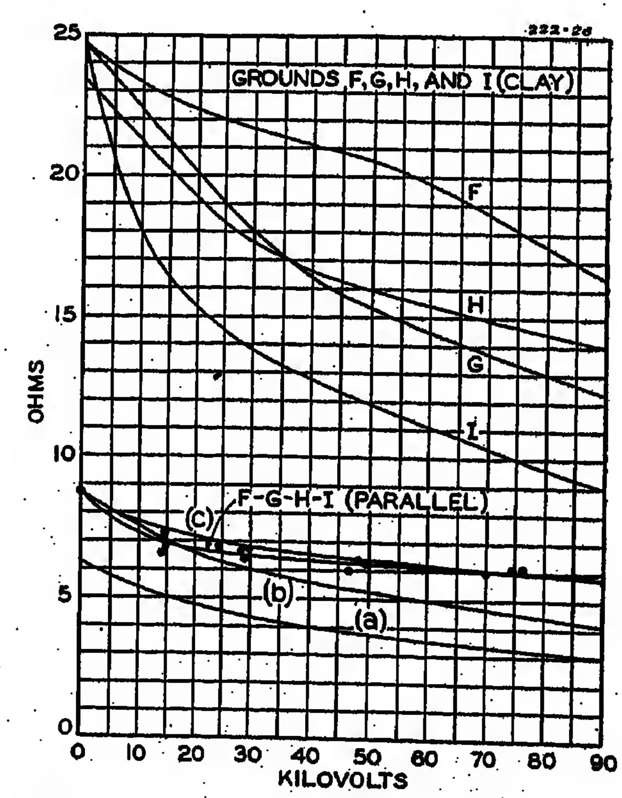

Figure 26. Method of determining impulse-resistance characteristic of parallel grounds from characteristics of component individual grounds

applied to ground F and the voltages V and V' measured respectively at F and E–H–G. The grounds E, H, and G are all spaced ten feet from F (see Figure 2) and are connected together in a group.

As the impulse current increases, the effective radius of F increases in proportion, and the ratio of V' to V should, therefore, increase; that is, a larger portion of the voltage drop should be outside the ten-foot radius. In Figure 17 the voltage developed on E–H–G is expressed as a per cent of the voltage at F so that the curve shows the variation of V'/V with the discharge current (crest). This ratio or coupling factor from a low current up to 10,000 amperes rises continuously, practically doubling in amount. These data further confirm that the effective size of the rod increases with the current.

In Figure 18 are reproduced oscillograms of the voltages and current and the variation of the coupling factor with the discharge. The voltage V' developed on E–H–G is of the same general form as the voltage V at F. The coupling factor V'/V naturally varies during the discharge. At crest current or slightly beyond, the effective radius and length of rod F reach a maximum; the coupling factor likewise rises to a maximum, and the resistance attains a minimum. As the current drops beyond crest, the sparking in the earth recedes, and ionization of the arcs subsides, so that the coupling factor falls off, and the resistance rises, both directed toward their 60-cycle values. From 20 microseconds (crest current) to 5 microseconds the coupling factor drops off. Still further down, two curves are shown, one dotted which represents the true coupling factor, and a heavy line through the circled dots which is merely numerically the ratio V'/V. The reason for the high ratio V'/V below five microseconds is found in the inductive effects and measurement. Due to the rapid current rise in the initial stage of the discharge, a voltage is picked up by the potential lead which runs some 30 feet from the grounds to the voltage divider. The lead is much the same whether V or V' is measured, with the result that an induced voltage of the same order is superimposed on the true voltage of the grounds. Thus the ratio V'/V below five microseconds does not represent the true coupling factor.

A curve has also been drawn on Figure 18 by dividing V' by I. This curve indicates the resistance outside the equipotential surface including E–H–G except for the first few microseconds which indicate inductive "kick." The resistance is practically constant, and, moreover, it is equal in value to the corresponding 60-cycle resistance, determined by taking 14.33 per cent of the 60-cycle resistance of ground F (see Table IX). This constant resistance shows that there is no change in the soil outside the ten-foot distance even for high currents.

Theoretical Considerations

This section deals theoretically with the physical processes that take place when ground rods carry impulse currents. The lowering of the resistance with increase of current is explained on the basis

**Due to the voltmeter resistance (283 ohms) the actual voltage is a small amount greater than the per cent value indicated. No correction made.

that at a critical current, a voltage gradient is attained at the rod surface causing the soil surrounding the rod to break down, thus increasing both the effective radius and length of the rod. The sketch insert in Figure 19 illustrates schematically the physical conditions which accompany a current above breakdown value. The irregular lines represent breakdown in the soil, and the dotted lines the enlarged effective dimensions of the rod. On this basis formulas and methods for determining the characteristic curves of grounds are developed. That breakdown of the soil may account for the lowering of the resistance had been proposed previously,[1,5,6] but the methods reported here enlarge on a quantitative approach which was set forth soon after the completion of the first paper.[7]

On the basis of the foregoing theoretical explanation, there should be for each ground a current at which breakdown starts. This current we shall designate as I_b. It is determined by plotting the ratio of impulse to 60-cycle resistance R_t/R_o versus the natural logarithm of the impulse current lnI. The best straight line is drawn through the points, and where it crosses the ordinate $R_t/R_o = 1$, lnI_b is established. This procedure is illustrated for ground C in Figure 19. The value of I_b for grounds C and D, determined from the data in Table IV of the first paper, and for grounds F, G, P, and M, determined from the data in Tables III and IV of this paper, are tabulated in Table X. For all the grounds but M, R_t is obtained from the ratio of crest voltage to crest current. In the case of ground M (sand), R_t is obtained from the ratio of crest voltage to the current corresponding to crest voltage. In Table X are given also other essential data on these grounds; namely, the dimensions of each rod, the 60-cycle resistance, the soil resistivity ρ_o, and the critical gradient g_c at which the soil breaks down. The latter two quantities are determined respectively from equations 5 and 7 in appendix II.

Let us consider first the lowering of the impulse resistance as caused by the increase in the effective radius of the rod, disregarding the increase in length. On this basis we have equation 10 which relates the ratio R_t/R_o to the current I. From the data in Table X substituted in the formula, curves are calculated for the grounds C, D, F, G, M, and P. These are shown dotted in Figures 20, 21, 22, and 23, and may be compared directly with the experimental values. It is of interest to note that the effective radius of the ten-foot rods in clay increases to about ten inches at 10,000 amperes.

A refinement is introduced considering both the increase in radius and the increase in length as indicated by equations 11, 12, and 13 of appendix II. A curve for ground C has been calculated from these equations, substituting established values of a_t and estimated values of L_t. This curve is plotted in Figure 20. A rapid increase in the length at low currents, reaching an increase of about ten per cent of the length (L_o) at the higher currents, accounts for the lowering of the curve as shown.

The difference between the calculated curves and the experimental results is due,

in part, to the various simplifying assumptions. We have assumed that the soil is homogeneous, that soil resistivity stays constant, and that breakdown in the soil is not accompanied by a voltage drop. Each of these assumptions is not fully valid, yet is sufficiently justified for an engineering approach. Allowing for the increase in rod length as discussed for ground C, and accounting for the voltage drop which accompanies breakdown, appear to bring the calculated curves for C, D, F, and G closer to the experimental data. The divergence for grounds M and P is apparently due to other factors which lower the characteristic at the higher currents a greater amount than the calculations indicate.

The validity of the breakdown process set forth above is further established by an analysis of the tests from which Figure 17 is obtained. Considering that the radius of F increases with current in the manner previously stated (equation 9, appendix II) and that the equipotential surfaces in the region included by E–H–G approach cylindrical form, the potential V' of E–H–G can be calculated as a function of current and is plotted in Figure 17 as the ratio V'/V. Other methods for calculating V' give essentially the same results. The agreement between experimental and calculated curves is apparent from the figure.

The procedure followed for a single rod can also be applied to parallel grounds. The methods are presented in appendix II. For two rods in parallel, the characteristic is given in equation 14, and for four rods arranged at the corners of a square, in equation 15. Calculated curves based on increase in radius only and experimental curves for parallel grounds C–D and F–G are compared in Figure 24. In these parallel grounds the two individual grounds in each arrangement are quite alike, and this similarity accounts for the close agreement between the calculated and experimental results. Allowance for the increase in the effective length of the rods with current would move the calculated curves in Figure 24 closer to the experimental curves in much the same manner as found for the single rods. The curves for the parallel ground F–G–H–I are plotted in Figure 25. The effect of the increase in length of the rods again is to move the calculated curve bodily down as described previously for other grounds.

The question arises whether the characteristic of a parallel ground may be predetermined from the characteristic curves of the individual grounds which comprise the parallel ground. In this connection ground F–G–H–I is examined in Figure 26, which shows resistance plotted against voltage. When an impulse is applied to grounds in parallel, the same voltage drop is present in each, and voltage is, therefore, used as the proper basis for comparison. In the figure the experimental characteristics are plotted and designated as F, G, H, I, and F–G–H–I. It is again to be noted that the single grounds differ. The characteristics of the four single grounds are first combined in parallel directly by the reciprocal relation as four completely independent grounds should be combined and are plotted in curve a. It is apparent that the mutual effect between the rods raises the resistance by an amount dependent on the mutual factor. For low current, the actual resistance for the four grounds in parallel is raised by a factor $0.35/0.25 = 1.4$ as found by equation 3, appendix I. Curve b is obtained by applying the factor 1.4 to curve a. Curve b follows the experimental curve at low currents but deviates at the higher currents, for the reason that the effective radius and length of the rods increase with current and the mutual factor becomes greater. The correct factor, which increases from 1.4 at low current to 1.65 at 10,000 amperes (62 kv), applied to curve a, thus gives curve c, which is the correct characteristic derived from the experimental curves of the four individual rods. Curve c compares favorably with the actual experimental characteristic of parallel ground F–G–H–I, and this comparison, therefore, shows that it is possible to predetermine the characteristic of a parallel ground from the experimental curves of the single grounds provided they are not too dissimilar.

Table X. Impulse Resistance Data for Ground Rods

Rod	Length Centimeters	Radius Centimeters	R_o Ohms	ρ_o Ohm-Centimeters	I_b Amperes	g_c Volts Per Centimeter
C	228	1.27	39.5	10,150	550	3,070
D	228	1.27	38.5	9,950	495	2,710
F	295	1.27	27.5	8,720	345	1,270
G	295	1.27	24.25	7,680	680	2,210
P	885	0.80	13.75	10,250	1,180	2,740
M	236	0.80	118	28,900	173	4,240

The foregoing analysis establishes that the decrease in resistance of driven grounds with increasing impulse current is due to the increase of effective radius and length. The agreement between calculated and experimental curves is close enough to establish that the soil surrounding a rod does have a critical voltage gradient at which it breaks down. This gradient is in the order of one to four kilovolts per centimeter. It follows from the equations, provided ρ_o and g_c of the soil are known, that the breakdown current I_b can be determined. Then from the dimensions of the rod or driven-ground system and the equations, the impulse characteristics of the grounds can be calculated. The need for further experimental study of the factors ρ_o and g_c is apparent.

In addition to providing a basic explanation of the physical processes involved, the results of this paper show that the calculated characteristic curve of a ground may be extrapolated with reasonable assurance to higher currents than the experimental data permit. Furthermore, the methods may be extended to determine the relative characteristics of grounds for various conductors and arrangements.

Effect of Discharge-Circuit Inductance and Conditions of Earth

Other important factors connected with the problem of grounds are the effect of the discharge-circuit or lead inductance and the conditions in the earth. A full discussion of these factors lies within the scope of the third paper proposed in the introduction. However, in the interest of a more complete survey of the problem they are dealt with here briefly.

A ground installation physically consists of a lead or tower structure which connects the grounded part of the electrical apparatus (protective device, apparatus tank, overhead ground wires, and so on) to the ground proper in the earth. The downlead or tower essentially can be considered an inductance, while the ground proper acts as a resistance in the manner discussed previously. The lead or tower inductance becomes particularly significant when steep-front currents of high magnitude, rising to crest in the order of a microsecond, are discharged to earth. Analysis shows that for high rates of rise of current, the voltage developed in a 25- to 50-foot lead or a 50- to 75-foot tower may well attain and exceed the ground-resistance drop. This lead or tower drop is of short duration and is practically over in one or two microseconds. Besides the lead or tower inductance, appreciable inductance may be present also in the ground proper, as is the case for grounds driven deep into the earth, or for a counterpoise spread

over a wide area. Operating experience in the field [8] and the results of tests and co-ordination of station apparatus on steep-front impulses[9] corroborate the importance of inductance effects in protection.

For grounds of very high resistance, the capacitance of the rod or ground conductor to the mass of the earth is not entirely a negligible factor. The distribution of the electric charges in the earth preceding the current discharge through the ground is still another factor that requires study. Other factors related to the problem of grounds which require particular attention arise from the variation of the soil resistivity, the soil structure, the geology, and related questions.[8,10–14]

Summary

The 16 grounds tested are typical of those found in practice and represent a variety of soils and conditions. The resistance varies with soils, moisture, and soil conditions. A ten-foot ground Meggers 20 to 40 ohms in clay, 70 to 120 ohms in moist sand, and 100 to 200 ohms in a mixture of gravel and clay. The annual variation of this ground from the mean is 10 to 25 per cent, depending on the soil, and is less for deeper grounds.

The impulse resistance decreases with increasing current. It varies with season in much the same manner as 60-cycle resistance. Rain and weather conditions have little immediate effect. The impulse resistance is practically independent of polarity and of wave form within the range applied. The per cent decrease in resistance becomes greater with high-resistivity soils. During the discharge the resistance drops rapidly attaining minimum or impulse value near crest current and rises as the current decreases.

A method for determining the impulse resistance has been developed. At a critical gradient, the soil breaks down increasing the effective radius and length of the rod. Then from the equations in the appendix the impulse characteristic can be calculated. Curves calculated are in substantial agreement with the experimental results.

Various parallel combinations of single grounds were investigated. The resistance of parallel grounds, both 60-cycle and impulse, can be derived from the resistance of the component grounds.

The lead and ground inductance becomes particularly significant for rapid current discharges when the inductance drop may exceed the ground resistance drop.

Appendix I. Method of Calculating 60-Cycle Resistance of Single and Multiple Grounds

The formula used to calculate the resistance of single grounds is that given by H. B. Dwight.[15]

$$R_1=\frac{\rho}{2\pi L}\left[\left[\ln\left(\frac{4L}{a}\right)-1\right]\right] \qquad (1)$$

where

R_1 = resistance of single rod in ohms
ρ = soil resistivity in ohms per cubic centimeter
L = rod depth in centimeters
a = rod radius in centimeters

This formula may also be used to determine the soil resistivity from the dimensions and resistance of a ground. The following formula for two grounds in parallel is also given by Dwight.

$$R_2=\frac{\rho}{4\pi L}\left[\left[\ln\left(\frac{4L}{a}\right)-1+\ln\left(\frac{2L+\sqrt{S^2+4L^2}}{S}\right)+\frac{S}{2L}-\frac{\sqrt{S^2+4L^2}}{2L}\right]\right] \qquad (2)$$

where

R_2 = parallel resistance of two rods in ohms
S = distance between rods in centimeters

The following formula was derived by Dwight's method for four grounds of equal length arranged in a square

$$R_4=\frac{\rho}{8\pi L}\left[\left[\ln\left(\frac{4L}{a}\right)-1+2\ln\left(\frac{2L+\sqrt{S^2+4L^2}}{S}\right)+\frac{S}{L}-\frac{\sqrt{S^2+4L^2}}{L}+\ln\left(\frac{\sqrt{2}L+\sqrt{S^2+2L^2}}{S}\right)+\frac{S-\sqrt{S^2+2L^2}}{\sqrt{2}L}\right]\right] \qquad (3)$$

where

R_4 = parallel resistance of four rods in ohms
S = length of any side of the square in centimeters.

Formulas were also derived for four equally spaced rods in a straight line and for two rods of unequal length. The lack of complete symmetry of these arrangements makes the formulas rather complex, and for this reason they are omitted.

There are two methods commonly used for the calculation of grounds. Both methods employ the artifice of images by projecting an image upward a distance equal to the depth of the ground. The earth's surface thus bisects the rod, and all currents close to the surface flow parallel to it, satisfying the actual conditions. The earlier method, developed by O. S. Peters,[16] replaces the ground by an ellipsoid of revolution, whose minor axis is the diameter of the rod, and whose major axis is twice the depth of the rod. The capacitance of an isolated ellipsoid may be calculated directly, and from this, the resistance by the formula

$$R=\frac{\rho}{2\pi C} \qquad (4)$$

where C is the electrostatic capacitance of the ellipsoid. The more recent method, developed by H. B. Dwight, uses the rod in its exact shape and is based on the simplifying assumption that the charge distribution along the surface of the rod is uniform. Calculating for various points on the rod, the potential induced by this uniform charge, and dividing the total charge by the average induced voltage, Dwight finds the approximate capacitance of cylinder. This is converted to resistance by formula 4.

The two methods have their advantages: the former method lends itself readily to the calculation of equipotential surfaces and field distribution, while it is easier to calculate resistance for parallel grounds and noncylindrical rods by latter method. With typical values of L, a, and ρ, Peters' formula gives a resistance from five to ten per cent higher than Dwight's. This is expected since the surface area of the cylinder is greater than for the ellipsoid. It must be remembered, however, that both formulas are approximations, and that their accuracy decreases with decreasing ratios of L/a.

Appendix II. Method of Calculating Impulse Resistance of Single and Multiple Grounds

The basic formula used to calculate impulse resistance has the same form as that for 60-cycle resistance. Equation 1 of appendix I is adapted to the symbols shown in the insert of Figure 19, as follows

$$R_o=\frac{\rho_o}{2\pi L_o}\left[\left[\ln\left(\frac{4L_o}{a_o}\right)-1\right]\right] \qquad (5)$$

Considering the increase in the effective radius (a_t) of the rod resulting from breakdown of the soil at high current as discussed under "Theoretical Considerations" equation 5 can be rewritten

$$R_t=\frac{\rho_o}{2\pi L_o}\left[\left[\ln\left(\frac{4L_o}{a_t}\right)-1\right]\right] \qquad (6)$$

The effective radius of the rod is determined as follows. Since the voltage gradient along the surface of the rod is the product of current density and soil resistivity (ρ_o), the critical value of this gradient (g_c) at which the radius (a_o) of the rod starts to increase, is determined from the critical current (I_b)

$$g_c=\frac{I_b\rho_o}{2\pi a_o L_o} \qquad (7)$$

For current I above I_b, the gradient at the effective radius assumes critical value and is expressed by

$$g_c=\frac{I\rho_o}{2\pi a_t L_o} \qquad (8)$$

From 7 and 8

$$a_t=\frac{a_o I}{I_b} \qquad (9)$$

This value of a_t is substituted in equation 6 and the ratio of R_t to R_o can be written

$$\frac{R_t}{R_o}=\frac{\ln\left(\frac{4L_oI_b}{a_oI}\right)-1}{\ln\left(\frac{4L_o}{a_o}\right)-1} \tag{10}$$

Next let us consider the increase in length with current as shown in the sketch of Figure 19. Referring to equations 5 and 6 and allowing for the increase in length, we can express the ratio of R_t to R_o as

$$\frac{R_t}{R_o}=\frac{L_o\left[\left[\ln\left(\frac{4L_t}{a_t}\right)-1\right]\right]}{L_t\left[\left[\ln\left(\frac{4L_o}{a_o}\right)-1\right]\right]} \tag{11}$$

The relation of a_t to the current can be approximated by equation 9 or better determined from

$$\frac{I}{I_b}=\frac{a_tL_t}{a_oL_o} \tag{12}$$

The effective length L_t may be written as a function of the current

$$L_t=L_o+kI \tag{13}$$

where the factor k is constant only for limited ranges of current.

The impulse resistance for two rods in parallel can be obtained by substituting the proper values of a_t and L_t in equation 2 of appendix I. The ratio of R_t to R_o can then be obtained, and for reference purposes it is designated as equation 14. The impulse resistance for four arranged in a square can be obtained by a similar substitution in equation 3, and the ratio of R_t to R_o for this combination is designated as equation 15.

The Application of Voltage Regulators to Aircraft Generators

L. W. THOMPSON
ASSOCIATE AIEE

F. E. CREVER
ASSOCIATE AIEE

Synopsis: The use of high-capacity d-c generators on aircraft has required the development of regulators with rapid response, high accuracy, and with features for parallel operation of variable speed machines. The fundamental requirements of light weight, ability to withstand shock and vibration, and to give low radio interference were vital factors considered in the development. A device incorporating these features is described and analyzed. Results of tests on these equipments have shown that regulators with these features are vital to the operation of the electrical loads of modern planes, both the military and commercial types. The tests show that the requirements have been met with devices suited to high production methods.

THERE has been, and it seems safe to predict, will continue to be an increasing use of electrical devices in modern aircraft, both military and commercial. In order to supply the increased load, larger capacity generators than ever before utilized are being used. The generators are driven at variable speed from the main engines of the aircraft over a speed range of approximately two to one. Depending upon the size and use of the aircraft, an auxiliary power plant driving a constant-speed generator may be used in addition. A d-c system employing a 24-volt battery is in common use requiring a 28.5-volt bus voltage in the plane. The main generators must be controlled so as to maintain proper voltage for the battery and the various loads and, at the same time, insure close load division between the generators when operating in parallel. Close load division is important to allow utilization of the complete installed generating capacity.

Paper 42-47, recommended by the AIEE committee on air transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing May 5, 1942.

L. W. Thompson is engineer and F. E. Crever is administrative assistant and engineer, both in the generator voltage regulator engineering department, General Electric Company, Schenectady, N. Y.

The authors acknowledge the suggestions of T. B. Holliday and E. G. Haven which were helpful in the development of regulators for high-power aircraft generators.

The Importance of Generator Voltage Regulators

Voltage regulators play an extremely important part in making a system of this type practical. In fact, the system cannot be operated without suitable voltage regulators, since the variable-speed generators operating at low-flux densities at high speed are unstable to manual control. If the problem of parallel operation with close load division is accomplished by the same device, the importance of the voltage regulators in the system is immediately apparent.

Previous to the rapid increase in electrical loads on aircraft 12-volt d-c generators of small capacity had been used under the control of vibrating contact voltage regulators. Principal sources of trouble with the vibrating regulators were contact deterioration, radio interference, and failure to provide close load division of generators operating in parallel. Regulators of this type are inadequate for the larger capacity machines, on account of the increased power that must be handled in the generator field circuit which aggravates the troubles experienced on the small capacity machines. In this respect regulators for use in aircraft are closely following the history of regulators employed in stationary installations where the vibrating types have been largely displaced by other types. Direct-acting regulators have been successfully employed in stationary installation for sev-

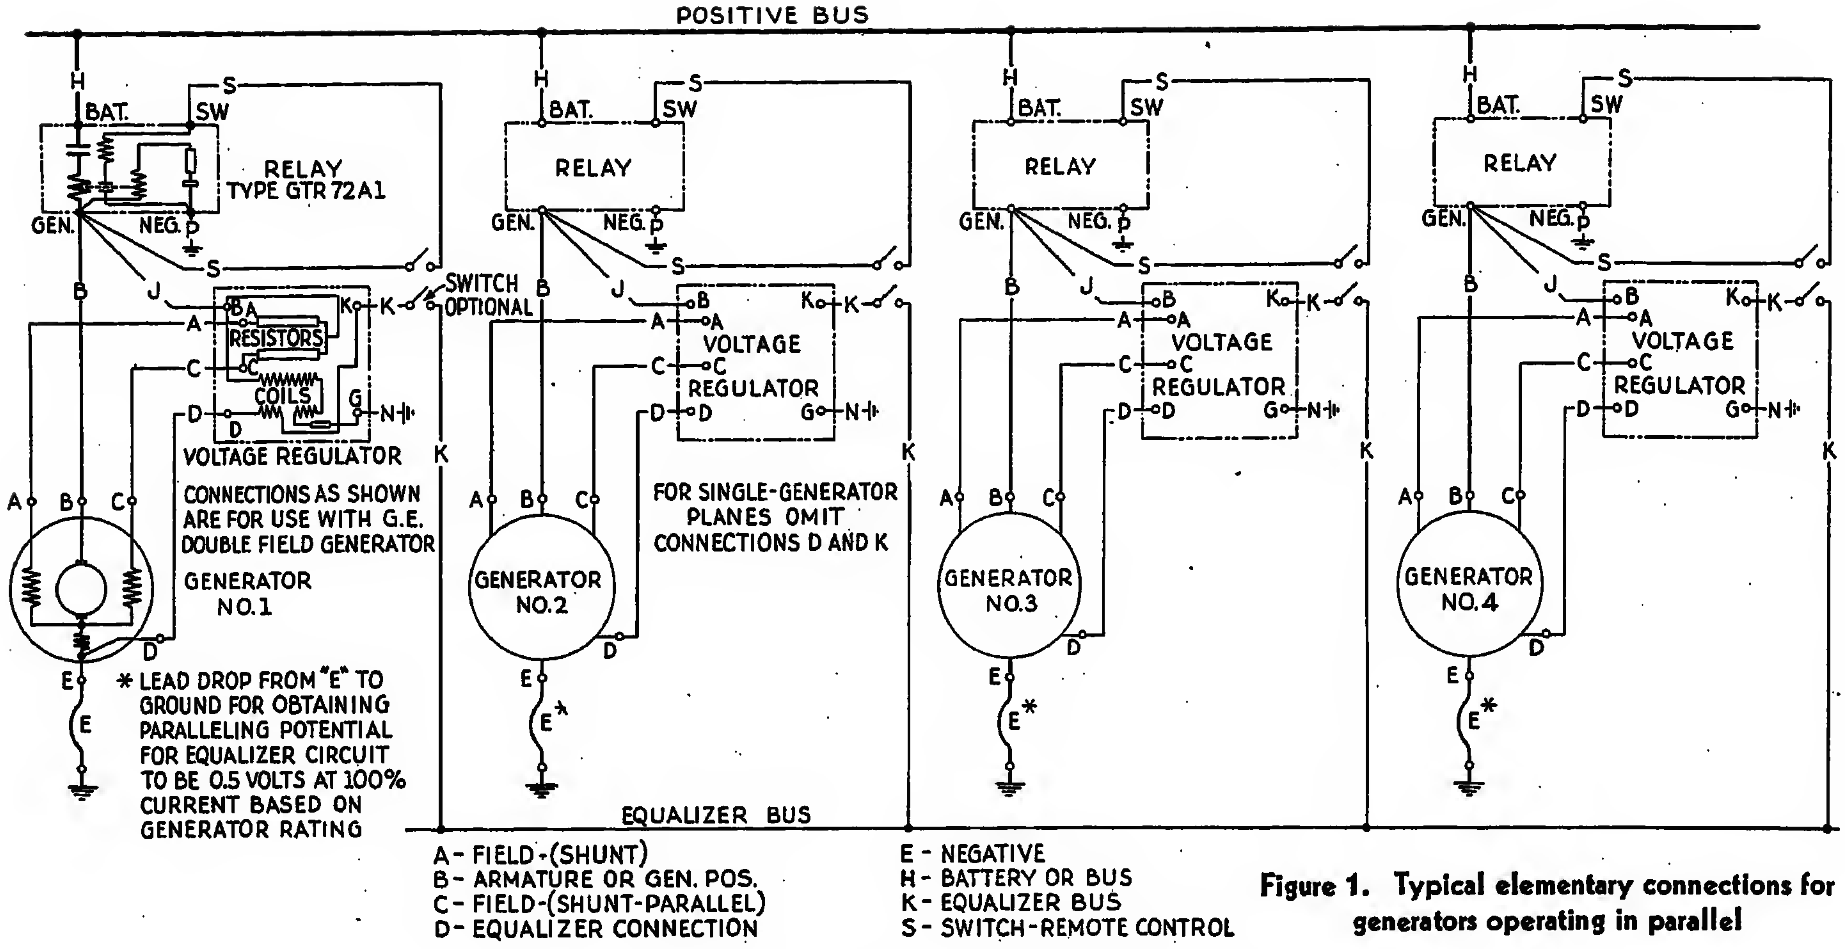

Figure 1. Typical elementary connections for generators operating in parallel

eral years both on a-c and d-c generators. Their record has been very good from a standpoint of reliability, low maintenance, and freedom from excessive radio interference. Principles and means of providing for parallel operation have been worked out, and a great deal of experience gained on stationary installations. It therefore seemed that such regulators could be successfully used in aircraft installation, provided the special problems incident to their installation in aircraft could be solved.

Primary requirements for aircraft installation

1. A minimum of weight.
2. Ability to withstand shock and vibration.
3. Operation over a wide temperature range (from −55 to +65 degrees centigrade).
4. Ability to operate over an atmospheric pressure range from sea level to high altitudes.

Secondary requirements to meet present day requirements

1. Readily adaptable to generators having different field characteristics.
2. Suitable to quantity manufacture.
3. Simplicity of adjustment.

A regulator based upon principles found satisfactory in stationary installation has been designed to meet both the primary and secondary requirements listed above.

The Type of Regulator Applied

This regulator is of the direct-acting type and has a magnetic circuit energized by windings through a diluting resistor from the voltage of the generator being regulated. The force developed by the magnetic circuit by virtue of the applied voltage is balanced against a spring. At the required voltage setting the force of the armature overcomes the calibrating spring and operates in succession a multiplicity of contacts to insert small steps of resistance into the field circuit of the generator to maintain the voltage at which the regulator is balanced. It is necessary to so design the magnetic circuit that the mechanical forces are just balanced by the electromagnetic forces for all positions of the regulator armature at the same applied voltage.

By using a sufficiently large number of contacts the operation is made nonvibrating in nature, and the power handled per contact is kept below the critical arcing limit.

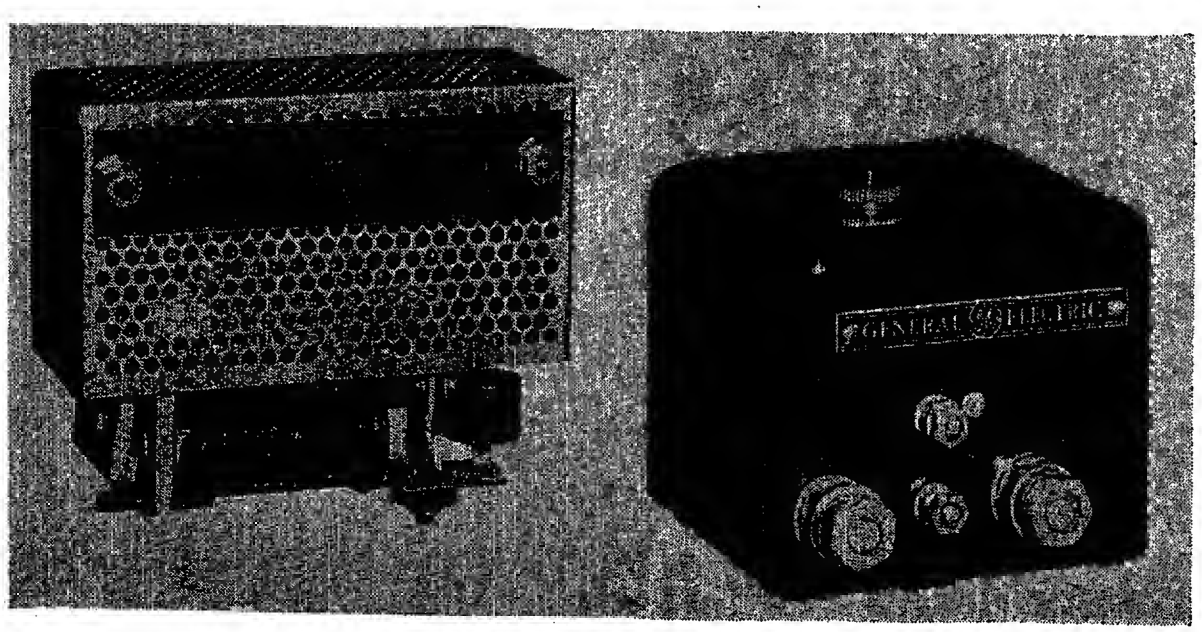

Figure 2. Plug-in-type regulator and relay for aircraft installation

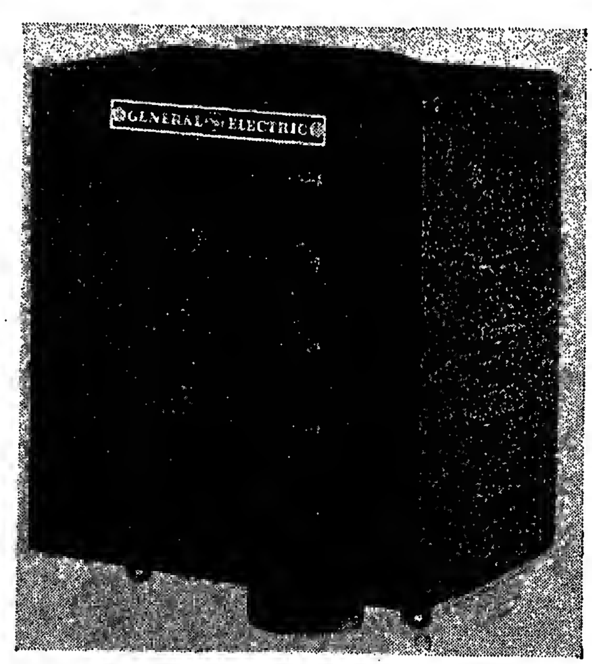

Figure 3. Regulator in separate case with *AN* corrector

Means for Accomplishing Parallel Operation

A second winding on the regulator is used to accomplish load equalization under parallel operation. The equalizing coils are connected as in Figure 1 and have been found very effective in obtaining equal load division of generators.

This method of equalization requires a small voltage drop (0.5 volt at rated load) in series with each generator. This drop does not cause a drooping voltage characteristic with load, as the voltage is regulated at a point beyond this drop. It does, however, cause a flow of current in the equalizing coils of the regulators when necessary to insure proper load equalization. In some instances the generators have an internal compensating winding which can be used to obtain the voltage drop for equalizing purposes. In order to obtain uniform drops and in order to insure interchangeability of generators of different manufacture, it has been the authors' recommendation that the potential drop required for equalizing purposes be made external to the generators, and in many instances the drop in the negative lead itself is utilized. In applications where the generator design is known, and an internal compensating winding is present, it is desirable to utilize this drop for equalizing purposes. In such instances potential dividers can be connected across these compensating fields to allow adjustment to compensate for differences in voltage drop.

Tests have been made with this scheme of equalization of load, and it has been demonstrated that close load division of generators in parallel can easily be obtained whether or not the speeds of the generators are equal.

When one or more generators in a group operating in parallel are disconnected, a drooping characteristic with load is obtained on the remaining units, unless the equalizing coil of the generator that is off the lines is opened. In some cases it is desirable to open the equalizer coil, and in other instances the drooping characteristic is desirable under these conditions, in order to allow the battery to share in supplying the higher load peaks.

In order to illustrate the practicability and desirability of the equalizing scheme shown in Figure 1, let us consider an example.

Suppose two regulators each having an accuracy of +1 per cent are to be operated in parallel and at a total load of twice the rating of one generator, the loads are to be divided within ten per cent of the rating of one generator.

Under the worst condition consider one regulator to be one per cent high and the other one per cent low on the basis of its potential winding alone. With the scheme using equalizing windings and 0.5-volt series drop at rated load, there will be at ten per cent difference in load 0.05 volt to cause current flow through the equalizing windings. The equalizing winding is designed so that this difference in voltage will cause a current to flow in the equalizing windings to change the ampere turns of the regulator one per cent of the total ampere turns, on one regulator in a direction to raise, and on the other in a direction to lower its voltage. These proportions have been found to be practical. There is a loss in the series resistors at rated load of approximately 1.75 per cent of the generator rating.

Now consider the same regulators connected without equalizing coils but with enough series resistance beyond the point of regulation to equalize the loads to the same degree. Assume that there is a difference in regulated voltage of two per cent with one regulator one per cent high and the other one per cent low. The series resistance between the regulated points must be such as to allow not over five per cent circulating current with two per cent voltage difference or 20 per cent resistance per generator circuit to obtain the same current equalization as with the scheme using equalizing coils. This is of course entirely impractical.

Other Considerations for Regulator Application in Aircraft

While regulators can be made to cover a range of field current requirements, it must be realized that the design of the generator field determines the power to be dissipated in the regulator. With fields of normal design the power dissipated for 200- and 275-ampere generators is about 65 watts. The aircraft manufacturer must provide sufficient ventilation for the dissipation of the heat.

While a regulator can stabilize generators that would be unstable on manual control, there are limits beyond which the regulator cannot stabilize the system. Generators with rising voltage characteristics as the load is increased are invariably unstable to a degree that the regulators cannot cope with on battery loads. This practically rules out the use of compound-wound variable-speed generators for aircraft application.

Regulators of the type described have been successfully applied on 120-volt systems. Also they have been applied to special purpose separately excited a-c generators by exciting the regulator coil through a dry-disc-type rectifier.

The Magnetic-Drag Tachometer

R. G. BALLARD
ASSOCIATE AIEE

Synopsis: A discussion of a magnetic-drag-tachometer equipment designed principally for aircraft use. The principle of operation makes possible an indicator which may be read very accurately under extreme conditions of aircraft use and at the same time may be easily adjusted and maintained. Because of the extreme reading accuracy obtainable, low inherent temperature errors and good compensation are essential. A method of obtaining these features is presented.

MECHANICALLY operated aircraft tachometers include the centrifugal and chronometric types; prior to the development of the magnetic-drag tachometer, remote indicating electrical types included the a-c generator and voltmeter combination and the d-c generator and voltmeter combination.

The disadvantage of the mechanically operated tachometer rests in the excess weight caused by the necessity for a flexible cable between the engine and the indicator.

Generator and voltmeter tachometers lie in two general classifications, namely:

1. Voltage-sensitive devices.
2. Frequency-sensitive devices.

The voltage sensitive instruments may consist of a voltmeter, connected directly to a d-c generator or connected through a copper-oxide rectifier to an alternating generator. It is necessary to maintain a fixed lead resistance between the indicator and generator, and any change in generator output is immediately reflected in the accuracy of indication.

The problem of overcoming some of the objections of the voltage sensitive instruments was solved by the development of a frequency-sensitive tachometer whose indication is proportional only to the frequency of the generator output. This tachometer consists of a voltmeter connected to an a-c generator with a copper-oxide rectifier and a saturated core transformer. The transformer core is saturated throughout the operating range of the aircraft engine, and the output of the transformer is consequently directly proportional to engine speed. This development permitted the exchange of generators or indicators without calibration adjustment, eliminated changes in calibration due to changes in generator output produced by vibration or temperature changes, and permitted the installation of tachometer equipment without making it necessary to maintain a fixed lead resistance.

As the size and speed of aircraft increased, due to the availability of more powerful engines, it became necessary to control the engine speed more accurately in order to obtain the most economical engine operation. High altitude operation presented the problem of increased accuracy of engine speed indication throughout the temperature range from approximately −40 degrees centigrade to +50 degrees centigrade, requiring marked improvement in temperature compensation. Due to the more accurate indication required, it became necessary to obtain tachometer equipment with a greatly increased scale length to provide more accurate readability.

Figure 1. Tachometer generator

It is the object of this paper to indicate how the problems outlined in the preceding paragraph were solved by the development of a tachometer operating on the magnetic-drag principle and to present pertinent details regarding the operation of representative tachometers.

Consideration of the application of tachometer equipment to aircraft indicated that the wide variation between the temperatures of the indicator and the generator, in combination with the very severe vibration of the generator, made it absolutely essential that the indicator be entirely frequency responsive. This is necessary, due to the changes in generator-output voltage caused by vibration and to temperature changes which vary the resistance of the generator circuit.

The generator-voltmeter tachometer with saturated core transformer overcame problems due to the effect of vibration and temperature changes on the generator; however, as was true with other types of remote electrical indication tachometers, the maximum scale length obtainable was 270 degrees. In order to increase this scale length materially, a tachometer operating on the magnetic-drag principle was developed.

The Magnetic-Drag Tachometer

The magnetic-drag tachometer consists essentially of a three-phase a-c generator, mounted on the aircraft engine, and an indicator, consisting of a synchronous motor operating a magnetic-drag assembly.

The problem of changes in generator output voltage was eliminated by the adoption of the generator and synchronous motor combination, which constitutes a frequency-sensitive system for transmitting an indication of engine speed to the indicator with absolute accuracy.

For many installations it is desirable to obtain engine speed indication at two different stations in the aircraft. This system is ideal for this application, since there is no change in indication, due to the addition of a second indicator in parallel with the first; synchronous motor operation in each indicator is only dependent upon the availability of sufficient power to operate both motors.

Generator (Figure 1)

Primary factors of light weight and small size, plus trouble-free operation, were problems which had to be met in the generator design.

Light weight was accomplished by the use of aluminum alloy for the end shields.

Light weight and small size were obtained by making use of a permanent magnet rotor with high magnetic energy content. The physical dimensions of the rotor required a magnetic material having

Paper 42-46, recommended by the AIEE committee on air transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 14, 1941; made available for printing May 5, 1942.

R. G. BALLARD is with the aircraft instrument engineering section, General Electric Company, West Lynn, Mass.

high coercive force, due to the short magnet length and in order to prevent demagnetization. Because of the extreme vibration encountered, it is necessary to have a material which is not readily affected by vibration. Alnico offered the answer to those requirements and is cast directly onto the rotor shaft.

In order to obtain high resistance to wear produced by vibration, stainless steel inserts were cast into the generator end shields.

As the aircraft-engine accessory drives often transmit to a considerable extent torsional oscillations originating at the crankshaft, the tachometer generator includes a long slender drive shaft carried within the hollow rotor shaft, having sufficient flexibility to prevent failure of the drive key as well as to accommodate small misalignments between generator and engine pad.

Two limiting conditions are necessary with regard to output of the generator:

1. With a single indicator connected to the generator, the voltage output at normal cruising speed must not exceed a certain limit in order to prevent excessive temperature rise in the indicator.

2. At the lowest operating speed, with two indicators connected to a single generator, the output voltage must exceed a certain minimum value, so that there will be sufficient power output available to start and operate the indicators at any temperature.

These requirements were met by taking advantage of the properties of the Alnico rotor which permitted shorter—hence lower resistance—turns, resulting in improved voltage regulation. Adjustment of voltage within the limits specified is obtained by means of an a-c knockdown coil after complete assembly of the generator; this adjustment also stabilizes the magnet to minimize effects of vibration.

Indicator

The indicator (Figure 2) as briefly described in a previous paragraph, includes a synchronous motor and a magnetic-drag assembly.

The requirements for a satisfactory motor include the ability to start and to run synchronously at any speed throughout the operating range, when two indicators are connected to a single generator, and yet not to overheat when connected singly to a generator. Since the generator output decreases with a decrease in engine speed, it is necessary that the indicator start with very low input at the lowest speeds. It is essential that the motor should meet these requirements with minimum weight and size and yet be simple and rugged for long life and ease of maintenance.

A unique motor assembly in conjunction with a conventional three-phase wound stator offered a solution to these requirements. The rotor assembly as shown in Figure 3 consists of a polarized rotor, a spring, and a hysteresis disk. The starting torque is supplied by the polarized rotor at low engine speeds, where the frequency is too low to produce appreciable torque in the hysteresis disk. As the generator frequency is increased by increasing engine speeds, a greater share of the torque is produced by the hysteresis disk, and the polarized rotor assists by bringing the motor into synchronism.

In order for the polarized rotor to perform the above functions, it was necessary to design a rotor with an extremely low moment of inertia and with high magnetic strength; a sintered oxide material was used for this application, resulting in

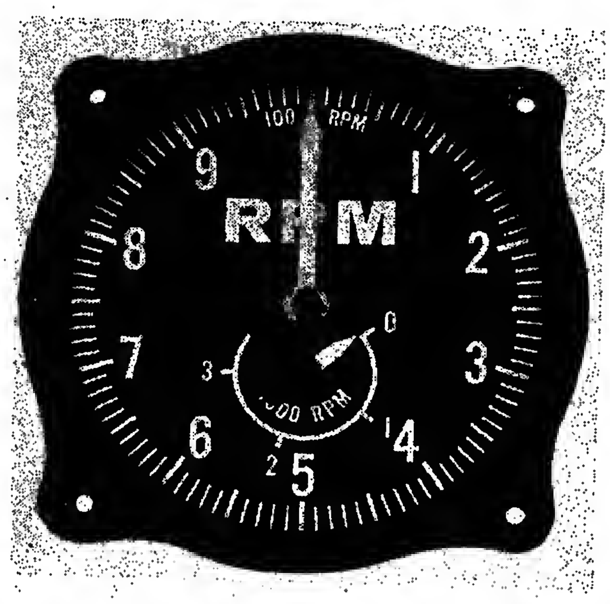

Figure 2. Magnetic-drag tachometer indicator

a rotor having approximately four-tenths the weight of any other available magnetic material.

The hysteresis disk is produced from an alloy of copper, nickel, and iron, heat-treated to produce the desired magnetic characteristics.

It was found that there was very definitely an optimum spacing between the polarized rotor and the hysteresis disk to obtain the best starting characteristics throughout the entire speed range.

Bearings for the indicator motor presented a major problem for the following reasons:

Generator output decreases as the generator speed is lowered, resulting in a very low indicator input at engine idling speeds, thus requiring low friction in the bearings to permit proper starting.

Bearing lubricant gradually becomes more viscous as the temperature is decreased, resulting in increased bearing drag.

Since bearing life is dependent upon amount

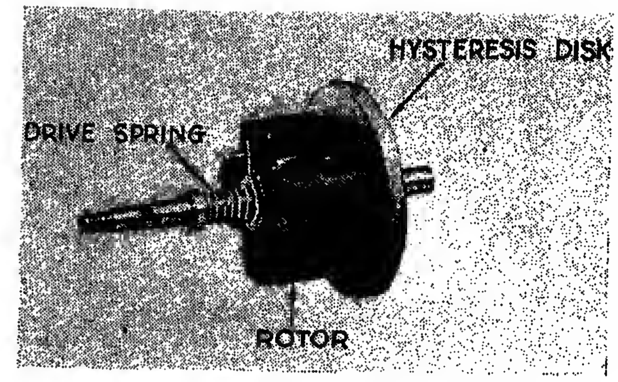

Figure 3. Indicator-rotor assembly

of lubrication it is desirable to supply the maximum quantity of lubricant possible.

In order to properly protect the ball bearings until ready for installation in indicators, they are stored completely filled with lubricant; when needed for assembly, each bearing is thoroughly washed and cleaned to remove all traces of the lubricant, the bearing is then dried, and a definite quantity of inhibited black fish jaw oil is applied to the bearing. Repeated laboratory tests have indicated the superiority of this oil with regard to rate of evaporation, acidity, and change with continued evaporation. The quantity of lubrication applied is dependent upon minimum operating temperature to which the particular instrument is to be exposed.

The magnetic-drag assembly may properly be divided into two sections, the rotating magnet assembly and the armature assembly.

Since the rotating magnet assembly (Figure 4) is a part of the rotor assembly of the synchronous motor, it is necessary to obtain a magnetic assembly with as low a moment of inertia as possible, which will produce the required torque on the magnetic-drag disk. To meet these requirements five pairs of Alnico magnets are arranged as shown in Figure 4; this arrangement concentrates the flux near the outside edge of the magnetic-drag disk with minimum weight of magnetic material.

The armature assembly includes the shaft, springs, and pinion gear illustrated in Figure 5, in combination with a drag disk and pointer. The magnet assembly of Figure 4 and the flat drag disk permit ready inspection of the air gap, and by

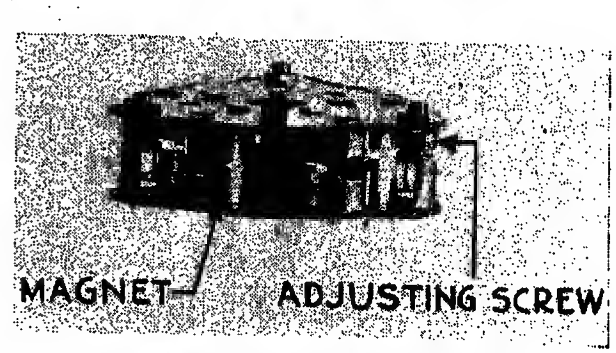

Figure 4. Rotating-magnet assembly

Table I. Comparison of Disk Materials

Material	Temperature Coefficient (Per Cent Per Degree Centigrade)	Conductivity	Density (Grams Per Cubic Centimeter)
Aluminum	0.34	60	2.7
Copper	0.385	100	8.9
Aluminum-manganese	0.040	12	2.8
Copper-manganese	0.036	15	8.8

means of adjusting screws, the element may be raised or lowered to centralize the disk in the magnet gap.

The spring assembly must permit $3^1/_2$ revolutions of the pointer, must be rigid enough to withstand the effects of vibration, and must be designed to operate well below the elastic limit in order to prevent appreciable changes in indication when deflected for long periods of time.

These spring problems were solved by the unique spring arrangement illustrated in Figure 5. Here two springs are effectively connected in series by a spring arm joining the outer turns of the two springs, the inner turn of one spring is fastened to the shaft, and the inner turn of the second spring is fastened to an adjusting arm mounted on the element plate. By this method of construction $3^1/_2$ revolutions of the pointer result in only $1^3/_4$ revolutions of each spring, permitting shorter and consequently more rigid springs. Increased stiffness of the spring is also allowed, since the torque per degree deflection of each is double the torque of an equivalent single spring. With this arrangement no restraining plates are required, and the spring arm prevents any possible entanglement of the two springs.

The pinion actuates the short pointer illustrated in Figure 2 to indicate the number of revolutions of the long pointer.

The magnetic-drag disk is made from an aluminum-manganese alloy in order to obtain minimum weight with the requisite conductivity and temperature coefficient. It is essential to obtain a temperature coefficient within certain definite limits in order to obtain optimum accuracy of indication for rapidly changing temperatures. Data for several disk materials are indicated in Table I, where the advantage of the aluminum-manganese alloy is evident due to the combination of light weight and low temperature coefficient.

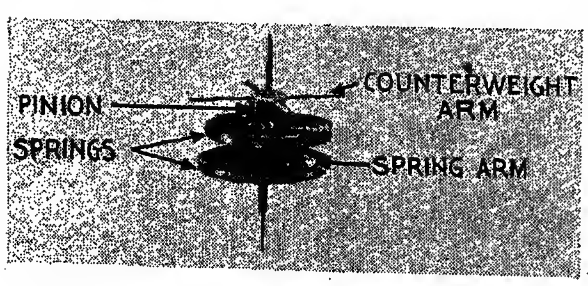

Figure 5. Spring assembly

Temperature Compensation

In order to obtain the required accuracy throughout a temperature range from −35 to +45 degrees centigrade, it is necessary to provide compensation for the changes in indication due to these temperature changes. Changes are produced by

(*a*) Magnets.

(*b*) Disk.

(*c*) Springs.

(*d*) Other very small effects such as those caused by expansion and contraction.

As the temperature decreases, the magnet strength increases, tending to produce an increase in indication; the disk conductivity increases, also tending to increase the indication, and the torque of the springs increases, tending to produce a decrease in indication. The temperature-torque coefficient of the springs is approximately 0.04 per cent per degree centigrade; by proper heat treatment of the disk alloy, it is possible to obtain a similar coefficient, thus cancelling the errors produced by the disk and springs.

Both the thin disk and the springs are similarly exposed to the air inside the instrument case, so that they will quickly respond to rapid changes in temperature in order to eliminate transient errors.

The temperature error produced by the magnets is indicated by curve *A* in Figure 6 for an indicated speed of 3,000 rpm; compensation is accomplished by the addition of temperature-sensitive magnetic shunts placed in the magnetic assembly of Figure 4.

As the magnetic flux increases with decrease in temperature, it is necessary to shunt the extra flux directly across the poles of the magnet to maintain constant flux in the disk gap. These shunts are placed underneath the clips which fasten the magnets to the plates in Figure 4.

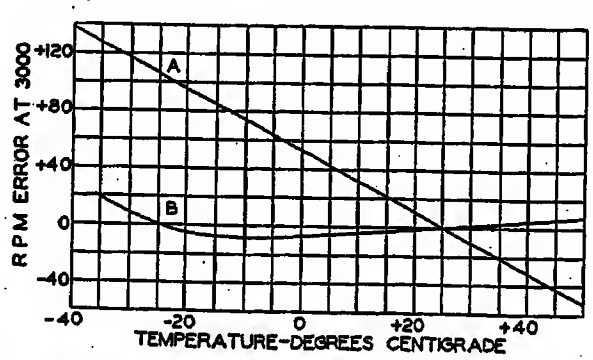

Figure 6. Temperature-compensation curves

A—Uncompensated indicator
B—Compensated indicator

The addition of a single type of temperature-sensitive material corrects the greater share of the fundamental change; this material is a nickel–iron alloy with a release point of approximately +90 degrees centigrade. This release point is the temperature at which the alloy becomes practically nonmagnetic.

Greater compensation is produced by this type of material above room temperature than below room temperature; to correct for this difference a copper–nickel alloy, with a release point at or slightly above room temperature, is added to produce the compensated curve *B* of Figure 6 for a representative instrument. Close contact between the temperature sensitive material and the magnets tends to maintain both materials at the same temperature regardless of the rate of change of temperature, thus eliminating transient temperature errors.

Calibration

A good tachometer should include:

1. Full-scale adjustment.
2. Zero adjustment.
3. Method of balancing element assembly.

Preliminary full-scale adjustment is obtained by the use of an a-c knockdown coil to reduce the air-gap flux produced by the rotating magnet assembly; by this method the magnet strength is reduced at least five per cent in order to stabilize the magnets and to bring the calibration within 0.1 per cent of the correct indication at full scale. After a calibration check has been completed throughout the scale range, final adjustment may be made by further application of the knockdown coil, or the indication may be increased by movement of any one or all of the three adjusting screws illustrated in Figure 4. These adjusting screws vary the air gap to increase or decrease the flux and permit ready and positive adjustment at any time.

Synthetic or Equivalent Load Curves

R. F. HAMILTON
MEMBER AIEE

Synopsis: This paper describes short approximate methods for the solution of several types of intangible problems which require load-curve analyses. Laborious effort may be expended in compiling results from a group of curves without greater precision than is believed possible to obtain from the use of one or a few synthetic curves which combine the characteristics under investigation, and permit the determination of such items as peak loads, losses, and required capacities of equipment.

LOAD curves are familiar to engineers. The variety of precision instruments which have been developed to draw them automatically, and the ever increasing number of uses to which they are applied would require, for adequate description, an historical record dating from the days of the rocker-beam steam engine. Today they are so commonplace that no attempt will be made herein to classify them, or to review methods generally applied.

There are particular types of problems in which the characteristics of a number of similar curves, taken in the aggregate, are more helpful than those of any single curve. For example, in a study made recently, including the load curves of many large industrial and utility companies, it became evident that laborious effort may be expended in compiling results from a group of curves, such as daily curves for a yearly period, with scarcely greater precision in the end than is believed possible to obtain from the use of one, or a few synthetic curves which combine the characteristics under investigation.

One problem occurs frequently in electrical calculations; that involving losses, and consequently a squared function of a current or load curve. This can determine principally the capacity of many kinds of equipment. Consider too the losses in transmission-line and cable circuits. The economical value of these conductors is a function of the annual energy loss, which in turn may depend upon several variable factors. Kelvin's law, in its application, presumes "an equivalent mean-annual current."

Or consider traction motors, rolling-mill motors, hoist and crane-equipment, generators and transformers in the service of loads which fluctuate rapidly over wide values; about which it may well be said that no two load curves are likely to be duplicates. It would seem that methods are needed for giving quick and reliable solutions for the capacities and losses involved.

The purpose of this paper is to examine some features of these problems and to present a few methods which have been evolved for their solution, with the thought that they may be of interest, and perhaps stimulate further investigation in the field of short solutions to these important problems.

Paper 42-36, recommended by the AIEE committees on power generation and power transmission and distribution for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted September 30, 1940; made available for printing December 11, 1941.

R. F. HAMILTON is a consulting engineer and is chief of the plant engineering unit of the Corps of Engineers, Washington, D. C.

Basic Elements

Load curves, as commonly understood, involve the rate of change of some physical quantity plotted as ordinates versus units of consecutive time as abscissae. Examples of ordinates are kilowatts, horsepower, amperes, gallons per minute, passengers per hour, car loadings per day. In utility work the ordinates customarily represent a rate of change of energy, which results in the area under the curve becoming a measure of the energy involved. Such curves may be reduced to a common denominator for comparison of shapes by making the maximum value and total time in each case equal to unity, and plotting the lesser values as fractions of these maxima. This procedure permits direct reading of those factors which are also expressed in fractions of the maxima, and, being without physical dimensions, the scales on the axes of co-ordinates need be numerical only.

The essential elements in the building of a synthetic load curve are the following:

1. T, the time or duration of the load; herein primarily the time of some definite cycle, or the transition period between extreme values; which period could be some fraction of a cycle.

2. N, the minimum value of the load.

3. M, the maximum value of the load.

After initial calibration it is often desirable to raise or lower the complete calibration curve in order to equalize the positive and negative errors. This is taken care of by the application of an adjusting arm which rotates the armature assembly; this adjustment is made with the instrument operating at any desired indication, thus permitting very accurate correction.

Addition of balance weights to the counterweight arms illustrated in Figure 5 permits adjustment to mechanically balance the armature assembly so that the instrument may be operated in any position.

Representative Data

Calibration curves for three representative tachometer indicators are shown in Figure 7; the solid curves are for increasing engine speeds, and the dotted curves are for decreasing engine speeds.

As explained in a previous paragraph, curve B of Figure 6 indicates the change in calibration for a typical indicator throughout the temperature range from −35 to +50 degrees centigrade.

Table II lists pertinent details for a representative tachometer installation consisting of two indicators and one generator.

Table II

Operating range	500–3,500 rpm (250–1,750 rpm generator speed)
Accuracy (+25 C)	±10 rpm
Generator weight	2.5 pounds
Indicator weight (each)	1.0 pounds
Indicator input (2,400 rpm)	5 watts
Position error	6 rpm
Magnetic effect (5 inches from compass needle)	0.5 degree
Indicator temperature rise (2,400 rpm)	35 C
Generator temperature rise (2,400 rpm)	20 C

4. *W*, the energy involved in the period considered.

5. *A*, the average value of the load.

6. ϕ, the load factor; the ratio of the average load to the maximum load.

7. θ, the loss factor; the ratio of the average loss to the maximum loss, or loss at the maximum load.

8. *K*, the variation factor; the ratio of the minimum load to the maximum load.

9. *r*, the root-mean-squared value of the loads.

10. *u*, the capacity factor; the ratio of the root-mean-squared value of the loads to the average value.

11. ρ, the capacity factor squared, or the ratio of the average loss to the loss at the average load.

By definition, these elements are connected by the simple relations:

$$N=KM,\ W=AT,\ A=M\phi,\ r=uA,\ r^2=\rho A^2,\ r^2=M^2\theta,\ \theta=\rho\phi^2$$

Just as the load factor (ϕ) is a fraction denoting the ratio of the average load to the maximum load, so the loss factor (θ) is a fraction expressing the ratio of the average loss to the maximum loss, and the variation factor (K) is a fraction giving the ratio of the minimum load to the maximum load.

Capacity factor is a useful ratio, always greater than unity, for expressing r in terms of A. For example, a capacity factor of 1.20, as applied to a piece of equipment, would mean that its rating for the period which may be considered must exceed the average load carried by 20 per cent, to care for the I^2R losses under variable load.

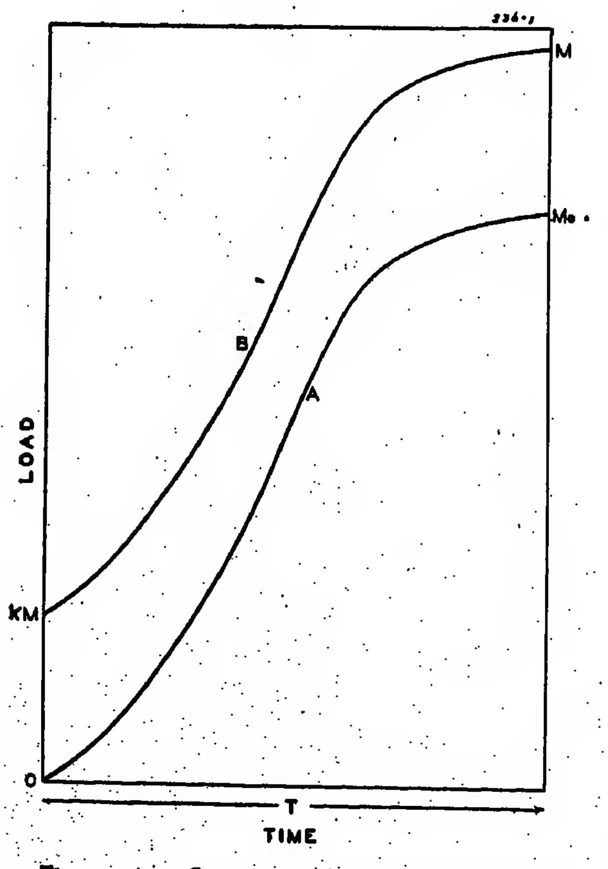

Figure 1. Curves of $f(t)$ and $f(t)+KM$

Fundamental Equations

Referring to Figure 1, assume that m is a continuous function of t for curves A and B. These curves are identical in shape, so that for any value of t the corresponding values of m for the respective curves differ by KM.

Let curve A be defined by $m=f(t)$, then curve B is defined by $m=KM+f(t)$. Then, as shown in appendix A, the load factor and loss factor corresponding to curve B may be expressed respectively as

$$\phi=K+(1-K)\phi_0 \tag{1}$$

and

$$\theta=\phi^2+(\rho_0-1)(\phi-K)^2 \tag{2}$$

In the above equations the symbols without subscripts refer to curve B, while those with the zero subscripts refer to curve A. These equations are fundamental and apply to all types of continuous functions. Equation 2 expresses the loss factor (θ) as the load factor squared (ϕ^2) plus some fraction (ρ_0-1) of the square of the difference between the load factor and the variation factor $(\phi-K)^2$.

The value of the fraction (ρ_0-1) depends on the shape of the curve so that the factor (ρ_0) may be said to identify the curve form. By definition

$$\rho_0=\frac{\theta_0}{\phi_0^2}$$

and from equation 2

$$\rho_0-1=\frac{\theta_0}{\phi_0^2}-1=\frac{\theta-\phi^2}{(\phi-K)^2}$$

or

$$\rho_0=1+\frac{\theta-\phi^2}{(\phi-K)^2}$$

A more suitable way of expressing the load as a function of time is in the form: $m/M=f(t/T)$. The maximum values of m/M and t/T will then be unity or 1.0, occurring when $m=M$ and $t=T$.

The function of t/T may take a variet of forms. One which has proved mo useful is given by $(t/T)^n$ which can b made to cover the parabolic types c power functions by using real positiv values for n, and the hyperbolic types b rearranging the configuration and usin negative values.[5]

The exponent (n) of $(t/T)^n$ is a func tion of the load factor (ϕ) and the varia tion factor (K), the relation being

$$n=\frac{1-\phi}{\phi-K} \tag{3}$$

Using $(t/T)^n$, the curve B of Figure 1 i expressed by

$$m=M\left[K+(1-K)\left(\frac{t}{T}\right)^{\frac{1-\phi}{\phi-k}}\right] \tag{4}$$

from which

$$\theta=\phi^2+\frac{(\phi-K)^2(1-\phi)^2}{(1-K)^2-(1-\phi)^2} \tag{5}$$

Thus is given a value for the loss facto (θ) in terms of the load factor (ϕ) and th variation factor (K). The path of th curve is determined by the values of K and ϕ, and the area under the curve i equal to the energy W ($W=\phi MT$).

For the special case in which K i equal to zero, the lower curve of Figure applies and

$$\theta=\frac{\phi}{2-\phi} \tag{6}$$

$$\rho=\frac{1}{\phi(2-\phi)} \tag{7}$$

Derivations of equations 3 to 7 inclusive, are shown in appendix B. The curves of Figure 2 give values of $(t/T)^n$ for values of n varying from 0.05 to 20.0 In Figure 3 are given curves of ϕ, θ and ρ as functions of n for two values of K, namely $K=0$ and $K=0.2$. In Figure 4 are given curves of ρ and θ as functions of ϕ for five values of K.

There is an endless variety of functions to which equation 1 may be applied. A

few have been tabulated in Table I. The accuracy desired may require that thought be given to apply the function best suited to the problem in hand, and in this connection it should be kept in mind that the lower limit which may be used for the load factor (ϕ) is determined by the load factor (ϕ_0) of the basic function. For example, for the parabolic type of curve represented by equation 4, the load factor (ϕ) may have any value from zero to unity. When the load factor exceeds the value of 0.5, the versine and hyperbolic-secant functions often apply. A little practice will lead to the proper selection upon inspection of the conditions.

Referring to Table I it will be noted that for some of the functions, two expressions are indicated for the loss factor (θ),

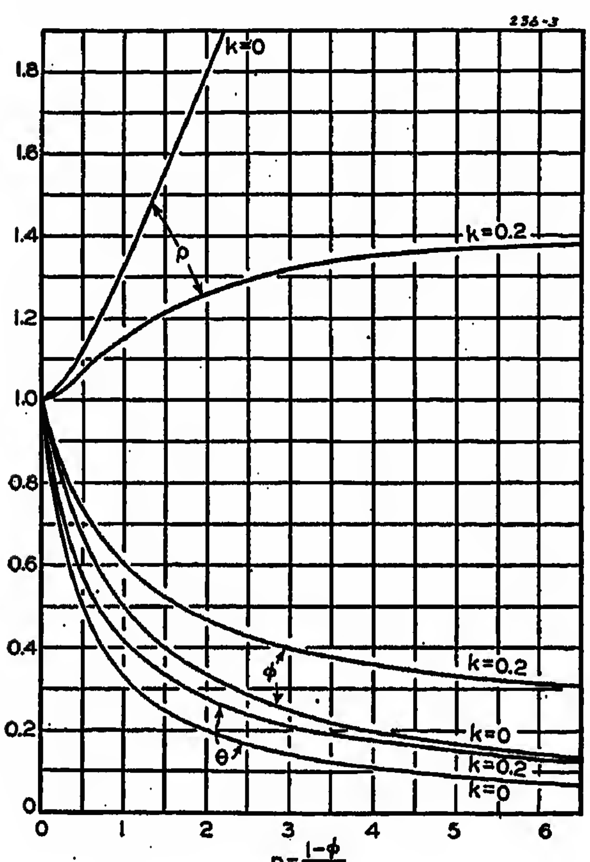

Figure 3. Curves showing variations of ϕ, θ and ρ in terms of n, where $n=\dfrac{1-\phi}{\phi-k}$

one being a function of $(\phi-K)$ and the other a function of $(1-\phi)$, which permits the calculation of two values for the loss factor. By taking an average of the two, a closer value of the loss factor can be obtained. If the curve fits the conditions exactly, the two will be equal in value.

Application to Power-Station Curves

Referring to Figure 5, an industrial load which covers one day's output from a power station is represented by curve A. By rearranging the load values in an increasing series, curve B is obtained. The two curves are equivalent for present purposes, for it is immaterial in what order the values occur so long as the magnitudes and corresponding durations remain unchanged. For both curves, the maximum load, the minimum load, the load factor, and the loss factor are identical.

It is entirely possible to construct synthetic curves having the same values of W, T, ϕ, ρ, and θ as have curves A and B, such as represented by curve C which is defined by formula 16 of Table I. However, this is not ordinarily the problem. What is desired are values for θ and ρ corresponding to the given values of ϕ and K for curves A and B. The accuracy with which the former can be determined will be governed by the formula selected from Table I to represent curve B of Figure 5. For example, using equation 5 above, which corresponds to formula 2 of Table I, a value of 0.344 is obtained for θ which is 5.5 per cent lower than the actual value of 0.364. It is to be noted that the slope of curve B is approximately zero at the lower and upper limits. For this condition, formula 13 of Table I would apply, from which a value of 0.366 is obtained for θ which is only 0.55 per cent above the actual value and therefore within acceptable engineering accuracy.

Along the same line consider curve A of Figure 6 which depicts a utility load curve of different shape. Again, curve B is curve A redrawn. The actual factors for these curves are $K=0.150$; $\phi=0.639$; and $\theta=0.478$. Using equation 5 above, a value of 0.461 is calculated for θ which is 3.6 per cent low. Since the value of ϕ exceeds 0.5, and considering the shape of curve B, formulas 14 and 15 of Table I are suggested. With the former, the value obtained for θ is 0.484, which is 1.2 per cent high; with the latter a value of 0.474 is obtained which is 0.8 per cent low. The graph for formula 14 is represented by curve D.

In both Figures 5 and 6, the curves B have been obtained by tabulating the average values of m for small intervals of t, and then arranging these values consecutively in ascending order. Since the area under each curve is $\int(m)dt$, or equally, $\int(t)dm$, the same result may be obtained by taking average values of t for small intervals of m. In either case, the resulting curve is the well-known load-duration curve, with the scale of abscissae reversed in direction.

Load-Curve Combinations

When daily load curves for a given system follow the same general pattern, one method of approach for the consideration of a longer period such as a month or year, is illustrated in Figure 7. The solid shown is obtained by arranging the days, not chronologically, but in th[illegible] increasing energy values, so th[illegible] of the front face measures the [illegible] the minimum day and that [illegible] face, the energy of the maxi[illegible] The volume then measures the [illegible] the total period. The hours i[illegible] day are represented by T_d an[illegible] in the period by T_y.

By making use of geometr[illegible] many relations can be estab[illegible] tween the daily and yearly [illegible] volved, depending upon the na[illegible] problem under consideration[illegible] left-hand curves of Figure 8 are [illegible] as representing two of the 365 [illegible] curves for a period of one year. [illegible] lying between these two, the[illegible] energy values can be repre[illegible] shown by the right-hand curve[illegible] under the latter measures t[illegible] energy. The various formulas w[illegible] heretofore been considered [illegible] plied, requiring only the sub[illegible] the energy value W for the [illegible] load value M in the appropriat[illegible]

An able exposition of the [illegible] seasonal variations in load [illegible] their components, classified a[illegible] day and character of load, has [illegible] by Farley C. Ralston. To th[illegible] interested in problems having [illegible] predictions of future demand a[illegible] his paper[3] is particularly rec[illegible]

The Use of Probable Value[illegible]

Another method for handli[illegible] periods, which is perhaps mor[illegible] tory, may be developed from t[illegible] teristics of a single curve, such [illegible] shown in Figure 9. This in[illegible] total hours during which the l[illegible] the value indicated.

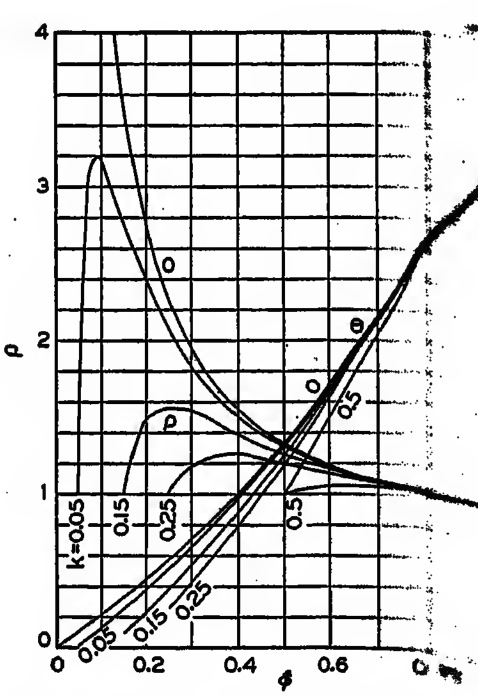

Figure 4. Curves showing value[illegible] in terms of ϕ for various valu[illegible]

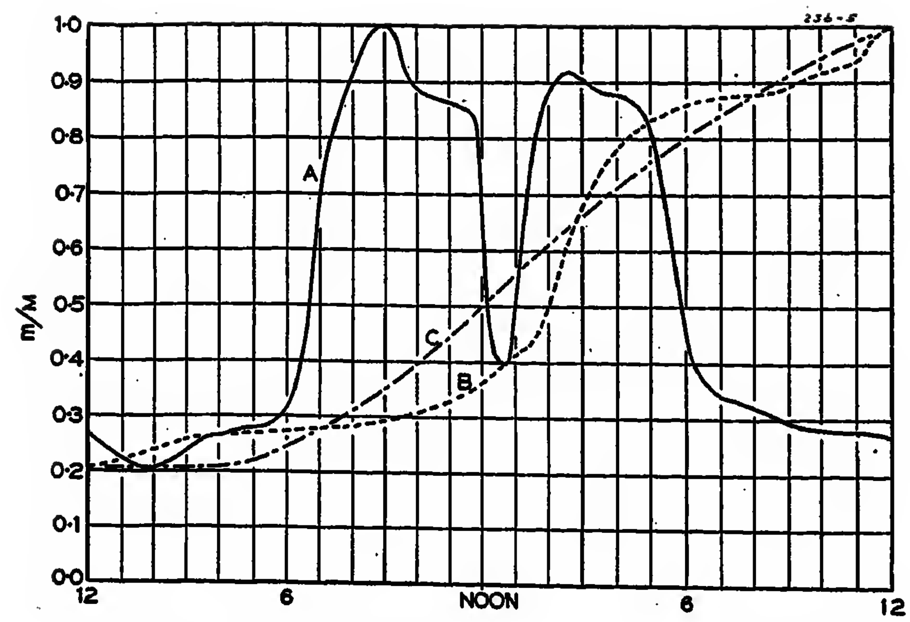

Figure 5. Industrial load curve

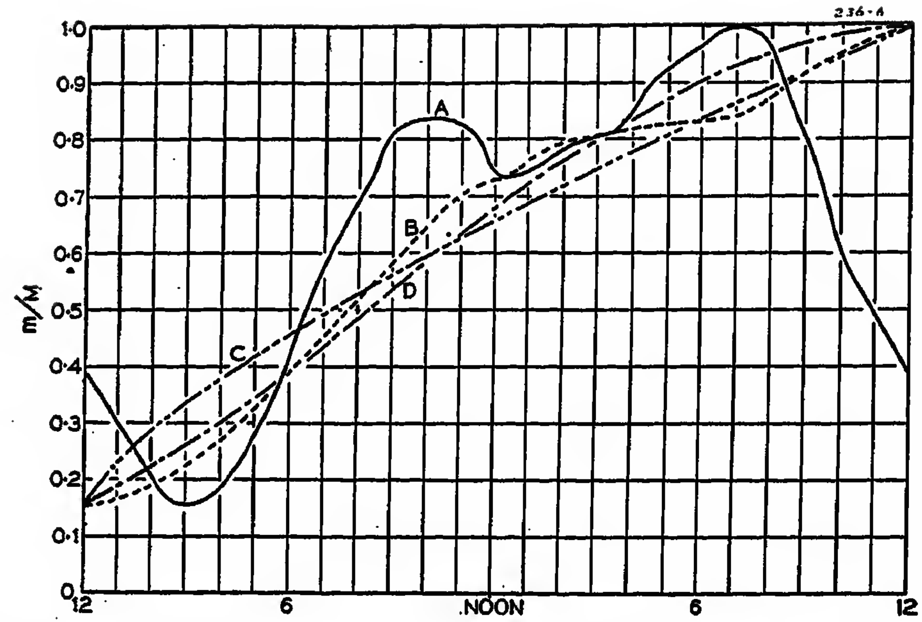

Figure 6. Utility load curve

Experience has demonstrated that, when a considerable number of days are combined in this manner, the curve tends to assume the general shape shown. This is due to the fact that extremely low and high values of load do occur, but less frequently than those nearer to the average value. This circumstance leads naturally to a comparison with the well-known frequency-curve as given in Figure 10. The mode of the latter corresponds to the time (T). Referring to Figure 9, the probability, or duration, of a load not less than C in value is measured by T_1, corresponding to P_1 in Figure 10, and therefore C corresponds to Q in value. In other words the probability of the load's being at least KM in value is unity; of its being M or greater, say $^1/_{48}$ or one-half hour each day, and between these two, as shown for intermediate values.[6,7]

The curve of Figure 9 is, in reality, a load-duration curve reduced to daily values. If a yearly period be covered, then by dividing each value of abscissae, given in hours, by 365, the curve represents a daily period, which, however, includes all values of the load encountered throughout the year; and p represents the time by which the daily peak is measured. Otherwise stated, if a one-hour peak be considered, $p=1.0$ for $T=24$ hours or $p={}^1/_{24}$ for $T=1.0$.

Should a maximum be so rare that its value is reached for one hour only during the year, then the value of p would be 1/8,760 for $T=1.0$. So p may be considered as a measure of the probability that the load will not be less than the value corresponding to D.

The equation for the load-duration curve of Figure 9 is

$$m=M\left[K+\frac{2}{\sqrt{\pi}}(\phi-K)\left(\log_e\frac{T}{t}\right)^{1/2}\right] \qquad (8)$$

and the loss factor corresponding thereto is defined by

$$\theta=\phi^2+\left(\frac{4}{\pi}-1\right)(\phi-K)^2$$
$$=\phi^2+0.27324(\phi-K)^2 \qquad (9)$$

where

$$p_0=\frac{4}{\pi}$$

This is a most useful form for application to utility loads and appears to increase in accuracy of results as the time under consideration increases.

Maximum-demand instruments will usually read the peak load as an average during the time considered, in which case the relations hold as given. Referring to Figure 9, the curve is sometimes considered as having the value (D) for the given period (p). For this condition the equations for the curve and corresponding loss factor are expressed by

$$m=M\left[K+(1-K)\left(\frac{\log_e\dfrac{T}{t}}{\log_e\dfrac{T}{p}}\right)^{1/2}\right] \qquad (10)$$

$$\theta=\phi^2+\left(\frac{4}{\pi}-1-\frac{cp}{T}\right)(\phi-K)^2 \qquad (11)$$

With reference to Figure 9, equation 10 applies between the limits for $t=p$ and $t=T$. Between the limits for $t=0$ and $t=p$ it is obvious that $m=M$ or $m/M=1.0$.

The value of c in equation 11 is a complicated function of p/T. Values of c can be had from curve B of Figure 13 for values of p/T up to 0.1, which is equivalent to 144 minutes in a 24-hour period. The term cp/T is empirical to make equation 11 similar in character to equation 9, the change in the value of θ being small for small values of p/T.

The derivations of these equations are included as appendixes C and D.

Comparison of Maximum Demands

The curve of Figure 9 may also be used as a basis for converting a peak demand, averaged for a given time interval, to some other time interval. For example, suppose a peak of M_2 is metered on a demand of t_2 minutes. Its value metered on a demand of t_1 minutes could be expressed by

$$M_1=N+(M_2-N)\frac{g_1}{g_2} \qquad (12)$$

The fraction g_1/g_2 is also a complicated function of p/T. Values of g_1/g_2 which are commonly used and can be substituted in equation 12 are given in Table II. It is to be noted that when $N=0$, the peaks

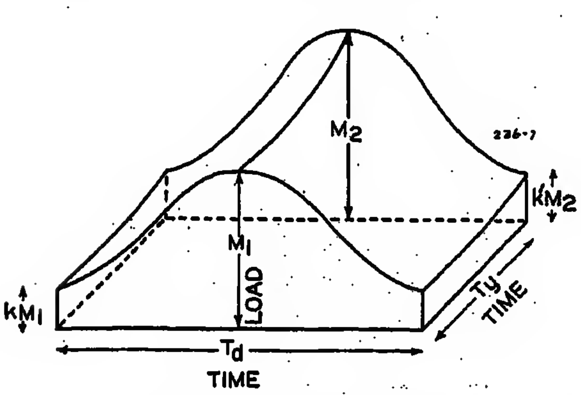

Figure 7. Grouping of daily load curves represented by a solid

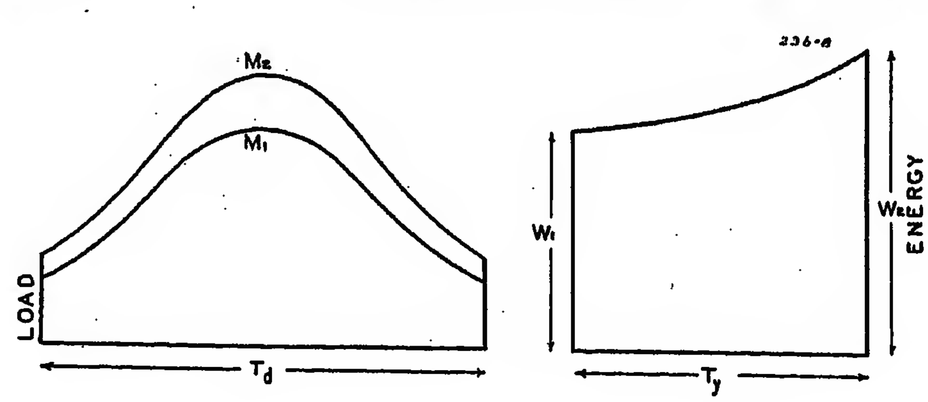

Figure 8. Grouping of daily load curves represented by an area

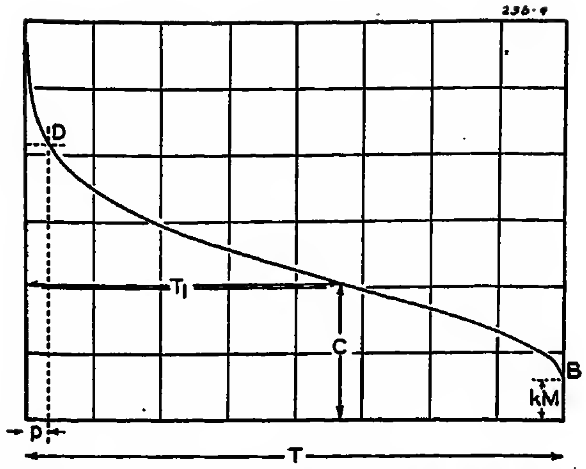

Figure 9. Load-duration curve reduced to daily values

are in direct ratio to the value of g_1/g_2. Relations other than those of Table II may be obtained by reading the values of g_1 and g_2 from curve A of Figure 13. The derivation of equation 12 is shown in appendix E.

Utility Distribution Losses

The losses attending a diversified distribution of energy can, as is well-known, be classified into two principal groups: those remaining practically constant, such as transformer-core losses, leakage, dielectric, and corona losses; and those which vary as the square of the current at each point and are known from experience to vary, practically, as the square of the total load.

Over a determined period, the sum of these two groups is known from meter readings at the points of generation and reception. If it happens in the two selected periods that the load factors and the average values of the losses differ sufficiently, then the loss factors determined in one of the manners outlined, furnish a method for segregating these variable and fixed losses.

Let L_1 = average loss corresponding to θ_1 and M_1

L_2 = average loss corresponding to θ_2 and M_2

L_0 = constant loss

Then as derived in appendix F

$$L_0 = L_2 - \frac{L_2 - L_1}{1 - \frac{\theta_1}{\theta_2}\left(\frac{M_1}{M_2}\right)^2} \qquad (13)$$

Curves of Demand Versus Energy

In the study of integrated power systems, it has been found that peak loads increase with added consumption in accordance with laws which give promise of analytical expression. Consider the load curves of the form shown in Figures 5 and 6. If each ordinate be increased by the same percentage, the total area, or energy, will be increased by an equal percentage, and the load factor will remain unchanged. Also, if the lower values are increased in general a greater percentage than is the percentage increase in the peak value, the resulting increase in energy will be accompanied by an increase in load factor. This latter type of growth is the desideratum of all utility men, but unfortunately the opposite seems more often to happen, namely, the peak increases at a more rapid rate than the energy, with a resulting decrease in load factor.

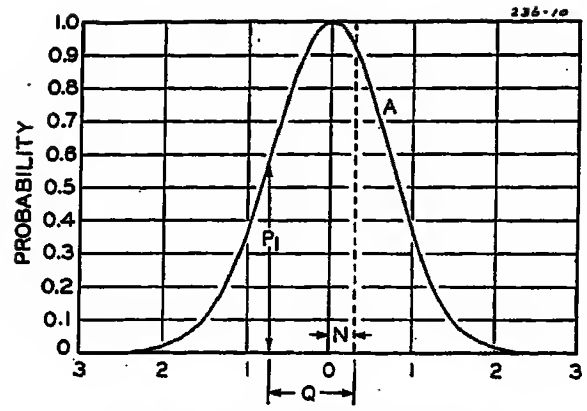

Figure 10. Probability curve

These relations can be analyzed with reference to the well-known load-energy curve illustrated in Figure 11. Referring to the latter, ϕ_0 is the load factor for a fixed period (T). The variation-factor is K_0. With the maximum value of M_0 and T as unity, the distance between C and B will be equal to $1-\phi_0$. Some line joining A and B will be the locus of the peak loads with variation of consumption.

Experience with growth in California lead engineers in that state to the belief that the curve from A to B is a parabola, tangent to AC at A and tangent to CB at B. Also, they and others feel that all load-energy curves can be expressed in this parabolic form.[1,2]

A general equation of the curve of Figure 11 derived in appendix G, may be given by:

$$\phi = 1-(1-\phi_0)\left[\frac{(W/M_0T)-K_0}{\phi_0-K_0}\right]^\beta \qquad (14)$$

where the exponent β can be determined for the specific case by obtaining values of M and the associated values of W, other than those of the terminal points.

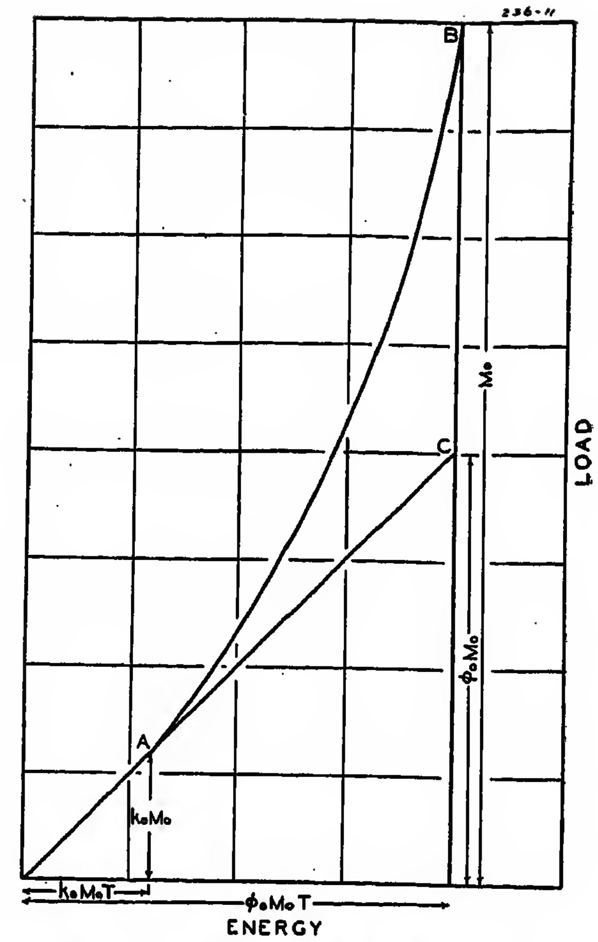

Figure 11. Peak-load versus energy curve

Some specific applications are illustrated in Figure 12. The load-energy curves are shown as full lines and the corresponding load-factor curves as dotted lines. Curve D is a parabola with points of tangency at A and B. Curve E indicates the relations for a linear increase of peak load with energy. Curve F is obtained for $\beta=1.0$. It is to be noted that the line O-C in Figures 11 and 12 represents the diagonal of a square of which ϕ_0 is one side.

In the Philadelphia district, it was determined a few years ago, that the growth in energy output and maximum yearly peak could be expressed closely by the same constant percentage increase. This condition would mean a constant yearly load factor. With reference to Figure 12, this condition, which represents a stabilization of the change in load factor, means that the curve E' will have become horizontal at some point beyond C, and the curve E continue beyond the

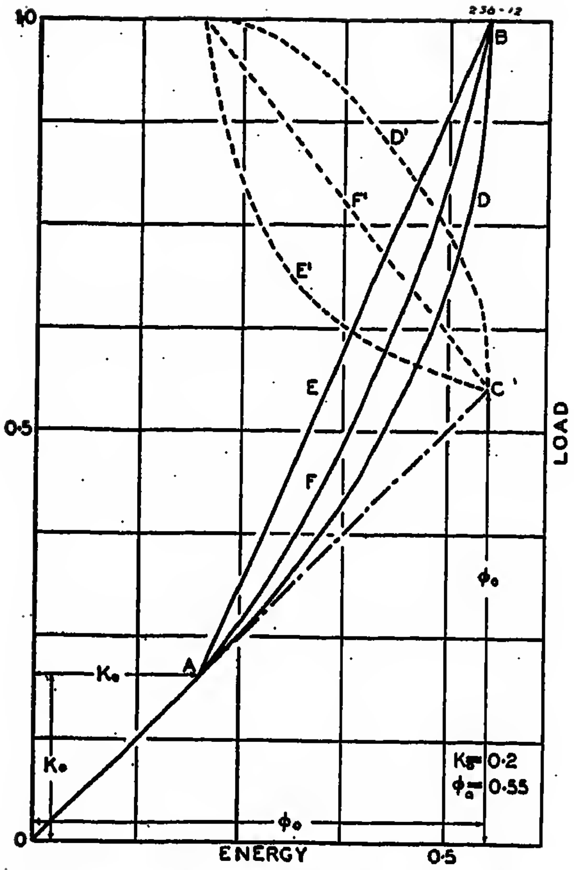

Figure 12. Peak-load versus energy and load-factor versus energy curves

point B as a straight line with less slope than the curve E has at B. In fact, this result would make curve E slightly concave downward at B.[3]

Combination of Equal Factors

In this discussion of load factors, it may not be amiss to rewrite two formulas which have proved most useful in determining the combined load factors or loss factors of a number of loads (Q in number) which occur at random and are about equal as to load factors, magnitudes, and durations.[4]

$$\phi_Q = \frac{1}{Q^{-1/\alpha}\left(\frac{1}{\phi_1}-1\right)+1} \tag{15}$$

$$\theta_Q = \frac{1}{Q^{-1/\psi}\left(\frac{1}{\phi_1}-1\right)+1} \tag{16}$$

For a uniform distribution of loads throughout the period considered, it would seem that the values of α and ψ should have a theoretical value of 2, to harmonize with the theory of least squares as applied to deviations. The author has found from experience that chiefly due to a nonuniform load distribution, over the time considered—such as a day—the values of α and ψ will be greater than 2. The actual values, once found for specific conditions, can be re-employed for others, in which the magnitudes involved may be quite different.

These formulas, the derivation of which is shown in appendix H, may be applied to many problems involving demand factors and diversity factors and have been found particularly helpful in the design of utility distribution systems, whether for electricity, gas, water, or sewage.

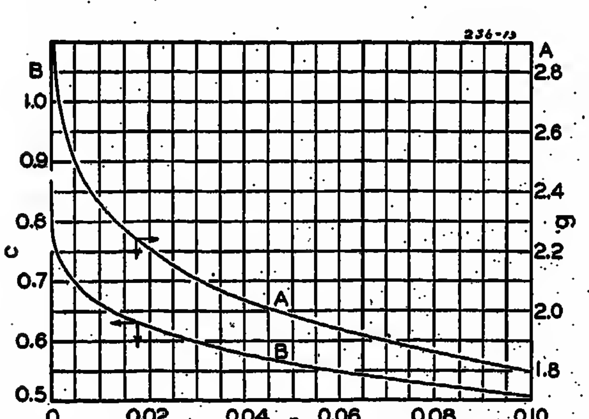

Figure 13. Values of c and g in terms of p/T

Conclusions

The formulas presented in this paper may be applied in many ways, and their effectiveness enhanced by the addition of constants derived from experience in actual calculations. Here, they demonstrate methods only.

Often comparison between the behavior of small loads and large loads is lost sight of through the differences in magnitudes and scales used. It is felt that a reduction to unity values is a first step in arriving at a greater simplicity in the visualization of essential factors.

In passing from the specific case to the more general, in which the elements of probability enter, it is believed that more useful and accurate solutions are obtained, especially in that field in which the elements have an economic significance which depends on yearly values.

There are many routes by which one may arrive at answers for the intangible problems to which these formulas are best suited. It is possible even to obtain rms values of loads drawn on circular charts by weighing the aggregate amount of paper included within the graphs; or the same results often may be gotten by instruments and meters. If this presentation assists some engineers in reducing the detailed labor of plotting, planimeter work, and summations, one of its purposes will have been accomplished.

To explain more fully direct methods of application, the solutions to some simple examples are included as appendix I.

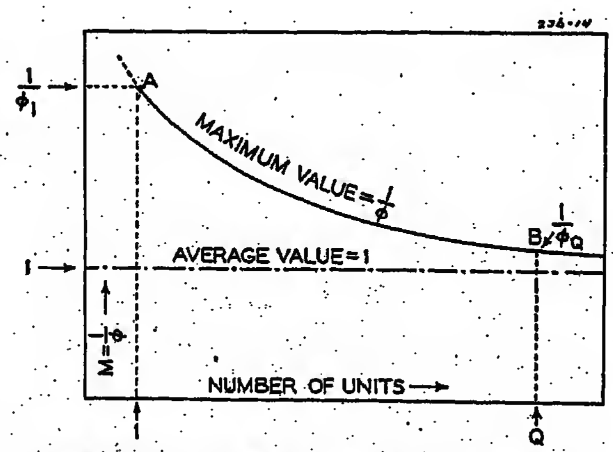

Figure 14. Curve of demand in terms of number of units contributing

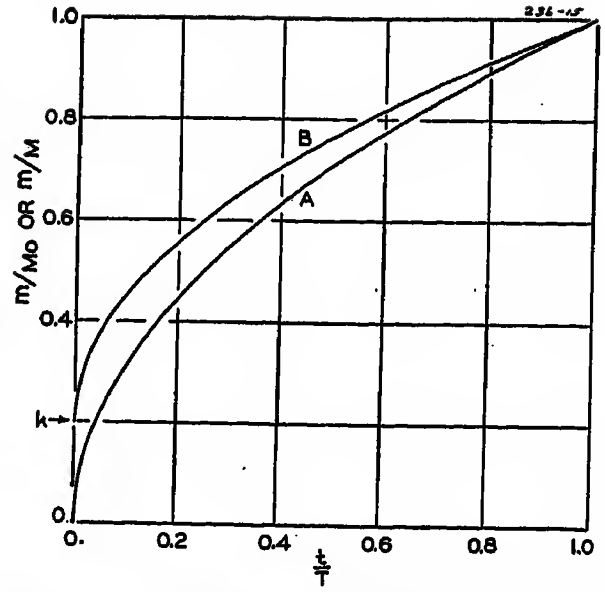

Figure 15. Curves of $f(t/T)$ and $f(t/T)+k$

Appendix A

Referring to Figure 1 of the paper, the equation for curve A can be expressed as

$m = f(t)$

then

$$W_0 = \int^T f(t)dt$$

and

$$\phi_0 = \frac{W_0}{M_0T} = \frac{1}{M_0T}\int_0^T f(t)dt$$

or

$$\int_0^T f(t)dt = \phi_0 M_0 T \tag{17}$$

for curve B

$m = KM + f(t)$

and

$$W = \int_0^T [KM + f(t)]dt$$

$$\phi = \frac{W}{MT} = \frac{1}{MT}\int_0^T [KM+f(t)]dt$$

$$= K + \frac{1}{MT}\int_0^T f(t)dt \tag{18}$$

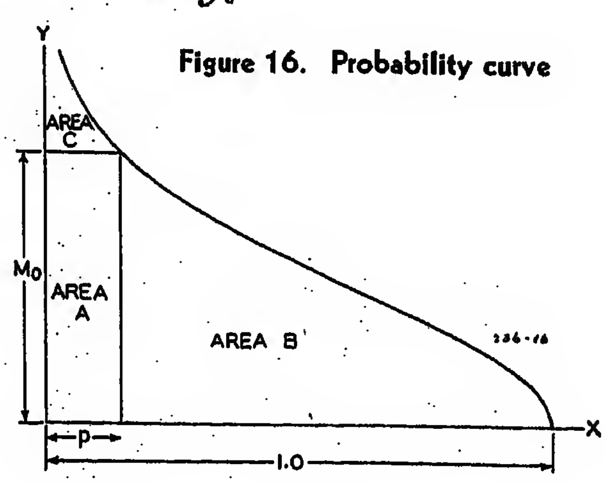

Figure 16. Probability curve

substituting equation 17 in equation 18

$$\phi=K+\phi_0\frac{M_0}{M} \tag{19}$$

but

$M=M_0+KM$ or $M_0=(1-K)M$ and

$$\frac{M_0}{M}=(1-K)$$

therefore

$$\phi=K+\phi_0(1-K) \tag{20}$$

By definition

$$\theta_0=\frac{1}{M_0{}^2T}\int_0^T[f(t)]^2dt \tag{21}$$

and

$$\theta=\frac{1}{M^2T}\int_0^T[KM+f(t)]^2dt \tag{22}$$

from which

$$\theta=\frac{1}{M^2T}\left[K^2M^2T+2KM\int_0^T f(t)dt+\int_0^T[f(t)]^2dt\right] \tag{23}$$

from equation 21

$$\int_0^T[f(t)]^2dt=\theta_0M_0{}^2T \tag{24}$$

substituting equations 17 and 24 in equation 23 and since

$$\frac{M_0}{M}=(1-K)$$

$$\theta=K^2+2K(1-K)\phi_0+(1-K)^2\theta_0 \tag{25}$$

from equation 20

$$\phi_0=\frac{\phi-K}{1-K}$$

and by definition

$$\rho_0=\frac{\theta_0}{\phi_0{}^2}$$

Therefore

$$\theta_0=\rho_0\phi_0{}^2=\rho_0\left(\frac{\phi-K}{1-K}\right)^2$$

substituting in equation 25

$$\theta=K^2+2K(\phi-K)+\rho_0(\phi-K)^2$$

from which

$$\theta=\phi^2+(\rho_0-1)(\phi-K)^2 \tag{26}$$

Appendix B

By plotting the curves of Figure 1 with

$$\frac{m}{M_0}=f\left(\frac{t}{T}\right)$$

and

$$\frac{m}{M}=K+f\left(\frac{t}{T}\right)$$

as shown in Figure 15, then if

$$f\left(\frac{t}{T}\right)=\left(\frac{t}{T}\right)^n$$

equations for curves A and B become respectively,

$$\frac{m}{M_0}=\left(\frac{t}{T}\right)^n \text{ and } \frac{m}{M}=K+(1-K)\left(\frac{t}{T}\right)^n$$

$$W_0=\int_0^1\left(\frac{t}{T}\right)^n d\left(\frac{t}{T}\right)=\frac{1}{n+1} \tag{27}$$

when

$$m=M_0=1.0,\quad t=T_0=1.0$$

$$\phi_0=\frac{W_0}{M_0T_0}=W_0=\frac{1}{n+1} \tag{28}$$

Since

$\phi=K+(1-K)\phi_0$ (from appendix A)

$$\phi=K+\frac{(1-K)}{(n+1)} \text{ from which } n=\frac{1-\phi}{\phi-K} \tag{29}$$

Then

$$\frac{m}{M}=K+(1-K)\left(\frac{t}{T}\right)^{\frac{1-\phi}{\phi-K}}$$

or

$$m=M\left[K+(1-K)\left(\frac{t}{T}\right)^{\frac{1-\phi}{\phi-K}}\right] \tag{30}$$

by definition

$$\theta_0=\int_0^1\left(\frac{t}{T}\right)^{2n}d\left(\frac{t}{T}\right)=\frac{1}{2n+1} \tag{31}$$

and from appendix A

$$\theta=\phi^2+(\rho_0-1)(\phi-K)^2$$

also by definition

$$\rho_0=\frac{\theta_0}{\phi_0{}^2}=\frac{1}{2n+1}\div\frac{1}{(n+1)^2}=\frac{n^2}{2n+1}+1$$

or

$$\rho_0-1=\frac{n^2}{2n+1}$$

so that

$$\theta=\phi^2+\left(\frac{n^2}{2n+1}\right)(\phi-K)^2$$

or

$$\theta=\phi^2+\frac{(1-\phi)^2(\phi-K)^2}{(1-K)^2-(1-\phi)^2} \tag{32}$$

Since

$$n=\frac{1-\phi}{\phi-K}$$

For the special case where $K=0$

$$\theta=\phi^2+\frac{(1-\phi)^2\phi^2}{1-(1-\phi)^2}=\frac{\phi}{2-\phi} \tag{33}$$

and

$$\rho=\frac{\theta}{\phi^2}=\frac{\phi}{(2-\phi)\phi^2}=\frac{1}{\phi(2-\phi)} \tag{34}$$

Appendix C

A common form for the equation of the probability curve shown in Figure 10 is

$$y=e^{-h^2x^2}$$

from which

$$x=\frac{1}{h}\left(\log_e\frac{1}{y}\right)^{1/2} \tag{35}$$

Let

$$x=\frac{m}{M_0}$$

and

$$y=\frac{t}{T}$$

then equation 35 becomes

$$\frac{m}{M_0}=\frac{1}{h}\left(\log_e\frac{T}{t}\right)^{1/2} \tag{36}$$

One half of the area under the probability curve is

$$\int ydx=\int_0^\infty e^{-h^2x^2}dx=\frac{\sqrt{\pi}}{2h} \tag{37}$$

which is also the area corresponding to W_0. From appendix B

$$W_0=\phi_0$$

and from appendix A

$$\phi_0=\frac{\phi-K}{1-K}$$

Therefore

$$W_0=\phi_0=\frac{\phi-K}{1-K}=\frac{\sqrt{\pi}}{2h}$$

from which

$$\frac{1}{h}=\frac{2}{\sqrt{\pi}}\cdot\left(\frac{\phi-K}{1-K}\right)$$

substituting in equation 36

$$\frac{m}{M_0}=\frac{2}{\sqrt{\pi}}\left(\frac{\phi-K}{1-K}\right)\left(\log_e\frac{T}{t}\right)^{1/2} \tag{38}$$

from appendix B

$$\frac{m}{M}=K+(1-K)\frac{m}{M_0}$$

so that

$$\frac{m}{M}=K+\frac{2}{\sqrt{\pi}}(\phi-K)\left(\log_e\frac{T}{t}\right)^{1/2}$$

or

$$m=M\left[K+\frac{2}{\sqrt{\pi}}(\phi-K)\left(\log_e\frac{T}{t}\right)^{1/2}\right] \tag{39}$$

for

$$m=M_0$$

and

$$t=T$$

$$\theta_0=\int_0\left(\frac{m}{M_0}\right)^2dt$$

or

$$\theta_0=\frac{1}{h^2}\int_0^1\left(\log_e\frac{T}{t}\right)d\left(\frac{t}{T}\right)$$
$$=-\frac{1}{h^2}\int_0^1\left(\log_e\frac{t}{T}\right)d\left(\frac{t}{T}\right)=\frac{1}{h^2}$$

then

$$\rho_0=\frac{\theta_0}{\phi_0^2}=\frac{1}{h^2}\div\left(\frac{\sqrt{\pi}}{2h}\right)^2=\frac{4}{\pi}$$

and

$$(\rho_0-1)=\left(\frac{4}{\pi}-1\right)$$

and

$$\theta=\phi^2+(\rho_0-1)(\phi-K)^2$$

or

$$\theta=\phi^2+\left(\frac{4}{\pi}-1\right)(\phi-K)^2 \tag{40}$$

With the curve of Figure 9 terminating at point D, when

$$t=p,\ m=D=M_0+KM$$

so that equation 36 becomes

$$\frac{m}{M_0}=\frac{M_0}{M_0}=1.0=\frac{1}{h}\left(\log_e\frac{T}{p}\right)^{1/2} \tag{41}$$

for the origin at $Pt\ O$, KM from which

$$h=\left(\log_e\frac{T}{p}\right)^{1/2}$$

substituting in equation 36

$$\frac{m}{M_0}=\frac{\left(\log_e\frac{T}{t}\right)^{1/2}}{\left(\log_e\frac{T}{p}\right)^{1/2}}=\left[\frac{\log_e\frac{T}{t}}{\log_e\frac{T}{p}}\right]^{1/2}$$

also

$$\left[\frac{\log_{10}\frac{T}{t}}{\log_{10}\frac{T}{p}}\right]^{1/2} \tag{42}$$

and

$$\frac{m}{M}=K+(1-K)\frac{m}{M_0}=K+(1-K)\left[\frac{\log_e\frac{T}{t}}{\log_e\frac{T}{p}}\right]^{1/2}$$

from which

$$m=M\left[K+(1-K)\left(\frac{\log_e\frac{T}{t}}{\log_e\frac{T}{p}}\right)^{1/2}\right]$$
$$=M\left[K+(1-K)\left(\frac{\log_{10}\frac{T}{t}}{\log_{10}\frac{T}{p}}\right)^{1/2}\right] \tag{43}$$

between the limits $t=p$ and $t=T$.

Appendix D

Derivation of values for c and g of equations 11 and 12 for a peak-load period of one hour in 24 hours ($p=1/24$). From appendix C the equation for the probability curve (Figure 16) may be expressed as

$$y=\frac{1}{h}\left(\log_e\frac{1}{x}\right)^{1/2} \tag{44}$$

where $y=M_0$ and $x=t/T$ then

$$\text{area } B=\frac{1}{h}\int_{x=p}^{x=1}\left(\log_e\frac{1}{x}\right)^{1/2}dx$$

let

$$z=\left(\log_e\frac{1}{x}\right)^{1/2}=\left(\log_e\frac{1}{p}\right)^{1/2}$$

when $x=p$. Therefore

$$\text{area } B=\frac{2}{h}\left[\left(\frac{z^3}{3}+\frac{z^7}{14}+\frac{z^{11}}{264}+\ldots\right)-\left(\frac{z^5}{5}+\frac{z^9}{54}+\frac{z^{13}}{1,560}+\ldots\right)\right]=\frac{0.801579}{h} \tag{45}$$

$$\text{area } (A+B+C)=\frac{\sqrt{\pi}}{2h}=\frac{0.886227}{h}$$
(from appendix C) (46)

then

$$\text{area } (A+C)=\text{equation 46 less equation 45}=\frac{0.084648}{h}$$

Defining g as the average load during the period p, the value of g is obtained from

$$g=\frac{\text{area } (A+C)}{p}=\frac{24\times0.084648}{h}=\frac{2.031552}{h} \tag{47}$$

Since the objective is to obtain a ratio for two values of g, there is no need to obtain a numerical value for h which cancels out, or one can use $h=1.0$. The numerator of equation 47 is therefore one point on curve A of Figure 13 which has been plotted for the value

$p=1/24$ or 0.04167

From equation 44

$$y^2=\frac{1}{h^2}\log_e\frac{1}{x}$$

and the area under this curve corresponding to section B =

$$\int_p^1\frac{1}{h^2}\left(\log_e\frac{1}{x}\right)dx=\frac{1}{h^2}\left[1-p\left(1+\log_e\frac{1}{p}\right)\right]$$

and for $p=1/24$

$$r_B^2=\frac{0.825914}{h^2} \tag{48}$$

From equation 44

$$M_0=\frac{1}{h}\left(\log_e\frac{1}{x}\right)^{1/2}=\frac{1}{h}\left(\log_e\frac{1}{p}\right)^{1/2}$$

and for $p=1/24$

$$M_0=\frac{1.782712}{h}$$

and

$$M_0^2=\frac{3.178062}{h^2}$$

so that the corresponding area under M_0^2 for section A becomes

$$r_A^2=M_0^2p=\frac{3.178062}{h^2}\times\frac{1}{24}=\frac{0.132419}{h^2} \tag{49}$$

$$r_A^2+r_B^2=\frac{0.825914}{h^2}+\frac{0.132419}{h^2}=\frac{0.958333}{h^2} \tag{50}$$

by definition

$$r^2=M^2\theta$$

so that

$$\theta_{A+B}=\theta_0=\frac{r_A^2+r_B^2}{M_0^2}=\frac{0.958333}{M_0^2h^2}$$

by definition

$$\phi=\frac{W}{MT}$$

and for $T=1.0$

$$\phi=\frac{W}{M}$$

then

$$\phi_{A+B}=\phi_0=\frac{W_A+W_B}{M_0}$$

$$W_A=M_0p=\frac{1.782712}{h}\times\frac{1}{24}=\frac{0.074280}{h}$$

$$W_B=\frac{0.801579}{h} \text{ from equation 45}$$

Therefore

$$\phi_{A+B}=\phi_0=\left(\frac{0.074280}{h}+\frac{0.801579}{h}\right)\frac{1}{M_0}$$
$$=\frac{0.875859}{M_0h}$$

$$\rho_0=\frac{\theta_0}{\phi_0^2}=\frac{0.958333}{M_0^2h^2}\times\frac{M_0^2h^2}{(0.875859)^2}$$
$$=1.249248 \tag{51}$$

and

$$\rho_0-1=1.249248-1.0=0.249248$$

From appendix C $(\rho_0-1)=(4/\pi-1)$ for curve without constant value for M_0 during period p. As a correction for effect of latter condition, assume

$$(\rho_0-1)=\left(\frac{4}{\pi}-1\right)-\frac{cp}{T}$$

where cp/T is correction factor. Then

$$(\rho_0-1)=0.249=\left(\frac{4}{\pi}-1\right)-\frac{cp}{T}$$

and for $p/T=1/24$

$c=0.5758$ which represents one point on curve B of Figure 13 which has been plotted for the value $p=1/24$ or 0.042.

Appendix E

Referring to Figure 9, let p_1 and p_2 be two intervals during which the corresponding peak loads M_1 and M_2 are measured as average values. Then from appendix D

$$g_1 = M_1 - KM = M_1 - N$$

and

$$g_2 = M_2 - KM = M_2 - N$$

since

$$KM = N$$

Therefore

$$\frac{M_1 - N}{M_2 - N} = \frac{g_1}{g_2}$$

or

$$M_1 = N + (M_2 - N)\frac{g_1}{g_2}$$

Appendix F

Total loss = constant loss + variable loss

or $L_1 = L_0 + CM_1^2\theta_1$
and $L_2 = L_0 + CM_2^2\theta_2$

then

$$L_2 - L_1 = C(M_2^2\theta_2 - M_1^2\theta_1)$$

where C = constant, from which

$$C = \frac{L_2 - L_1}{M_2^2\theta_2 - M_1^2\theta_1}$$

and

$$L_0 = L_2 - M_2^2\theta_2\left(\frac{L_2 - L_1}{M_2^2\theta_2 - M_1^2\theta_1}\right)$$

or

$$L_0 = L_2 - \frac{L_2 - L_1}{1 - \left(\frac{\theta_1}{\theta_2}\right)\left(\frac{M_1}{M_2}\right)^2}$$

Appendix G

Referring to Figures 11 and 12, it is seen that the load factor varies from a value of 1.0 at the base load to a value of ϕ_0 at the maximum peak and output for a given time, the line OC being the locus of the peaks for unity load factor. The curve defining this variation may be expressed by

$$(1-\phi) = C(W - K_0M_0T)^\beta$$

where C = constant, when

$$\phi = \phi_0,\ W = \phi_0 M_0 T$$

so that

$$(1-\phi_0) = C(\phi_0 M_0 T - K_0 M_0 T)^\beta$$

from which

$$C = \frac{(1-\phi_0)}{(\phi_0 M_0 T - K_0 M_0 T)^\beta}$$

Therefore

$$(1-\phi) = (1-\phi_0)\left[\frac{W - K_0M_0T}{\phi_0M_0T - K_0M_0T}\right]^\beta$$

$$= (1-\phi_0)\left[\frac{\frac{W}{M_0T} - K_0}{\phi_0 - K_0}\right]^\beta$$

and

$$\phi = 1 - (1-\phi_0)\left[\frac{\frac{W}{M_0T} - K_0}{\phi_0 - K_0}\right]^\beta$$

Appendix H

Referring to Figure 14, it is assumed that the average load for one of Q units is the same as the average value for a single unit. If the average load be taken as unity, the maximum load for a single unit becomes $1/\phi_1$ and for each of Q units, $1/\phi_Q$. Some curve connecting A and B represents the variation of $1/\phi$ with Q.
When $Q \rightleftarrows \infty$, ϕ and $1/\phi \rightleftarrows 1$, the average.
When $Q = 1$, $\phi = \phi_1$ and $1/\phi_1$ is the maximum for 1 unit.

Curve A-B may be expressed in the hyperbolic form

$$\left(\frac{1}{\phi} - 1\right)^\alpha \times Q = C \tag{52}$$

where C = constant. When

$$\phi = \phi_1 \quad Q = 1$$

and

$$C = \left(\frac{1}{\phi_1} - 1\right)^\alpha$$

When

$$\phi = \phi_Q \quad Q = Q$$

and

$$C = \left(\frac{1}{\phi_Q} - 1\right)^\alpha \times Q$$

then

$$\left(\frac{1}{\phi_1} - 1\right)^\alpha = \left(\frac{1}{\phi_Q} - 1\right)^\alpha Q \tag{53}$$

and

$$\left(\frac{1}{\phi_Q} - 1\right) = Q^{-1/\alpha}\left(\frac{1}{\phi_1} - 1\right) \tag{54}$$

or

$$\frac{1}{\phi_Q} = Q^{-1/\alpha}\left(\frac{1}{\phi_1} - 1\right) + 1 \tag{55}$$

so that

$$\phi_Q = \frac{1}{Q^{-1/\alpha}\left(\frac{1}{\phi_1} - 1\right) + 1} \tag{56}$$

For the special case when the minimum load is zero, so that $N = KM = O$, equation 56 becomes

$$\phi_Q = \frac{1}{Q^{-1/\psi}\left(\frac{1}{\phi_1} - 1\right) + 1} \tag{57}$$

also

$$\theta = \frac{\phi}{2-\phi} \quad \text{or} \quad \phi = \frac{2\theta}{1+\theta}$$

from appendix B
substituting in equation 57

$$\frac{2\theta_Q}{1+\theta_Q} = \frac{1}{Q^{-1/\psi}\left(\frac{1-\theta_1}{2\theta_1}\right) + 1} \tag{58}$$

from which

$$\theta_Q = \frac{1}{Q^{-1/\psi}\left(\frac{1}{\theta_1} - 1\right) + 1} \tag{59}$$

Appendix I

Equipment I²R Losses and Capacities

1. A 400-ton suburban train is operating on a schedule for which the average current in the traction motors is 20 per cent of the maximum. To find a figure for the increase in copper losses in the motors if trailers be added to make a total train-weight of 600 tons:

(*a*) The accelerating relays and starting-resistance grids are not altered, and the same schedule is kept by less coasting.

(*b*) The relays are altered to permit 25 per cent more accelerating current.

(*a*) Let

W_1 = energy consumption of motors for 400-ton train
W_2 = energy consumption of motors for 600-ton train

Then

$$W_1 = \phi_1 M_1 T_1; \quad W_2 = \phi_2 M_2 T_2$$

and

$$\frac{W_2}{W_1} = \frac{\phi_2}{\phi_1}$$

Since

$$M_1 = M_2 \text{ and } T_1 = T_2$$

Since

$$W_2 = 1.5W_1 \quad \phi_2 = 1.5\phi_1$$
$$\phi_1 = 0.2$$

Therefore

$$\phi_2 = 0.3$$

From equation 6

$$\theta_1 = \frac{\phi_1}{2-\phi_1} = \frac{0.2}{1.8} = 0.111$$

$$\theta_2 = \frac{\phi_2}{2-\phi_2} = \frac{0.3}{1.7} = 0.176$$

Per cent increase in copper losses

$$= \frac{\theta_2 - \theta_1}{\theta_1} \times 100 = \frac{0.176 - 0.111}{0.111} \times 100$$

= 58.6 per cent. Say 59 per cent.

(b) $W_1=\phi_1 M_1 T_1$ and $W_2=\phi_2 M_2 T_2$
But $W_2=1.5W_1$; $M_2=1.25M_1$ and since $T_1=T_2$
Therefore

$$W_2=\phi_2 M_2 T_2=1.5W_1=1.5\phi_1 M_1 T_1$$

or

$$\phi_2\times 1.25 M_1 T_2=1.5\phi_1 M_1 T_1$$

or

$$\phi_2=\frac{1.5\phi_1}{1.25}=\frac{1.5\times 0.2}{1.25}=0.24$$

Then

$$\theta_1=\frac{\phi_1}{2-\phi_1}=\frac{0.2}{1.8}=0.111$$

and

$$\theta_2=\frac{\phi_2}{2-\phi_2}=\frac{0.24}{1.76}=0.136$$

Let L_1 = present copper loss
L_2 = new copper loss

Then

$$\frac{L_2}{L_1}=\frac{C\times 0.136\times(M_2)^2}{C\times 0.111\times(M_1)^2}=\frac{0.136}{0.111}(1.25)^2=1.92$$

where C is a constant
or $L_2=1.918L_1$
Per cent increase in copper loss is 92 per cent.

2. An induction motor is to be applied to a load which is expected to fluctuate between no load and 500 horsepower momentarily, and it is known that 60 horsepower-hours must be delivered at the shaft during a 20-minute cycle. To determine the minimum necessary rating of this motor:
Given:

$M=500$ hp; $W=60$ hp-hr; $T=1/3$ hr; $K=0$

Then

$$A=\frac{W}{T}=60\div 1/3=180 \text{ hp}$$

and

$$\phi=\frac{A}{M}=\frac{180}{500}=0.36$$

From equation 7

$$\rho=\frac{1}{\phi(2-\phi)}=\frac{1}{0.36\times 1.64}=1.694$$

By definition $r=uA$ and $r^2=\rho A^2$ or

$r=A\sqrt{\rho}=180\sqrt{1.694}=234$ horsepower

which is the required rating. The next higher standard rating is 250 horsepower, and a motor of this capacity will serve, provided it has sufficient torque to carry the 500-horsepower peak.

3. A motor-generator set supplying a reversing rolling-mill motor consumes 150,000 kilowatt-hours during a 24-hour run. Switchboard instruments show that the power to this set fluctuates between 400 and 12,000 kw with almost constant power factor. The cable system to the motor is known to have a loss of 50 kw on a 3,000-kw load. It is required to find the average loss in the cables, and the transformer capacity needed for this load only, if a separate bank be installed to carry this set and cable losses. Power factor 0.83. Given:

$W=150{,}000$ kwhr; $M=12{,}000$ kw; $KM=400$ kw; $T=24$ hr

$$A=\frac{150{,}000}{24}=6{,}250 \text{ kw} \quad \phi=\frac{6{,}250}{12{,}000}=0.5208$$

$$K=\frac{400}{12{,}000}=0.0333$$

Cable Losses

$$\text{At maximum load}=50\times\left(\frac{12{,}000}{3{,}000}\right)^2=800 \text{ kw}$$

$$\text{At minimum load}=50\times\left(\frac{400}{3{,}000}\right)^2=0.89 \text{ kw}$$

say 1.0 kw

Average cable losses $=\theta\times$ loss at maximum load $=\theta\times 800$

From equation 5

$$\theta=\phi^2+\frac{(\phi-K)^2\times(1-\phi)^2}{(1-K)^2-(1-\phi)^2}$$
$$=(0.521)^2+\frac{(0.521-0.033)^2(1-0.521)^2}{(1-0.033)^2-(1-0.521)^2}$$
$$=0.350$$

therefore average cable losses $=0.350\times 800=280$ kw

For Transformer

Maximum load = 12,000+800 = 12,800 kw
Average load = 6,250+280 = 6,530 kw
Minimum load = 400+ 1 = 401 kw

Then

$$\phi=\frac{6{,}530}{12{,}800}=0.510$$

$$K=\frac{401}{12{,}800}=0.031$$

and

$$\theta=\phi^2+\frac{(\phi-K)^2\times(1-\phi)^2}{(1-K)^2-(1-\phi)^2}$$
$$=(0.510)^2+\frac{(0.510-0.031)^2(1-0.510)^2}{(1-0.031)^2-(1-0.510)^2}$$
$$=0.339$$

$r^2=M^2\theta$ or $r=M\sqrt{\theta}=12{,}800\sqrt{0.339}$
$=7{,}450$ kw

and at 83 per cent power factor the transformer capacity required = 8,980 kva, say 9,000 kva.

Extrapolation of Demands

4. On one of the days of maximum load a utility company had a peak load of 245,000 kw and an output of 3,116,400 kilowatt-hours. On a day of less load the output was 2,508,000 kilowatt-hours with a peak of 190,000 kw. With this basis, to determine the peak which may be expected when the daily output reaches 3,500,000 kw, the base load is 35,000 kw.
Given:

$M_0=245{,}000$ kw $\quad W_0=3{,}116{,}400$ kwhr
$M_1=190{,}000$ kw $\quad W_1=2{,}508{,}000$ kwhr

$K_0M_0=35{,}000$ kw

or

$$K_0=\frac{35{,}000}{245{,}000}=0.143$$

$T=24$ hr $\quad W_2=3{,}500{,}000$ kwhr

$$\phi_0=\frac{W_0}{M_0T}=\frac{3{,}116{,}400}{245{,}000\times 24}=0.53$$

$$\phi_1=\frac{W_1}{M_1T}=\frac{2{,}508{,}000}{190{,}000\times 24}=0.55$$

From equation 14

$$\phi_1=1-(1-\phi_0)\left[\frac{\frac{W_1}{M_0T}-K_0}{\phi_0-K_0}\right]^\beta$$

or

$$0.55=1-(1-0.53)\left[\frac{\frac{2{,}508{,}000}{245{,}000\times 24}-0.143}{0.53-0.143}\right]^\beta$$

from which $\beta=0.140$

Therefore

$$\phi_2=1-(1-0.53)\times\left[\frac{\frac{3{,}500{,}000}{245{,}000\times 24}-0.143}{0.53-0.143}\right]^{0.140}=0.52$$

$$M_2=\frac{W_2}{\phi_2T}=\frac{3{,}500{,}000}{0.52\times 24}=280{,}000 \text{ kw}$$

5. To find a value for the increase in demand in an apartment house which may be caused by the installation of 125 electric refrigerators and 125 electric ranges. Each refrigerator is reported to consume 240 watts and about 40 kilowatt-hours monthly. Each range has an average peak of 3,500 watts and consumes about 125 kilowatt-hours monthly.

For the Refrigerators

$M_1=240$ watts $\quad T=24\times 30=720$ hrs per month
$W_1=40{,}000$ watt-hours $\quad Q=125$

$$A_1=\frac{40{,}000}{720}=56 \text{ watts} \quad \phi_1=\frac{A_1}{M_1}=\frac{56}{240}=0.23$$

From equation 14

$$\phi_Q=\frac{1}{Q^{-1/\alpha}\left(\frac{1}{\phi_1}-1\right)+1}$$
$$=\frac{1}{\frac{\left(\frac{1}{0.231}-1\right)}{\sqrt[3]{125}}+1}=0.60$$

where α assumed to have a value of 3.0.

Therefore

maximum coincident demand (M_{Q1}) =

$$\frac{56\times125}{0.60}=11{,}700\text{ watts, say 12 kw}$$

and

$$\text{demand factor}=\frac{11{,}700}{125\times240}=0.39$$

For the Ranges

$M_2=3{,}500$ watts $\quad T=720$ hr

$W_2=125{,}000$ watt-hours $\quad Q=125$

$$A_2=\frac{125{,}000}{720}=174\text{watts}\qquad \phi_2=\frac{174}{3{,}500}=0.050$$

$$\phi_Q=\frac{1}{\dfrac{\left(\dfrac{1}{0.05}-1\right)}{\sqrt[3]{125}}+1}=0.21$$

therefore

maximum coincident demand (M_{Q2}) =

$$\frac{174\times125}{0.21}=103{,}600\text{ watts, say 104 kw}$$

and

$$\text{demand factor}=\frac{103{,}600}{125\times3{,}500}=0.24$$

Since the two peaks can be coincident the combined maximum demand is 104+12= 116 kw, and the over-all demand factor=

$$\frac{116}{125(0.24+3.5)}=0.25$$

6. Measurements taken at a transformer bank which supplies a group of 300 residences show a peak of 130 kw and an average load of 24 kw. The maximum consumption rate in these homes is known to be about one kilowatt each. To determine the expected demand in a similar group of 450 houses; also for one of 1,000 houses.

For the Group of 450 Houses

Given for 300 houses

$$M_1=1\text{ kw}\qquad A_1=\frac{24}{300}=0.08\text{ kw}$$

$$\phi_1=\frac{0.08}{1}=0.08$$

$$M_Q=130\text{ kw}\qquad A_Q=24\text{ kw}\qquad \phi_Q=\frac{24}{130}=0.185$$

$$Q=300\qquad \text{Demand factor}=\frac{130}{300\times1}=0.433$$

From equation 14

$$\phi_Q=\frac{1}{Q^{-1/\alpha}\left(\dfrac{1}{\phi_1}-1\right)+1}$$

$$=\frac{1}{300^{-1/\alpha}\left(\dfrac{1}{0.08}-1\right)+1}=0.185$$

from which $\alpha=5.96$. For the 450 houses $Q=450$ and

$$\phi_{Q1}=\frac{1}{(450)^{-\frac{1}{5.96}}\left(\dfrac{1}{0.08}-1\right)+1}=0.195$$

and maximum demand for 450 houses =

$$\frac{24}{0.195}\times\left(\frac{450}{300}\right)=185\text{ kw}$$

$$\text{demand factor}=\frac{185}{450\times1}=0.41$$

For 1,000 houses

$$\phi_Q=\frac{1}{(1{,}000)^{-\frac{1}{5.96}}\left(\dfrac{1}{0.08}-1\right)+1}=0.217$$

maximum demand for 1,000 houses =

$$\frac{24}{0.217}\times\left(\frac{1{,}000}{300}\right)=369\text{ kw}$$

and

$$\text{demand factor}=\frac{369}{1{,}000\times1}=0.37$$

Distribution and Transmission Losses

7. During two periods within a year, for 31 days and 59 days respectively, the records of a utility company show the results given in Table A.

Required to find the constant losses of the distribution system:

Table A

Generated Kwhr	Sold Kwhr	1-Hr Peak, Kw	Minimum Load Kw
86,421,000	72,080,000	242,000	41,100
146,566,000	122,498,000	195,300	35,000

Given:

$M_1=242{,}000$ kw

$T_1=31$ days

$K_1M_1=41{,}000$ kw

$W_1=86{,}421{,}000$ kwhr

$M_2=195{,}300$ kw

$T_2=59$ days

$K_2M_2=35{,}000$ kw

$W_2=146{,}566{,}000$ kwhr

Then

$$A_1=\frac{86{,}421{,}000}{31\times24}=116{,}200\text{ kw}\qquad A_2=\frac{146{,}566{,}000}{59\times24}=103{,}500\text{ kw}$$

$$\phi_1=\frac{116{,}200}{242{,}000}=0.48\qquad \phi_2=\frac{103{,}500}{195{,}300}=0.53$$

$$L_1=\frac{86{,}421{,}000-72{,}080{,}000}{31\times24}=19{,}300\text{ kw}\qquad L_2=\frac{146{,}566{,}000-122{,}498{,}000}{59\times24}=17{,}000\text{ kw}$$

$$K_1=\frac{41{,}100}{242{,}000}=0.17\qquad K_2=\frac{35{,}000}{195{,}300}=0.18$$

From equation 9

$$\theta=\phi^2+0.273(\phi-K)^2$$

Then

$$\theta_1=(0.48)^2+0.273(0.31)^2=0.257$$

$$\theta_2=(0.53)^2+0.273(0.35)^2=0.314$$

From equation 13

$$L_0=L_2-\frac{L_2-L_1}{1-\dfrac{\theta_1}{\theta_2}\left(\dfrac{M_1}{M_2}\right)^2}=17{,}000-\frac{17{,}000-19{,}300}{1-\dfrac{0.257}{0.314}\left(\dfrac{242{,}000}{195{,}300}\right)^2}=8{,}100\text{ kw}$$

8. A projected transmission line is to deliver 100 million kilowatt-hours annually with a line loss not to exceed five million kilowatt-hours. There will be a base load of 5,000 kw and a peak of 25,000 kw. The permissible line loss at the maximum load is required.

$M=25{,}000$ kw $\quad KM=5{,}000$ kw

$W=100{,}000{,}000$ kwhr $\quad L=5{,}000{,}000$ kwhr

$T=8{,}760$ hr

$$A=\frac{100{,}000{,}000}{8{,}760}=11{,}420\text{ kw}$$

$$\phi=\frac{11{,}420}{250{,}000}=0.457$$

$$K=\frac{5{,}000}{25{,}000}=0.2$$

Table B

Company	Peak Load Kw (M_1)	Duration of Peak (Minutes) (p/T × 1,440)	Production Kwhr (Thousands) (W)
A	310,000	60	1,414,828
B	148,200	15	630,941
C	407,500	20	2,152,529
D	204,000	30	1,022,187
E	55,300	5	221,384

Company	ϕ	K	KM_1	M_1-KM_1	g_2/g_1	$M_i=KM_1+(M_1-KM_1)g_2/g_1$
A	0.521	0.208	64,600	245,400	1/0.924	330,200
B	0.486	0.194	28,800	119,400	1/0.935	140,400
C	0.603	0.241	98,300	309,200	1/0.959	394,800
D	0.572	0.229	46,700	157,300	1/1.000	204,000
E	0.457	0.183	10,100	45,200	1/0.852	48,600

K assumed as 0.4ϕ $\qquad \phi=W/8{,}760M_1$ $\qquad g_2/g_1$ from Table II

From equation 9

$$\theta=\phi^2+0.273(\phi-K)^2=(0.457)^2+0.273)\times(0.457-0.2)^2=0.227$$

$$\text{Average loss}=\frac{5{,}000{,}000}{8{,}760}=571\text{ kw}$$

$$\text{Loss at maximum load}=\frac{\text{average loss}}{\theta}=\frac{571}{0.227}=2{,}520\text{ kw}$$

9. An isolated feeder circuit supplies a manufacturing plant 40 million kilowatt-hours annually, metered at the plant. On the maximum day the peak was 12,000 kva at 0.85 power factor; consumption 123,000 kilowatt-hours; base load 1,800 kva. On the minimum day the peak was 9,000 kva at 0.90 power factor; consumption 105,000 kilowatt-hours with a base load of 1,500 kva.

At a load of 3,000 kva, the feeder loss is 120 kw. The annual feeder loss is required to determine if additional copper is warranted.

Given:

Annually

$W=40{,}000{,}000$ kwhr

Maximum Day

$W_2=123{,}000$ kwhr
$M_2=12{,}000\text{ kva}=10{,}200$ kw
$K_2M_2=1{,}800$ kva

$$K_2=\frac{1{,}800}{12{,}000}=0.15$$

$$\phi_2=\frac{123{,}000}{24\times10{,}200}=0.502$$

$$(\phi_2-K_2)=(0.502-0.15)=0.352$$

$$(1-K_2)=1-0.15=0.85$$

Minimum Day

$W_1=105{,}000$ kwhr
$M_1=9{,}000\text{ kva}=8{,}100$ kw
$K_1M_1=1{,}500$ kva

$$K_1=\frac{1{,}500}{9{,}000}=0.167$$

$$\phi_1=\frac{105{,}000}{24\times8{,}100}=0.540$$

$$(\phi_1-K_1)=(0.540-0.167)=0.373$$

$$(1-K_1)=1-0.167=0.833$$

Using curve of function 11 of Table I

$$\theta=\phi^2+{}^1/_{15}[3(\phi-K)^2-3(\phi-K)(1-K)+2(1-K)^2]$$

$$\theta_1=(0.540)^2+{}^1/_{15}[3(0.373)^2-3(0.373\times0.833)+2(0.833)^2]=0.349$$

$$\theta_2=(0.502)^2+{}^1/_{15}[3(0.352)^2-3(0.352\times0.85)+2(0.85)^2]=0.313$$

then

$$L_1=120\times\left(\frac{9{,}000}{3{,}000}\right)^2\times0.349=377\text{ kw}$$

$$L_2=120\times\left(\frac{12{,}000}{3{,}000}\right)\times0.313=602\text{ kw}$$

Using the conception of a solid as illustrated by Figure 7, the value of the energy (W_m) for the theoretical mid-section can be obtained by assuming that the daily energy consumption varies in accordance with formula 2 of Table I so that

$$\frac{w}{W_2}=K+(1-K)\left(\frac{t}{T}\right)^n$$

or

$$w=\left[K+(1-K)\left(\frac{t}{T}\right)^n\right]W_2$$

where $n=\dfrac{1-\phi}{\phi-K}$ and $w=W_m$ when $\dfrac{t}{T}=0.5$

For the above equation, K is obtained by the ratio of W_1 to W_2 or

$$K=\frac{105{,}000}{123{,}000}=0.8537$$

The average daily energy consumption is

$$W_a=\frac{40{,}000{,}000}{365}=109{,}600\text{ kwhr}$$

so that

$$\phi_1=\frac{109{,}600}{123{,}000}=0.8910$$

then

$$n=\frac{1-0.8910}{0.8910-0.8537}=2.922$$

and

$$W_m=[K+(1-K)(0.5)^{2.922}]W_2$$
$$=[0.8537+(0.1463\times0.1319)]123{,}000$$
$$=107{,}400\text{ kwhr}$$

By direct interpolation

$$M_m=8{,}100+[10{,}200-8{,}100]\times\frac{107{,}400-105{,}000}{123{,}000-105{,}000}=8{,}730\text{ kw}$$

and

at the average power factor of

$$\frac{0.90+0.85}{2}=0.875$$

$$M_m=\frac{8{,}730}{0.875}=10{,}000\text{ kva}$$

and

$$\phi_m=\frac{107{,}400}{24\times8{,}730}=0.513$$

Assume

$$\frac{K_m}{\phi_m}=\frac{\dfrac{K_1}{\phi_1}+\dfrac{K_2}{\phi_2}}{2}=\frac{\dfrac{0.167}{0.540}+\dfrac{0.150}{0.502}}{2}=0.304$$

so that

$$K_m=0.304\phi_m=0.304\times0.513=0.156$$

then

$$\theta_m=(0.513)^2+{}^1/_{15}[3(0.357)^2-3(0.357\times0.844)+2(0.844)^2]=0.323$$

and the loss corresponding to the mid-section load curve is

$$0.323\times120\times\left[\frac{10{,}000}{3{,}000}\right]^2=413\text{ kw}$$

The volume of the solid representing the losses, to correspond to Figure 7 may be considered as that of a prismatoid, the formula for which is

$$V=\frac{1}{6}h(A+B+4C)$$

where

V = volume
h = distance between end faces A and B
$A+B$ = area of end faces
C = area of mid-section

then

$h=365$ days
$A=602\text{ kw}\times24$ hours
$B=377\text{ kw}\times24$ hours
$C=413\text{ kw}\times24$ hours

So that

$$\text{annual kwhr loss}=\frac{365}{6}\times24[602+377+(4\times413)]=4{,}133{,}000\text{ kwhr}$$

and

$$\text{the average loss}=\frac{4{,}133{,}000}{24\times365}=472\text{ kw}$$

Comparison of Maximum Demands

10. Utilities A to F report the peak loads and energy generated during a year shown in Table B. For comparative purposes, it is necessary to express all peaks on a 30-minute basis. See formula 12.

Acoustics and the Quiet Train Ride

WILLIAM A. JACK
NONMEMBER AIEE

Synopsis: This paper discusses those fundamentals of acoustics which are important in attacking practical problems in noise reduction. A description is given of the instruments suitable for measuring the physical quantities involved. The train problem is analyzed, and data taken by the author on a relatively quiet type of coach are presented. The various methods of noise control which may be applied to a coach are discussed, and data are presented indicating the possibilities of each method.

I. Some Fundamentals on Sound and Hearing

THE auditory sensation is subjectively simple, and so familiar that the average reaction to the acoustical engineer and his load of instruments is: "I know it's noisy, why measure it; I don't see why your meter readings jump around; you have measured two sounds which are certainly different to our ears, and your meter gives the same reading; the decibel is a silly unit; all I want is a few square feet of absorbing material which will soak up the sound." The critical gentleman may certainly be forgiven, because his viewpoint is understandable. Nevertheless, there are very definite reasons for the techniques and vocabulary of acoustical analysis and for the variety of methods which may be needed to bring about the desired quiet ride.

Sound in Air

Sound, considered physically in air at a point, is a fluctuation in the barometric pressure above and below normal atmospheric pressure. It may be simply a sinusoidal pressure variation with time, or it may be of the greatest complexity. Using a 1,000-cycle-per-second pure tone the ear is found to be

(*a*) Sensitive—it can hear as sound a pressure variation of 2.96×10^{-9} pounds per square inch.

(*b*) Rugged—it can give a hearing sensation (with some discomfort) for a pressure variation of 9.35×10^{-2} pounds per square inch.

These are rms values. This is a remarkable range, covering a pressure ratio of 3.16×10^7 to 1. The pressure variation is usually spoken of simply as the sound pressure. The threshold of hearing varies with frequency, the ear being less acute at each end of its range. Below 20 cycles and above 15,000 cycles, the hearing sensation is not stimulated no matter how large the sound pressure.

The ear can tell us something about pressure and frequency. It has remarkable powers in judging the quality of complex sounds. It cannot remember loudness accurately, however, for even a short time. A pressure gage is needed, with indicating or recording devices, so that a measure of the pressure variation with time, at a point, may be taken. We may wish to get the instantaneous variation over the cycle, or we may be satisfied with an rms reading. When we have these we have all the data the ear ever had, and furthermore we have everything the air can tell us at this point. What we are able to deduce from it depends on experience with a variety of sound sources, and on the relations between the physical disturbance in the air and the hearing reactions of an auditor.

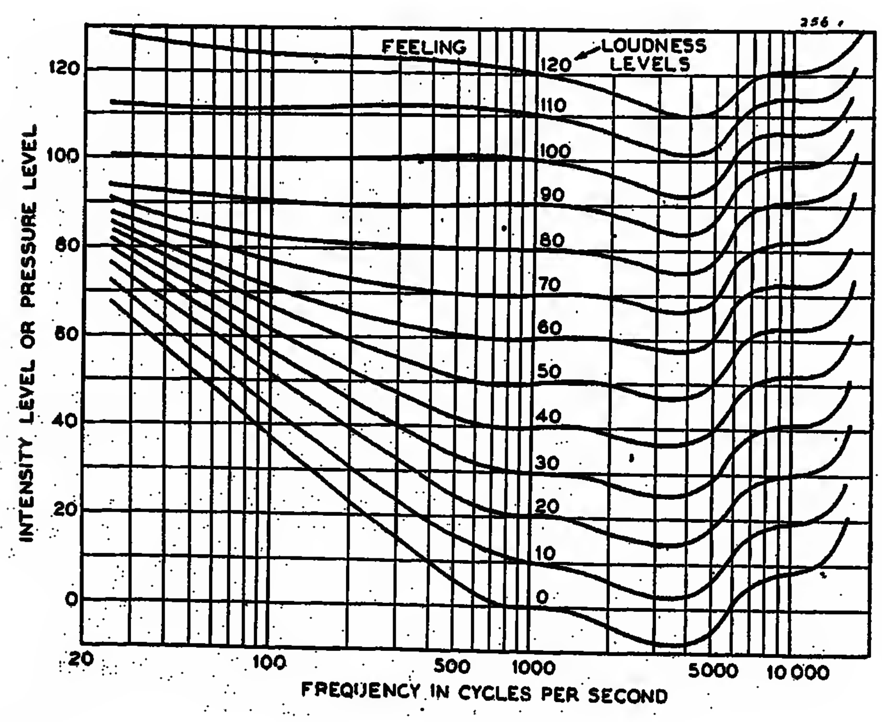

Figure 1. Loudness contours, showing how the sensation of loudness varies with frequency and pressure level

Pressure levels are in decibels; loudness levels are in phons

Decibels

The pressure units given above are inconvenient numbers and cover so wide a range that logarithmic plots would have to be used. The concept of the decibel has been adopted, because it reduces the above pressure range to 150 steps. This is useful, because it is approximately true that 150 variations in loudness may be detected in passing through this range. The difference in decibels between two sound pressures, P_2 and P_1, P_2 being the larger, is defined as

$$\text{decibel difference} = 20 \log_{10} \frac{P_2}{P_1} \qquad (1)$$

The decibel involves a ratio always. When a train noise is said to be 80 decibels, it refers to 80 decibels above some reference pressure. This reference has now been standardized at 2.96×10^{-9} pounds per square inch rms.*

The pressure level of a sound pressure P, expressed in pounds per square inch rms is

$$20 \log_{10} \frac{P}{2.96\times10^{-9}} \text{ decibels} \qquad (2)$$

If desired, sound readings may be given in pressure units. Meters are usually calibrated to read directly in pressure level, which answers most purposes very well.

The practicing acoustical engineer finds the relation between pressure level reduction in physical units and human reaction about as follows.[2]

1 decibel—Barely detectable
5 decibels—Definite improvement, worth some expenditure
10 decibels—Striking improvement, worth considerable cost
20 decibels—Outstanding improvement
25 decibels—Almost like "off and on"

For practical purposes discussed later, decibel here can be replaced by the closely related loudness level unit, phon.

Paper 42-56, recommended by the AIEE committee on land transportation for presentation at the AIEE winter convention, New York, N. Y., January 26–30, 1942. Manuscript submitted November 12, 1941; made available for printing January 6, 1942.

WILLIAM A. JACK is research engineer, acoustical engineering section, Johns-Manville Research Laboratories, Manville, N. J.

The author acknowledges the friendly advice of J. S. Parkinson, under whose direction much of the data presented in this paper were taken.

*Standard nomenclature employs centimeter-gram-second units. The rms pressure at the threshold of hearing at 1,000 cycles is 0.000204 bar. See reference 1.

This table is true for initial pressure levels of 60 to 90 decibels, the range in which most noise-quieting problems lie. It is difficult to converse at 100 decibels and virtually impossible at 120 decibels. In an extremely noisy environment such as a ship engine room, acoustically untreated, a reduction from 120 decibels to 110 decibels might not be judged as "worth considerable cost." The level would still be unpleasantly high and conversation would still require great effort.

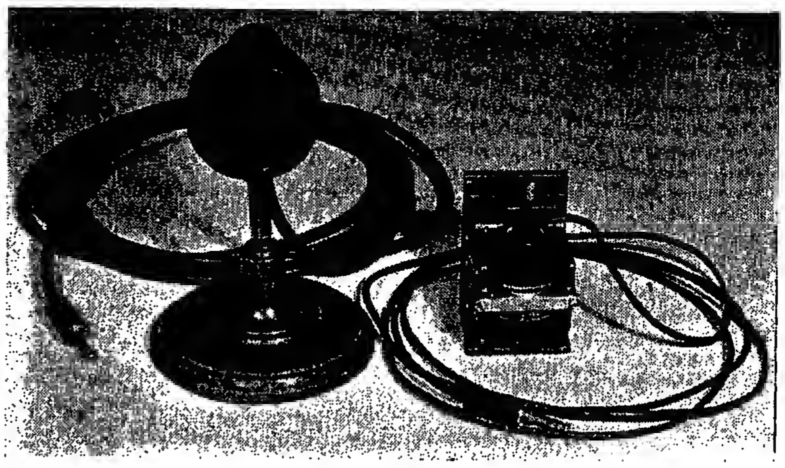

Figure 2. Typical transducers

Dynamic microphone (left) and dynamic vibration velocity unit

Vibration and Sound

In addition to the sound pressure affecting his ears, the coach passenger is subjected to direct vibration through the seat cushions, the floor, and those portions of the wall and window he may lean against. Except for outside noise entering through air leaks and inside sources such as fans, the sound pressures in the coach are built up by vibrating surfaces.

The air particles near a vibrating surface which acts as a sound source move with the same displacement and frequency as the surface and in phase with it. If the vibrating surface moves at 1,000 cycles per second with an rms velocity of 1.92×10^{-6} inches per second, the nearby sound pressure will be 2.96×10^{-9} pounds per square inch, which is the threshold of hearing. Accordingly we may write, when V is expressed as inches per second rms

Vibration velocity level =

$$20 \log_{10} \frac{V}{1.92\times10^{-6}} \text{ decibels} \quad (3)$$

A velocity gage is needed, with indicating or recording devices so that a measure of the velocity variation with time, at a point, may be taken. We may wish to get the instantaneous variation over the cycle, or we may be satisfied with an rms reading. When we have these, we have more than the ear in air can get, because we may explore various surfaces with a probe and determine their individual vibration characteristics. The ear in air can judge merely the pressure characteristics at that point, and the pressure at that point may be dictated by several sources plus the effect of room acoustics. If desired, vibration readings may be given in velocity units. It is convenient to express them in decibels of vibration velocity level. If a surface has a vibration velocity level of 80 decibels, it will generate near it a pressure level of 80 decibels.

Displacement, Velocity, Acceleration

Just because a surface has a large displacement, it must not be thought that a loud sound will result, nor is it necessarily true that a small displacement results in a weak sound. The pressure level near the surface depends on the *velocity* of the vibration, which is a function of both displacement and frequency. Displacement and acceleration may be of interest when stresses, unbalance, metal fatigue, and passenger bodily comfort are under consideration. They may be measured by special instruments, or they may be computed from readings of vibration velocity level and frequency.

For sinusoidal vibrations we have the following relations:

$$x = B_m \sin(2\pi ft) \quad (4)$$

$$\frac{dx}{dt} = v = B_m 2\pi f \cos(2\pi ft) = B_m 2\pi f \sin\left(2\pi ft + \frac{\pi}{2}\right) \quad (5)$$

$$\frac{d^2x}{dt^2} = a = -B_m 4\pi^2 f^2 \sin(2\pi ft) = B_m 4\pi^2 f^2 \sin(2\pi ft + \pi) \quad (6)$$

where

x, v, a = instantaneous values of displacement, velocity, acceleration

B_m = maximum displacement of particle from neutral position

f = frequency of vibration in cycles per second

t = time in seconds

Equation 4 describes a particle whose displacement varies sinusoidally with time, f cycles per second, between the limits $+B_m$ and $-B_m$. Let us assume $t=0$ is now. The equation shows that the particle displacement is now zero, about to increase positively. Equation 5 describes the velocity of this particle. It is similar to the displacement but differs in amplitude and phase. The equation describes a particle whose velocity varies sinusoidally with time, f cycles per second, between the limits $+B_m 2\pi f$ and $-B_m 2\pi f$. At f cycles per second, one cycle is completed in $1/f$ seconds. When $t=0$, the particle velocity is the maximum, $+B_m 2\pi f$, about to decrease. At a time $1/4f$ seconds earlier, ($t = -1/4f$), the velocity was zero about to increase positively. This is a sufficient value for t which makes $\sin(2\pi ft + \pi/2) = 0$ and about to increase. This is the same state the displacement is in now. Thus, the velocity "leads" the displacement by $1/4f$ seconds, which is the time required to execute one-quarter cycle. With the convention of representing a vibration as the projection of a vector rotating in a circle, the velocity leads the displacement by 90 degrees. Equation 6 describes the acceleration of this particle. It is similar to the displacement but differs in amplitude and phase. The equation describes a particle whose acceleration varies sinusoidally with time, f cycles per second, between the limits $+B_m 4\pi^2 f^2$ and $-B_m 4\pi^2 f^2$.

Table I. RMS Displacements, Velocities, and Accelerations Over the Range of Sound Levels and Frequencies

Units Are Inches, Inches Per Second, Inches Per Second Squared

Frequency	0 Decibel D	0 Decibel V	0 Decibel A	80 Decibels D	80 Decibels V	80 Decibels A	150 Decibels D	150 Decibels V	150 Decibels A
1	3.06×10^{-7}	1.92×10^{-6}	1.21×10^{-5}	3.06×10^{-3}	1.92×10^{-2}	1.21×10^{-1}	9.67	60.7	3.81×10^{2}
10	3.06×10^{-8}	1.92×10^{-6}	1.21×10^{-4}	3.06×10^{-4}	1.92×10^{-2}	1.21	9.67×10^{-1}	60.7	3.81×10^{3}
100	3.06×10^{-9}	1.92×10^{-6}	1.21×10^{-3}	3.06×10^{-5}	1.92×10^{-2}	1.21×10^{1}	9.67×10^{-2}	60.7	3.81×10^{4}
1,000	3.06×10^{-10}	1.92×10^{-6}	1.21×10^{-2}	3.06×10^{-6}	$1.92 < 10^{-2}$	1.21×10^{2}	9.67×10^{-3}	60.7	3.81×10^{5}
10,000	3.06×10^{-11}	1.92×10^{-6}	1.21×10^{-1}	3.06×10^{-7}	1.92×10^{-2}	1.21×10^{3}	9.67×10^{-4}	60.7	3.81×10^{6}

When $t=0$, the particle acceleration is zero about to increase negatively. At a time $1/2f$ seconds earlier ($t=-1/2f$), the acceleration was zero about to increase positively. This is a sufficient value for t which makes $\sin(2\pi ft+\pi)=0$ and about to increase. This is the same state the displacement is in now. Thus the acceleration leads the displacement by $1/2f$ seconds, which is the time required to execute one-half cycle, or the acceleration leads the displacement by 180 degrees. The phase differences are indicated directly in equations 5 and 6 as $\pi/2$ and π respectively. The explanation has been given to help visualize the actual time differences involved, and what the differences mean in terms of the complete cycle.

In Table I are given the rms displacements, velocities, and accelerations associated with 0, 80, and 150 decibels pressure levels. The units are respectively inches, inches per second, and inches per second squared. These tabulations represent physical conditions, and the decibel is a physical unit. For example, a vibration of an air particle at one cycle per second having an rms displacement of 3.06×10^{-3} inches develops an rms velocity of 1.92×10^{-2} inches per second and is thus 80 decibels pressure level. Due to the limitations of the ear, this would not evoke the sensation of hearing. However, it is perfectly possible for a vibrating surface or air particle to have this motion. This vibration in a surface could be detected by the fingers. Sound pressure levels of 150 decibels at 1,000 cycles have been measured in airplane motor test houses. Such levels are reachable by generating nonstreamline flow in air by propellor blades or causing high-speed jets to impinge on sharp edges. They are not reachable generally by flat surfaces vibrating normal to their plane. Note that the rms acceleration associated with this level is 3.81×10^{5} inches per second squared. This is approximately 1,000 times gravity ($a_g=386$ inches per second squared). A large force would be required to move even a lightweight panel at this acceleration, and the mass reactions throughout the panel would be so high the inherent stiffness would not be great enough to make the panel vibrate as a plane.

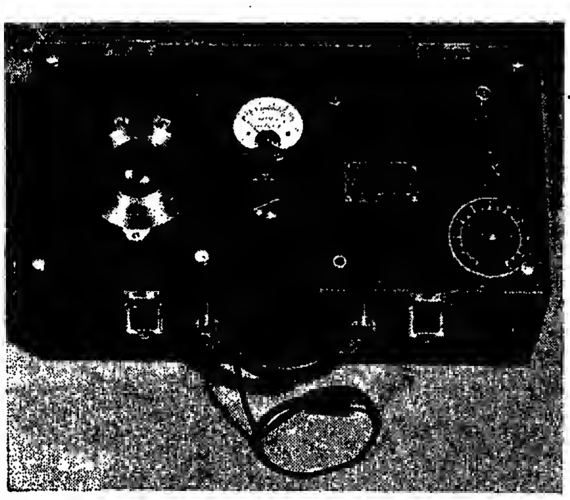

Figure 3. One type of electrical filter

Heterodyne type passing a narrow band of frequencies

So far we have discussed mainly a physical way of designating sounds and vibrations. Ear sensations have been referred to in terms of the threshold of hearing at 1,000 cycles, the region of pain at 150 decibels, and the reaction of an auditor to various decibel steps in noise reduction. We will now discuss loudness level and its relation to pressure level for pure tones.

Pressure Level and Loudness Level

The loudness level of a pure tone is defined as the pressure level of the equally loud 1,000-cycle tone, a matter decided by the vote of a sound jury.[1] The unit is the phon. Figure 1 shows this relationship in the form of equal loudness contours. The loudness level in phons of a 1,000-cycle tone is the same as the pressure level in decibels. For any other frequency the loudness level varies with the pressure level, varying both with frequency and with pressure level. In general, the ear lacks acuity at low frequencies and low pressure levels. Typical values are given in Table II. The tabulated values are decibels pressure level. Using the "70 phons" column for example, the table shows that 82 decibels are required at 50 cycles to evoke the hearing sensation of 70 phons loudness level, but only 67 decibels are required at 3,000 cycles to evoke the sensation of 70 phons. The "0 phons" column gives the minimum pressure levels in decibels necessary to evoke the sensation of hearing. For example, the ear threshold is 53 decibels higher at 50 cycles and 36 decibels higher at 100 cycles than it is at 1,000 cycles. At 3,500 cycles the ear is most acute. At high levels the ear has a substantially flat response, as shown by the "100 phons" column. The response at intermediate levels is indicated by the "40 phons" and "70 phons" columns.

Table II. Pressure Levels in Decibels Required Over the Frequency Range to Give Four Loudness Levels

	Loudness Levels—Phons			
Frequency	0	40	70	100
50	53	72	82	100
100	36	62	78	100

4,000	−7	38	67	92
5,000	−5	39	69	95
7,500	6	51	81	105
10,000	8	52	82	105

Adding Decibels

If the measured sound pressure in air at a point is P_1, the energy E_1 flowing through a unit area in unit time is given by

$$E_1=kP_1^2 \tag{7}$$

where k is a constant of proportionality depending on the system of units selected. Accordingly, from equations 2 and 7, letting P_0 represent the threshold pressure, and E_0 the threshold energy

$$\text{Pressure level}=20\log_{10}\frac{P_1}{P_0}$$

$$=10\log_{10}\frac{P_1^2}{P_0^2}=10\log_{10}\frac{E_1}{E_0} \tag{8}$$

Suppose that a single source of sound causes a measured pressure level L_1. The energy associated with it is E_1. Suppose that we stop the first source and sound

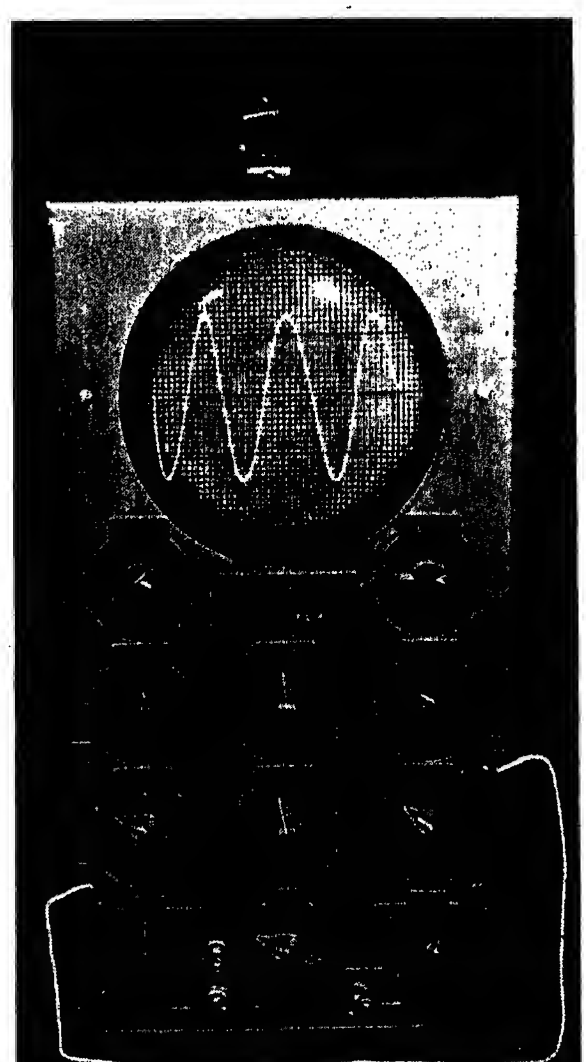

Figure 4. Oscilloscope

Used in study of wave form of original sound, indicating instantaneous variations over the cycle

a second source, which causes a measured pressure level L_2, with an associated energy E_2. If now we sound both sources together, the energy passing through the point of measurement will be E_1+E_2. For the random phase relationships which occur with multiple wall reflections and radiation from complex sources, the new pressure will be $\sqrt{P_1^2+P_2^2}$, where P_1 and P_2 are the pressures associated with L_1 and L_2. Using equation 8 and the fact that associated energies add arithmetically, it may be shown that if Δ is the difference in decibels between L_1 and L_2, L_1 being the larger, the new pressure level is obtained by adding β to L_1 as shown in Table III.

Handling the Analysis

Suppose that an analysis of pressure level under representative conditions has been made. The pressure levels measured are given in Table IV, column 1. In column 2 are the loudness levels from these, obtained from the loudness contours of Figure 1. Single frequencies near the mid-points of the bands were used to represent the bands: 30, 150, 300, 600, 1,200, 2,400, 3,600, 6,000 cycles.

The "total" figures for the decibel values of columns 1 and 4 could have been obtained by computing the energies in the bands, adding the individual energies to get the total energy, then converting back to pressure level. Actually the short-cut method of Table III was used, which is entirely satisfactory. Strictly speaking, individual band loudness levels in phons do not add as decibels do, but the author has found that a total figure obtained this way is a practical method of assigning a single number having some meaning in terms of the sensation of hearing. This is not the preferred method. Noise-reduction problems should be judged by the reduction in each band. This is discussed at greater length under "multiple sources."

Suppose that an outstanding improvement is desired in the total loudness level. By our standard, this calls for a 20-phon reduction from 88 to 68 phons. Most commercial band spectra give a total that is 2–5 decibels (or phons) higher than the highest single component. In this case, we might guess at a design objective of 64 phons for the loudest band after acoustical correction, with the other bands reduced to something under 64 phons, and write down column 3. This desired spectra has been made to drop off in the high frequency end, as experience has shown the high frequencies have a heavy "annoyance weighting." The total turns out to be 69 phons or a reduction of 19 phons. We will let this trial stand. In column 4 the phons loudness level of column 3 have been converted to decibels pressure level, using the loudness contours of Figure 1. Column 5 shows the decibel reductions necessary in each band to produce the desired loudness level projected in each band. It may prove impossible to effect an 11-decibel reduction for example, in the 50–100 band within the price, weight, and space limitations imposed upon train problems, but by this type of analysis a rational method is available for surveying and attacking a complicated situation.

Multiple Sources

Table IV is a general procedure based on measuring the interior level. It is usually necessary to investigate further a complex structure such as a train to determine the contribution of each source to the interior pressure level. Sometimes controlled experiments can be run, such as driving the compressors with the train stationary, or checking the floor transmission by an artificial sound source. More often the interior must be probed for vibration velocity level and an estimate made as to why certain panels vibrate and what can be done to reduce their contributions to interior pressure level.

Suppose that near a certain passenger position a complete survey of likely sources is made. Hypothetical data for the 400–800-cycle band are presented in Table V. From this tabulation we can make certain informed guesses.

The noise from the air conditioner appears to come directly through the air to the passenger, as no panels have been discovered which can account for 50 decibels. The noise when "at speed" appears to be due to (*a*) sound pressures generated at the wheels striking the floor and coming through in part, or (*b*) broadcasting of sound energy from the floor surface, or both. The floor may be driven strongly from the frame, which is subjected to road shocks. Table V does not tell us whether the other panels vibrate at the levels shown, because they are part of the strongly vibrating floor system, or because external sound pressures cause them to vibrate at these levels.

The data suggest that measurement of external levels under the coach and at window height would throw further light on the mechanism of sound transfer. As the air-borne pressure level due to the compressor is 60 decibels, reducing the "at-speed" floor contribution much below 57 decibels is a waste of time and money, unless the compressor is also reduced. This is a direct consequence of the decibel additive relationship shown in Table III. With 60 decibels and 57 decibels, the total is 61.8 decibels. If the floor contribution were removed entirely, the pressure level could drop only 1.8 decibels which is not an important amount.

The noise from the compressor appears to come through the floor either by its air-borne noise striking the underside of the floor or by structural vibration or both. With a tube-like structure such as a coach, an intense source in one portion, such as vestibule noise leaking through a

partly open door, will be distributed as air-borne sound. This type of trouble is readily detected, however, by exploring likely panels and air spaces for intense local sources.

A most practical and important aspect of the decibel additive relationship of Table III occurs when the contributions of each frequency band to the total are considered. Usually the total level is dictated by the most intense band, which in transportation is in the low frequency end. If all the energy above 500 cycles were removed, the *total* level would not decrease by an amount sufficient to measure. The ear would notice a big difference, and it has been the author's experience[3] that reductions in the higher frequencies are useful out of all proportion to their contributions to total level. The ear will readily detect the difference in a coach when hisses, rattles, squeaks and high-pitched whines have been eliminated. It will judge this coach definitely quieter than before, even though the low-frequency components which dictate total level have not been reduced. A band analysis will show the higher frequencies have been reduced substantially, and this portion of the measurement will be in good agreement with the ear judgment.

Sound in a Closed Space

The pressure level built up inside a closed space by air-borne sound striking the outside may be computed closely enough for practical purposes by a formula derived from a simplified mathematical analysis.

$$PL_i = PL_o - TL - 10 \log_{10} \frac{a}{A} \qquad (9)$$

where

PL_i = average inside pressure level
PL_o = pressure level of the sound outside striking the transmitting area A
TL = transmission loss of the area A
a = total sabines absorption inside the closed space
A = transmitting area in square feet

Transmission loss is the decibel drop produced on air-borne sound by a sound barrier, measured close to each side, under conditions that discount the effect of reflected waves. The sabines absorption of a surface is the product of its area in square feet by its coefficient of sound absorption. The coefficient may be thought of as the percentage of energy absorbed at one incidence when a ray of sound strikes the surface at a random angle.

If a closed space has few sabines initially, PL_i can be reduced appreciably by adding an efficient acoustical treatment. Generally speaking, more improvement is possible in working with TL alone than in working with acoustical treatment alone for sources outside the space. Adding a treatment is discussed further in section III.

II. Electrical Instruments Suitable for Noise-Reduction Problems

We have seen that

(*a*) The sound pressures and vibration velocities of interest to the acoustical engineer are quantities covering an enormous range but, even at their largest, small by ordinary standards.

(*b*) The ear responds in a complex manner depending on both the frequency and intensity of the sound in question.

(*c*) It is important to measure the changes in each frequency band.

Rugged instruments of adequate analyzing power are required.

It is safe to say that the developments of the vacuum-tube amplifier and the high-quality microphone have allowed the engineering practice of acoustics to reach its present stage. Because proper electrical instruments are available, field problems can be analyzed in a rational manner, numbers can be assigned to physical measurements which have meaning in terms of human ear reactions, and corrective measures, developed by the experimental method in the laboratory, can be applied to the field problems.

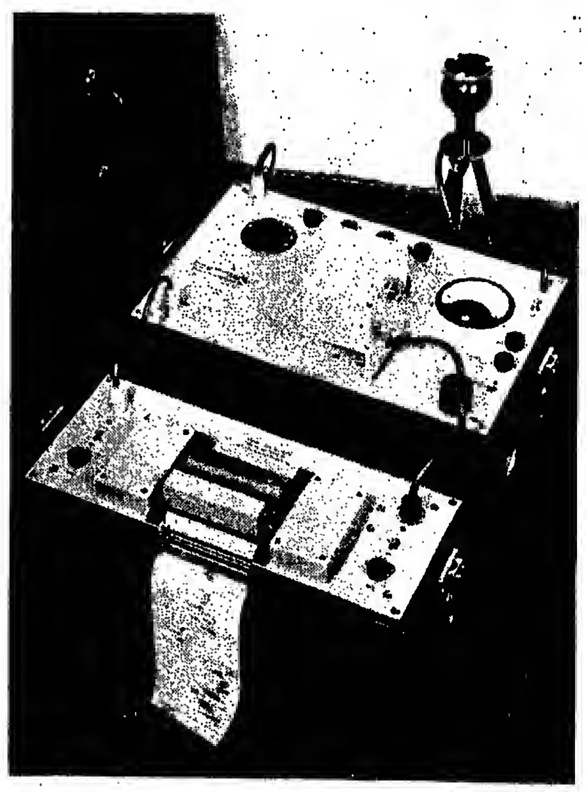

Figure 7. Complete analyzing equipment

Makes graphic record which can be read as pressure level against frequency. Analyzer passes a narrow band of frequencies, covering audible range automatically

The displacements associated with frequencies below 20 cycles are sometimes large. Because of this, the curve of displacement against time often can be traced by the seismic type of instrument with mechanical leverage to obtain desired amplification. Optical magnification types are also available. This region is of interest in investigations of riding comfort. See, for example, the work by Jacklin[4] and his associates. The problems of measuring and correcting unbalance in rotating machinery have been the subject of extensive investigations outside the scope of this paper. See, for example, publications by Thearle[5] and Rushing.[6]

The acoustical engineer in the wide regions of the audible spectrum finds indispensable the electrical method of measurement, because frequency analysis is desirable, and the displacements associated with his problems are very small indeed. In general, the instrument assembly consists of four parts:

Transducer.
Amplifier.
Filter.
Final indicating or recording means.

A transducer is a device which has an electrical output similar to the mechanical input to the device. The output energy can be amplified by the desired amount necessary to give the final reading. Filter networks which will give a frequency discrimination can be inserted ahead of the final reading, enabling the frequencies involved in the original vibration to be investigated.

What follows is not intended to be an exhaustive catalogue of sound measuring equipment. It does describe in general terms the types which the author has found useful in the field and laboratory.

(1) Transducers

(a) Microphones

1. *Dynamic.* A diaphragm exposed to sound pressure carries a coil moving in a permanent magnetic field. A preferred type is resistance controlled, having a substantially flat response over the frequency range. The velocity of the diaphragm, and hence the voltage output of the coil, is proportional to the sound pressure.

2. *Condenser.* This microphone consists in its elements of two plates close together which form a condenser in the amplifying circuit. Sound pressure moves one of the plates, causing a voltage fluctuation. The natural frequency is high, and the damping and polarizing voltages are such that the response is substantially flat. This type usually requires a built-in stage of amplification which may be inconvenient in the field.

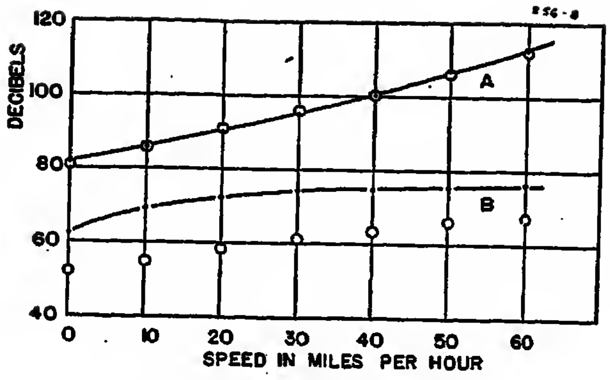

Figure 8. Train noise

Graph of total pressure level versus speed
Curve *A*—Noise underneath
Curve *B*—Noise inside at passenger head level
Circles—Associated loudness levels

3. *Ribbon.* A thin metallic ribbon exposed to sound pressure moves in a permanent magnetic field. With the back of the ribbon enclosed, this microphone responds to the sound pressure on the exposed face and is nondirectional. With both sides of the ribbon open to the sound field, the microphone responds to the pressure gradient and is insensitive in the plane of the ribbon. This is often called a velocity microphone. The two types are sometimes combined into one microphone having a substantially unidirectional response.

4. *Crystal.* A crystal of Rochelle salt exhibits the piezoelectric effect, generating an electromotive force when deformed. Sound pressures cause this deformation and the microphone using this principle has a substantially flat response.

(b) Vibration Pickups

These instruments are, in general, similar to microphones but are adapted to measure directly vibration in a mechanical part, rather than to respond to the sound pressure built up by moving air particles. The self-contained dynamic type carries a stylus fastened to a coil moving in a permanent magnetic field. The stylus is positioned against the vibrating member and partakes of its

Table VI. Improvement Due to Double Acoustical Floor in Motor Coach

Frequency Bands	Conventional Floor VVL	Acoustical Double Floor VVL	Reduction in Vibration Decibels

1,024–2,048	69	56	13
2,048–4,096	64	52	12
4,096–8,192	42	34	8

motion exactly. The case of the instrument, due to its inertia and weak coupling spring, remains at rest in space. Voltage output is proportional to coil velocity and, thus, to the velocity of the investigated part. For laboratory work a coil may be fastened to the vibrating part and made to move in a magnetic field, or a plate forming part of a condenser may be attached. A crystal pickup is available which is light (two ounces) and useful where the heavier dynamic type would interfere with the free motion of the part. The crystal may be mounted with a free corner, and the case shaken by the vibrating part. The output of this crystal type increases with frequency, for constant velocities of vibration. This may be useful where increased weighting should be given to higher frequencies. It is possible to use an equalizing circuit which will correct for the rising characteristic of this type.

(2) Amplifiers

The design of amplifiers covers a wide range beyond the scope of this paper. In general, high gain of the order of 120 decibels with a flat frequency characteris-

tic is needed. Commercial sound level meters are now provided with two frequency weighting networks. Amplifier circuits usually include an attenuator graduated in decibels. The complete reading consists of the attenuator setting plus the final meter reading.

(3) Filters

For obtaining a single figure representing pressure level, commercial meters, as mentioned in paragraph 2, have provision for a flat frequency characteristic in the 100 phons loudness level range, and two weighting networks, related to the equal loudness contours of Figure 1, one for the 70 phons and the other for the 40 phons range. The author prefers to make frequency analyses with a band pass filter, covering the audible range of octave steps. The filtering action is obtained with coil and condenser circuits controlled by a single tap-switch. Narrow pass filters are available with band widths as small as five cycles. There is another type with a band width of a fixed percentage of the frequency to which it is tuned. Both the heterodyne method with a fixed filter and the selective amplifier method operating on the degeneration principle are available. The types which permit aural monitoring with a telephone receiver are useful, as important components in the original noise may be identified by ear in a preliminary survey. Narrow band filters can be used to obtain accurately the frequency of a disturbing component. In certain cases this can be related to known occurrences such as tooth contact frequency in a particular pair of gears. Sources are sometimes identified this way.

(4) Final Indicating or Recording Means

The useful output of an amplifier is a-c. This can be delivered to an oscillograph or oscilloscope, or it can be rectified and indicated as rms volts on a meter graduated in decibels. The oscilloscope gives visual evidence of the complexity of the original sound wave, but its use is normally confined to the laboratory. For field work, good results are obtained by the rms type of meter in conjunction with frequency analysis. Level recorders are available for making charts of pressure level variation with time. For the particular problem of measuring reverberation time in room acoustics, a recorder which can follow quick changes in level is needed. Decay characteristics as high as 200 decibels per second are encountered in broadcasting studios, for example. The level recorder is useful in making frequency analyses in narrow band widths. The analyzer and recorder are driven by synchronous motors so that the abscissa can be read in terms of frequency, and the ordinate in pressure level of the passed band.

Figures 2–5 show some of the individual units described above. Figure 6 shows a sound-level meter ordinarily used with a crystal microphone, here used with a crystal type of vibration pickup. This particular design has a control box with integrating circuits which may be set for displacement, velocity, or acceleration. The photograph shows it set for velocity. It will then give a single reading proportional to the velocity of the stylus which would turn out, for the average field problem, to be due to the single most intense frequency component of velocity. For information regarding less intense components, a frequency analyzer can be used between the pickup and the sound-level meter. Without analyzer equipment, a rough check on frequency distribution can be obtained by displacement and acceleration readings, and by using the weighting networks on the sound-level meter. Figure 7 shows a setup for making an automatic frequency analysis with a graphic recorder. With elaborate equipment of this type, data can be taken rapidly and in the detailed form necessary for the complete handling of acoustical problems.

III. Train Noise and the Techniques for Reducing It

Certain assumed measurements have been discussed in the first section of this paper for purposes of illustrating the principles involved. Measurements on actual train noise made by the author are presented in Figures 8–10. These data have been selected as representing the over-all aspects of the problem. No attempt is made in this paper to compare various designs. The data selected, however, are from extensive tests on a rather quiet type.

Noise and Vibration Paths

In Figure 11 are indicated schematically the various paths that sound energy from three representative sources may take on its way into the coach to disturb the passenger. The noise radiated from the wheels and trucks and the shocks delivered to the center plate depend upon spring design. A discussion of the reduction of these disturbances by design modifications is outside the scope of this paper. On the benefits of rubber springing see, for example, the paper by Hirshfeld and Piron.[7]

The simplest way to control a noisy source is to surround it with a barrier having an adequately high transmission loss (*TL*). The air-borne noise radiated from the compressor surfaces of Figure 11, for example, could be reduced in this way. There may be practical considerations such as space limitations or need for free air flow for cooling the machine. The direct structural path between the compressor and the floor may transmit vibrations which will reradiate from the floor to the air inside the coach. If necessary, the compressor may be isolated with resilient mountings. Proper isolation provides flexible connections to the machine. With due precautions for maintaining alignment between driving and driven units, mountings of high compliance and, consequently, high isolation may be used.

Direct leakage of air-borne sound through openings may nullify the results of careful work on other phases. Such

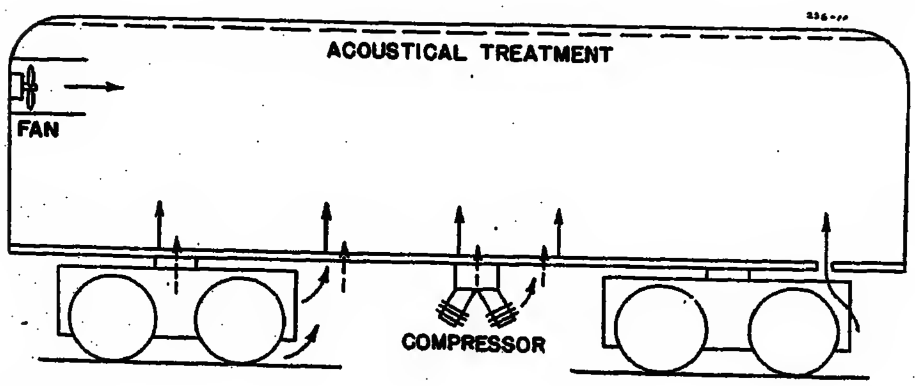

Figure 11. Schematic diagram of noise sources and energy paths in coach

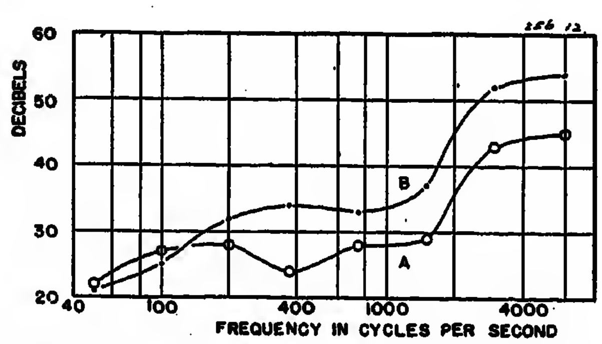

Figure 12. Transmission loss of coach floor

Graph of *TL* versus frequency

Curve *A*—Untreated floor
Curve *B*—Floor with deafening plate screwed to floor members and rock-wool blanket between floor and plate

openings should be kept at a minimum. For example, a good window construction having a TL of 30 decibels, if opened two inches, is no better than a very ordinary construction with a TL of 20 decibels kept closed.

A fan of an air-conditioner system may deliver noise along with the air. Large reductions are possible by treating a run of duct with sound-absorbing material.

The floor is subjected to an intense air-borne noise as indicated in Figures 8 and 9. It also is vibrated by way of the structural path from the wheels. Figure 10 indicates that the inside pressure level at the middle frequencies is due to the transmission of air-borne noise. At the lower frequencies it appears that structural vibration contributes importantly to the inside pressure level. The TL of the floor can be increased by various means, and it can be isolated from the structure. If the floor must help in adding strength to the structure, isolation is not feasible. An extra floated floor may be a possibility.

Sound Barriers and Enclosures

Structures with substantially rigid connections throughout have a transmission loss linearly proportional to the logarithm of the weight per square foot. See for example the work by Knudsen[8] and many others. The average TL at the nine frequencies commonly used is expressed by

$$TL = 22.4 + 14.3 \log_{10} w \qquad (10)$$

The weight w for a typical coach floor is ten pounds per square foot. Substituted in equation 10, this gives an average TL of 36.7 decibels. For convenience,

Table VII. Improvement Due to Vibration Isolation

15-Hp Motor on Concrete Slab

Frequency Bands	Slab Vibration Velocity Levels: Motor Bolted Directly	Motor on Springs	Motor on Rubber	Reduction—Decibels: By Springs	By Rubber
0–64	105	72	85	33	20
64–128	83	90	62	33	21
128–256	81	51	49	30	32
256–512	76	53	47	23	29
512–1,024	65	45	44	20	21
1,024–2,048	54	29	29	25	25
2,048–4,096	43	10	23	33	20

this equation may be thought of as giving the TL at 1,024 cycles. Measurements on a wide variety of homogeneous structures show that for a fixed weight the TL increases four decibels per octave, and for a fixed frequency increases four decibels on doubling the weight. These are averages for many tests. A single panel or wall may deviate five decibels or more from these predictions at any one frequency due to resonances. The average over the frequency range usually will be within two decibels of equation 10.

If we wish to improve the TL of the above floor by ten decibels, a single floor weighing 50 pounds per square foot is indicated. This would be prohibitive in any practical transportation problem. Broadcasting-studio construction methods can be used in a suitable way. The TL of a three-pound-per-square-foot barrier by equation 10 is 29.2 decibels. Using our original figure of 36.7 decibels, we might hope that with a three-pound extra floor properly applied, the losses would add to a total of 65.9 decibels. Because the two must be used close together and joined compliantly to the same structure or to each other, the indicated high total is not reachable. However, by proper structural isolation, and using sound-absorbing material between the two floors, 48 decibels may be obtained.

Table VIII. Improvement in Decibels Due to Vibration Isolation

Train Floor on Shear Rubber Isolators Compared to Floor Mounted on Steel Blocks

Frequency	Design A 3/8-Inch Thick—0.2-Inch Deflection	Design B 5/8-Inch Thick—0.4-Inch Deflection	Design C 3/4-Inch Thick—0.3-Inch Deflection
100	8	10	21
225	8	15	20
375	7	21	12
512	12	22	21
750	10	11	14
1,024	9	13	10
1,500	9	17	14
2,048	9	12	15

Thus, we have exceeded the estimated performance of a 50-pound homogeneous floor by using a special 13-pound composite floor.

Actual field figures on the vibration performance of a double acoustical floor in a motor coach in terms of vibration velocity level are presented in Table VI. The isolated element was only one pound per square foot with rock wool between the floors. If the base floor had been increased homogeneously by this amount, the decrease in VVL would have been negligible. By adding this light weight with proper attention to the acoustical principles involved, a substantial decrease in VVL of the important radiating surface was obtained.

The addition of sound-absorbing material and a deafening plate, screwed to the under side of the floor-stiffening members, provides a smaller but definite improvement. Figure 12 shows transmission loss versus frequency for a typical coach floor tested in the laboratory, using a large test section 86 inches by 78 inches. The walking surface was 5/8 inch Chanarch poured with sufficient magnesite to fill in the slots of the Chanarch and extend above it one-half inch. Five two-inch Z bars provided stiffening. Are movable 22-gauge deafening plate was screwed to the Z bars.

Vibration Isolation

A vibrating piece of equipment, such as the compressor mentioned above, radiates air-borne noise directly from its metal surfaces and usually vibrates the structure to which it is rigidly bolted. The structural vibrations will travel long distances with negligible loss, and cause trouble by radiating sound inside enclosures which have sufficient TL to bar the air-borne sound striking them directly.

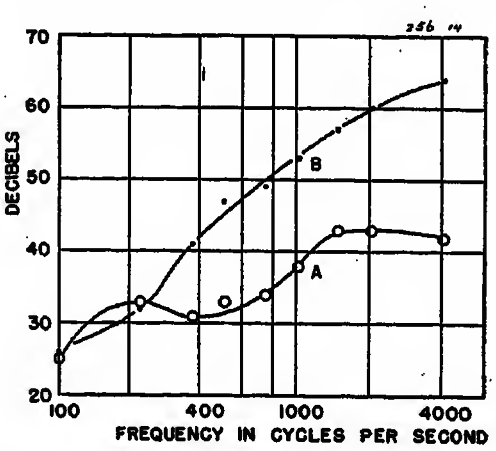

Figure 14. Transmission loss of coach floor

Graph of TL versus frequency

Curve *A*—Untreated floor
Curve *B*—Floor with deafening plate attached to floor members by shear rubber isolators and rock-wool blanket between floor and plate

The remedy consists in isolating the equipment by rubber or springs. The improvement may be striking, and, where this step may be taken, it is the most important single method available.

Table VII shows the large reductions brought about by a commercial type of isolator using the controlled spring principle in combination with rubber. This particular application was to lessen the vibration in the concrete slab under a 15-horsepower motor. Vibration velocity levels of the slab are given. Data on the conventional type of bonded rubber isolator used in shear are also given. It was less efficient than the controlled spring design, but the reduction in vibration by its use was large. For these tests, the set of isolators, both spring type and rubber type, were loaded to 0.35-inch deflection.

The same principle may be used in isolating the floor from the supporting structure. Table VIII gives actual reductions by laboratory tests on such a construction using rubber in shear. An electrical driving unit was attached to the structure so that it vibrated the subframe at the desired frequency over the entire frequency range. The vibration velocity level of the floor surface was measured at each frequency with a rigid structural connection and with three variations of shear rubber isolators.

Data such as these indicate by actual tests that best isolation results are obtained with the greatest deflection permissible, and, for a given deflection, it is advantageous to use the thickest rubber.

If a motor is to be isolated so that its vibrations are to be kept out of the structure, or a floor is to be mounted so that vibrations in the structure will not enter the floor, theory calls for suspending the motor or floor by compliant means so that the natural frequency of the suspended system is well below the disturbing frequency, commonly called the driving frequency. The theoretical reduction in decibel form,[9] for any value of the driving frequency, is

$$20 \log_{10} \frac{\sqrt{(c\omega)^2+(k-m\omega^2)^2}}{\sqrt{k^2+(c\omega)^2}} \qquad (11)$$

where

m = mass of suspended weight (slugs)
k = pounds to produce one-foot deflection in the compliance
c = pounds force required to maintain unit velocity
$\omega=2\pi f$ where f is the driving frequency in cycles per second

Experience has indicated that the actual decibel reductions obtained in

Table IX. Theoretical Reductions Due to Vibration Isolation for Various Static Deflections

Commercial Amount of Damping

Static Deflection Inches	Natural Frequency—Cycles Per Second	Reduction—Decibels Driving Frequency—Cycles Per Second: 20	50	100	200	500
1/16	12.56	4	23	35	44	54
1/8	8.86	9	29	39	48	58
1/4	6.28	18	35	44	52	61
1/2	4.43	24	39	48	56	64
1	3.13	31	44	52	59	67

commercial installations are less than half of the theoretical values.

Good isolation calls for mountings soft enough to deflect one-eighth inch or more under the static load of the suspended part. The natural frequency f_n in cycles per second is

$$f_n=3.13\sqrt{\frac{1}{\delta}} \qquad (12)$$

where δ = static deflection in inches

Isolator *B*, for example, of Table VIII supported 40 pounds per inch of isolator with a deflection of 0.4 inch. This means a k value of 1,200 pounds. Using an isolator one inch long the damping factor c, evaluated by the methods of reference 9, was 0.23 per inch of isolator. Most commercial materials have damping factors similar to this, which are small in comparison to the masses and stiffnesses involved.

A plot of equation 11 for $c=0.23$ and $c=0$ is given in Figure 13, using $m=40/386$ and $k=1,200$. This is a plot from theoretical considerations. The natural frequency is 4.95 cycles per second, and for a driving frequency of this value there is an amplification of 23 decibels with the commercial damping measured, and an infinite amplification for no damping. The curves cross the 0-decibel line at $\sqrt{2}\times 4.95=7.0$ cycles and show increasing isolation for higher frequencies. Above seven cycles the damped curve lies below the non-damping curve, but the theoretical detrimental effect of a small amount of damping is of less practical importance than the departure of actual systems from the simple one-degree-of-freedom system here assumed.

Table X. Improvement Due to Ceiling Acoustical Treatment in Coach

Frequency	Sabines Absorption: Before	Added	After	Reduction—Decibels
128	140	150	290	3.1
256	225	336	561	4.0
512	354	594	948	4.3
1,024	354	594	948	4.3
2,048	314	546	860	4.4
4,096	265	492	757	4.6

The theoretical value of using the softest mounting possible, from the isolation standpoint, is seen in Table IX. As noted above, actual reductions are of the order of one-quarter to one-half theoretical. Above resonance a useful simplified form of the isolation equation, corrected so as to give the range of actual reduction is

$$10 \log_{10} \frac{f}{f_n} \text{ to } 20 \log_{10} \frac{f}{f_n} \qquad (13)$$

where f_n = natural frequency of the suspended system
f = driving frequency

Instead of screwing a deafening plate directly to the floor members, as in Figure 12, isolation may be utilized. Figure 14 shows transmission loss versus frequency taken in the laboratory for a typical coach floor 86 inches by 41 inches. The deafening plate was attached by shear rubber isolators, and rock wool was used between the plate and the test floor The improvement was very marked.

Panel Damping

The addition of damping compounds to vibrating panels is useful in shortening the decay time of transient vibrations, and in lessening the response at resonant frequencies. Automobile doors, for example, when slammed, emit a clanging tinny sound, due to exciting segmental vibrations in the thin gauge metal by the sudden shock. With a damping compound added, the slam noise becomes a dull thump, and the improvement is remarkable. The usefulness of this method for controlling the vibrations of forced drive, however, has been greatly overrated. If a panel system has pronounced resonances from forced drive, it could be controlled by this method, but it is so easily done by touching the point of maximum amplitude that this type of problem does not usually come to the attention of the acoustical engineer. Figure 15 shows the effect of a good damping treatment of the conventional type on a circular 18-gauge panel mounted in rigid clamping rings 12 inches internal diameter. The panel was driven through resonance by an electromagnet actuated by an audio oscillator and the pressure level three inches away measured. A drop of 20 decibels at the resonant frequency was attained, but away from resonance the levels were changed very little. The resonant peak for the treated panel is at a lower frequency because the

treatment increased the effective mass of the panel without adding sufficient compensating stiffness.

Ceiling Acoustical Treatment

The average energy density built up by a source of fixed acoustical power in a closed space is inversely proportional to the sabines absorption in the space. If the space has a_1 sabines initially, and the total number of sabines is increased to a_2 by adding acoustical treatment, the decibel reduction in pressure level will be

$$10 \log_{10} \frac{a_2}{a_1} \tag{14}$$

Equation 14 shows that relatively large reductions will be obtained by treating a given ceiling area, for example, with a material having an 0.85 coefficient if a_1 is small. If a_1 is initially large, then smaller reductions will be obtained.

The sound-absorption coefficient varies with frequency. The most efficient commercial material having the largest sale today has the following coefficients:

128	256	512	1,024	2,048	4,096	*NRC*
0.25	0.56	0.99	0.99	0.91	0.82	0.85

The last value is the noise reduction coefficient, which by current practice is the linear average of the coefficients at 256, 512, 1,024, and 2,048. It is assigned in an effort to give a single figure rating of a material. The author, however, believes in judging noise reduction by the improvement over the frequency range.

Suppose the inside of a coach is 60 feet by 10 feet by 9 feet high. Assume 40 upholstered seats at seven sabines each (at 512 cycles) and 2,460 square feet of metal, glass, and floor surface at an average coefficient of 0.03 (at 512 cycles). The total sabines at 512 cycles are $40\times7+2{,}460\times0.03=354$. Suppose that the 600 square feet of the ceiling is to be treated with the above material. The original steel ceiling surface contributed 18 sabines at 512, which would then be covered. This is not enough to affect the final result, and this small correction will be neglected here. Making some justifiable assumptions on the sabines originally present at frequencies other than 512 cycles, we can prepare Table X, showing the sabines before and after acoustical treatment and the decibel reductions computed by equation 14. The reductions are of the order of 3–5 decibels. If we had started with a coach having less sabines initially, such as the suburban motor type with leather seats, the reduction by adding an acoustical treatment would be higher, ranging up to eight decibels in the middle and high frequencies.

The contribution of ceiling acoustical treatment to human comfort, particularly in making conversation easier, seems to be out of all proportion to the decibel reductions figured on a sustained tone analysis.[3] Reverberation times are cut in half by treatments which account for a three-decibel reduction in average pressure level. It may be that it is this shortening effect on rail clicks and rattling dishes and silverware which accounts for the substantial improvement in ceiling-treated dining cars, for example. These die away quickly, and the syllables of conversation, maintained for a relatively long time, are heard. High frequencies which might reflect back on the passenger from a hard ceiling are partially absorbed with an acoustical ceiling.

Duct Acoustical Treatment

Fans and air conditioners sometimes cause trouble due to air rush and fan or equipment noise delivered with the air. If a run of duct is available in which acoustical treatment may be placed, the noise delivered to the passengers can be reduced greatly. Papers by Parkinson[10] and Sabine[11] deal with the practical aspects.

A rule of thumb for lining ducts is to treat a length equal to at least ten times the smallest duct dimension. The reduction obtained varies of course with the efficiency of the absorbing material and to some extent with the size of the duct. For a six-inch square duct lined for sixty inches with a material having a coefficient of 0.50, Parkinson's curves show 14 decibels, and Sabine's formula computes to 16 decibels. Fan and air-rush noise covers a wide frequency range. It has been found fairly satisfactory to correct for 256 cycles. The reductions at other frequencies which are obtained by the usual acoustical duct-lining materials are then acceptable for most applications.

Figure 16 gives results on silencing a difficult conditioner problem. The only available place for treatment was at the air-discharge grille in a space 48 inches by 76 inches cross section, and it was required that the treatment be 30 inches long. Lining only the sides of such a short run of this large section would be inadequate. The treatment adopted was one-inch rock-wool boards placed five inches on centers dividing the space into 13 flues each 30 inches long and 48 inches by 4 inches cross section. Data taken with an octave band pass analyzer have been plotted at frequencies near the midpoint of the bands, and a smooth curve drawn. The grille was in the ceiling, and the readings were taken at head level beneath it. Due to the predominance of the band centered at 375 cycles, the total noise was reduced by the order of four decibels, but reductions in the various bands ranged up to 20 decibels. By ear the improvement was very marked. Before treatment, the noise generated by air rush and water sprays could be heard the full length of the corridor beneath the grille—about 50 feet. After treatment, it was necessary to stand directly under the grille to hear the disturbance.

Conclusion

Acoustics is a reasonably complex science. Good instrumentation is available for attacking practical problems. The quiet train ride is obtainable by a rational application of known techniques,

A Turbine-Governor Performance Analyzer

Discussion and author's closure of paper 41-158 by W. O. Osbon, presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941, and at the AIEE winter convention, New York, N. Y., January 26–30, 1942, published in AIEE TRANSACTIONS, 1941, November section, pages 963–7. The following discussion was presented at the 1942 winter convention.

P. B. Juhnke (Commonwealth Edison Company, Chicago, Ill.): Concerning Mr. Osbon's paper many questions come to one's mind. We recently completed a series of measurements to determine the sensitiveness of the governors of the machines on our system, and, curious to say, we found a range considerably beyond anything we had anticipated, some of the larger and most modern units having a regulation ranging up to 20 per cent; whereas machines of older vintages had a regulation of 10 per cent or less. Perhaps the underlying reason for the poorer regulation of the latest machines is that they were intended for base load, and this poorer regulation was thought to be an asset in that field. These premises for future machines may well be reviewed as to their validity, as the subject of system regulation during the last five years has made tremendous strides, and a lower per cent of regulation in the future should no longer be the liability it was once thought to have been.

R. Sheppard and C. Concordia (General Electric Company, Schenectady, N. Y.): There has been considerable discussion recently of turbine speed-governing characteristics and of their effects on power-system operation. Of the many aspects of governor response, it has previously been indicated[1,2,3] that probably two of the most important are the dead or insensitive frequency band, within which the governing system as a whole will not respond, and the steady-state incremental speed regulation (the ratio of speed change to load change for a small change from normal speed). That is for the reasons that on most large power systems, with their accompanying large rotary inertias and relatively small load changes, the frequency changes are rather slow, and the principal contributing factor in delaying the governor response is not the dynamic lag, due to governor inertia, oil flow, steam, or water storage, and so forth, but the frequency dead band, due to backlash, friction, valve lap, and so forth. It is evident that the slower is the frequency change, the more apparent the effect of dead band becomes, and the less the dynamic lags appear. Dead band appears inherently as a frequency lag (that is, a more or less definite small frequency change is required before the control mechanism will respond), while the dynamic effects appear inherently as time lags. Thus with small frequency changes and long times involved, the relative importance of dead band becomes obvious.

Moreover, with the small frequency changes usually encountered on large power systems, the effective magnitude[2] of the machine response, that is, the effective incremental speed droop, is greatly affected by dead band. This does not imply that one can forget the dynamic lags. These lags, together with the incremental regulation, on the one hand, affect the degree of frequency stability when the machine is not connected to the system during synchronizing, and, otherwise, when the machine is connected to the rest of the system, affect the system frequency fringe, particularly the magnitude of self-excited frequency oscillations produced by dead band.

Because of these considerations, it has been concluded that dead band should be made as small as possible.[1,2,3] Once such a conclusion has been reached, it becomes desirable to know what can be done, and how far one should go to produce improvement in those systems requiring it. A first step is to determine the characteristics of governing systems presently in operation. The results of a few of such measurements of governor response which have been made on turbines operating on several power systems are reported in this discussion.

Description of Measuring Instrument

The measuring device which has been designed and used to determine the significant response characteristics of turbine speed-governing systems is similar in principle to that developed and recently described[4] by Mr. J. E. Allen of The Pennsylvania Water and Power Company. Some of its features are:

1. The instrument shows directly the principal characteristics of interest: dead band and incremental speed regulation. No replotting or working up of data or complicated interpretation of the results is necessary, except for multiplication of the valve travel record by a factor to take account of the lever ratio between valve motion and carriage motion, and of the ratio between turbine kilowatt input change and valve motion at the point in question.

2. The measurement does not interfere with normal operation of the machine and requires little time. Shutting down or even any special loading schedule is not required, and no restraint is imposed on the normal or emergency functioning of the governor.

3. The indications are accurately recorded.

4. The indications are easily understood and easily interpreted in terms of both the effect of governor performance on system operation and the effects of governor characteristics on governor performance.

Figure 2. General Electric photoelectric frequency meter with rocking chart carriage for turbine-governor tests

The instrument used in most of these measurements is essentially an adaptation of the engine-indicator card principle, in which system frequency is automatically plotted against steam valve motion. Thus, referring to Figure 1 of this discussion, as the frequency starts to change from, for example, an upward swing to a downward swing, the turbine valve may not respond until a definite change in frequency has been attained; then the valve will begin to move at a rate depending on the ratio of the rate of change of frequency to the incremental regulation. The two most important factors, dead band and incremental regulation, are thus shown very simply on a single record. Moreover, as there are always minor frequency swings occurring on the system, no special means for producing the motions are required. Experience has shown that the changes are usually sufficiently slow so that the dynamic lags do not unduly affect the pictures obtained. To obtain data on the more rapid transient response which may occur with large load changes or loss of load, oscillographic methods have been used.

In the tests reported here, frequency is recorded by means of a General Electric photoelectric frequency recorder on a card mounted on a carriage mechanically connected by a wire or cord to the steam valve, operating piston, governor beam, or to any point the motion of which is desired. The motion is usually amplified by a lever or crank in order to obtain a suitable plotting

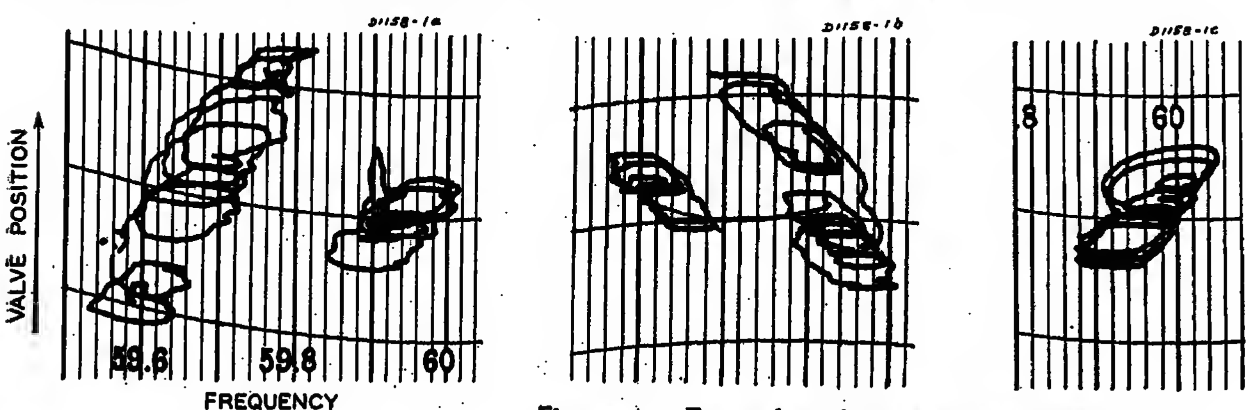

Figure 1. Examples of governor response

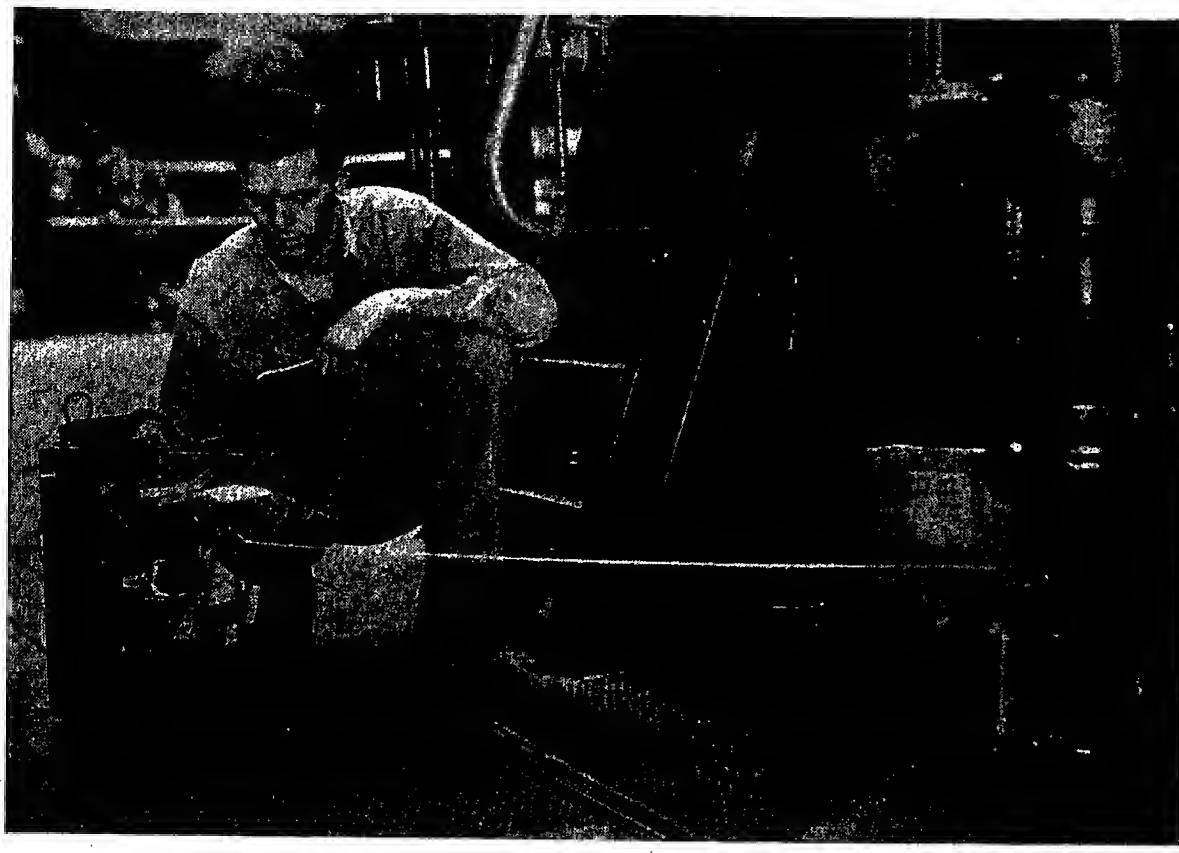

Figure 3. Turbine-governor response recorder in use

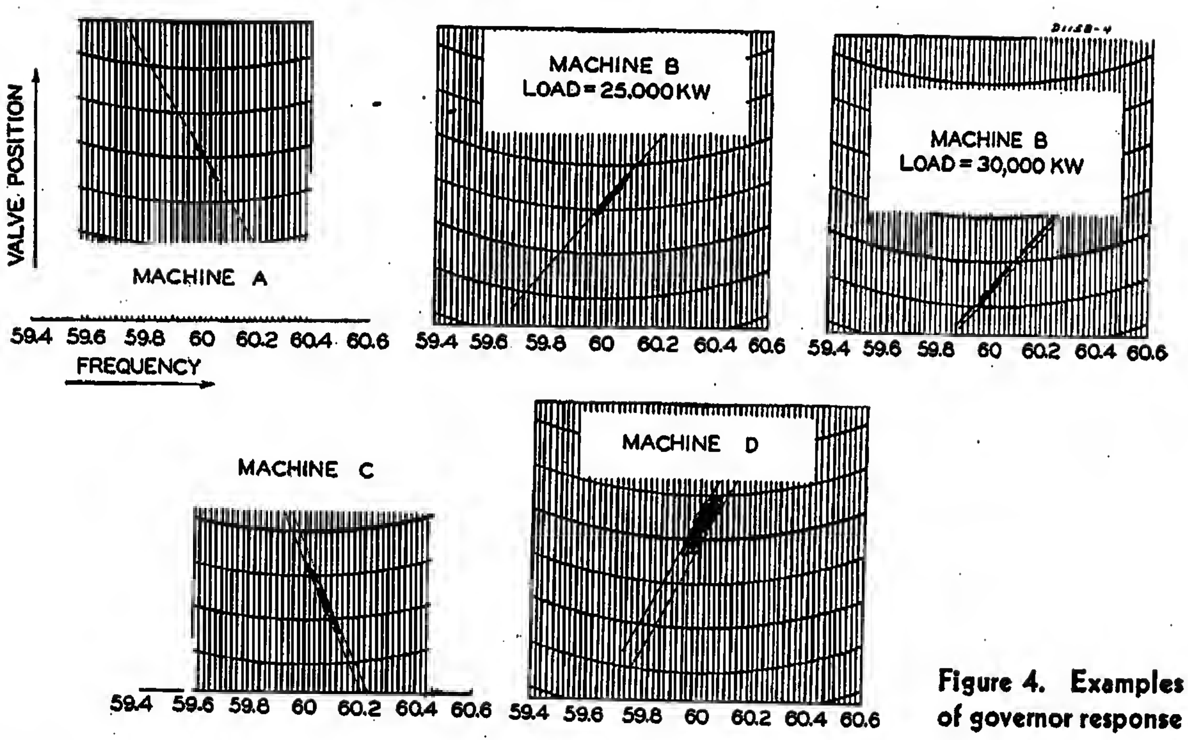

Figure 4. Examples of governor response

scale. It is thus possible to determine the amount of dead band contributed by each component of the mechanism. The frequency recorder, with the carriage for recording mechanical motions in place, is shown in Figure 2 and in use in Figure 3 of this discussion.

Further Examples of Test Results

Figure 4 of this discussion shows examples of the records obtained on a few of the machines tested. Machines *A* and *C* have two-stage hydraulic relays, while machines *B*, *D*, and *E* have only one-stage relays. The dead band is seen to vary from practically zero to about 0.1 per cent in these machines. However, because of the relative scarcity of data, it cannot be inferred that these values are representative of all machines, or even that they indicate probable values of dead band on other machines. Parallel lines have been drawn on some of these charts in order to illustrate further the procedure used to determine dead band, which is taken as the horizontal distance between the parallel lines and incremental regulation, which is proportional to the change in speed, or frequency, divided by the change in valve position.

Conclusion

In conclusion, it may be remarked that this method of governor testing to determine dead band and incremental regulation has shown itself to be very useful and informative. Further similar tests can probably be made by interested power companies, with mutual advantage to these companies and to the manufacturers of turbine-governing equipment. We take this opportunity to acknowledge the co-operation of our associates and of the many power companies that have contributed time and effort to make these measurements possible.

W. O. Osbon (In collaboration with A. F. Schwendner, nonmenber; Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Concerning Mr. Juhnke's remarks we are assuming that he means over-all steady-state regulation with the speed changer in the no-load position when he refers to a regulation of 20 per cent. Present practice for larger central-station units calls for four to six and not more than eight per cent over-all steady-state regulation. Six per cent regulation should satisfy most central-station generating systems. Load limiting devices which can be adjusted to relieve the governor of control are supplied with units intended for use as base load units. In any event the instruments described in the paper will aid greatly in measuring the speed regulation of existing machines and in determining the requirements for new ones.

The discussion by Messrs. Sheppard and Concordia brings out the fundamental differences between the governor analyzer and the instrument used by them. The governor analyzer was developed primarily for the purpose of giving information about the performance of each of the elements which make up the complete governing system. It shows not only the over-all response of the governor, but reveals also how much each individual element contributes to the final result. The instrument described by the discussers, on the other hand, gives only the values of frequency dead band and incremental governor regulation. Other instruments must be used to determine the elements of the governing system responsible for the result. It serves well to give a rough quick determination of dead band, provided that the rate of frequency change is smaller than the rates of response of the governor and of the recording instrument. If the rate of frequency change is higher, the width of the recorded dead band will be distorted by the lack of response. The photoelectric recorder used by the discussers is definitely limited in its rate of response. This effect is apparent in Figure 1 of the discussion where certain of the loops are definitely oval in shape. When such records are obtained, there is no way of knowing that the lack of response is not due to dynamic lags in the governor itself, rather than to the limitations of the instrument.

The governor analyzer, on the other hand, is capable of following the most rapid frequency changes likely ever to be encountered. Consequently not only does the running chart obtained with the analyzer indicate the dead band, but also, by checking the motion of the valve against frequency changes of different rates, the maximum rate of frequency change that the governing system is able to follow can be established. The value of dead band, which is a steady-state phenomenon, can be separated definitely from the dynamic lags. It is admitted that considerable work is required to obtain these data, but the additional information obtained adequately compensates for the trouble.

The statement by Messrs. Sheppard and

Concordia that incremental regulation can be obtained directly by the use of their instrument is somewhat misleading. They correctly define incremental regulation of a generating unit as "the ratio of speed change to load change for a small change from normal speed." Their instrument, however, gives only the ratio of speed change to valve movement. Because of curvature in the valve lift characteristic, the ratio of load change to valve motion must also be carefully measured. The determination of the correct value of this ratio for a particular load point is as important as the measurement of the governor regulation itself. By recording simultaneously all the quantities required for a determination of incremental regulation of a generating unit, the governor analyzer leaves nothing open to question.

Messrs. Sheppard and Concordia state that no special loading schedule is required when using their instrument. This statement also is misleading. It is true that dead band and regulation can be measured at one particular load, but a complete investigation of governor characteristics requires measurements at a number of different load points. That the discussers recognize this fact, in spite of their statement to the contrary, is indicated by their Figure 4 in which measurements on machine *B* at two different load points reveal different values of incremental governor regulation.

Control of Tie-Line Power Swings

Discussion and authors' closure of paper 42-72 by C. Concordia, H. S. Shott, and C. N. Weygandt, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, June section, pages 306–14.

Earle Wild (Commonwealth Edison Company, Chicago, Ill.): The paper by Messrs. Concordia, Shott, and Weygandt is a valuable contribution to the study of supplementary control. The conclusions, however, are applicable in but few cases today. The optimum regulation is seldom needed, and most tie-line controllers are probably not used at over ten per cent of this rate. It is possible that there are some cases where limited tie-line facilities and large highly variable loads could use the principles developed. The Chicago experience does not indicate any trend in this direction, but does indicate that a reasonable, orderly and fairly slow correction is satisfactory, permitting the large momentary power swings to be absorbed by the inertia of the large interconnection, but—all important—having a continuous correction of the tie-line load trends of longer duration.

J. E. McCormack (Consolidated Edison Company of New York, Inc., New York, N. Y.): The operating companies are interested in the characteristics of governors, frequency controllers, and other regulating devices to the extent that these equipments function with each other and with the other electric and steam equipments in the generating station. The rate of response of a governor or a frequency controller is only one of a series that includes the rate of response of the boiler control equipment, stokers, coal pulverizers, and the like. In general, the maximum available rate of response of the present electrical equipment in the frequency or load-control schemes is faster than the rate of response of the steam plant. If faster response of the supplementary control system is required, attention must be turned to the steam plant in order to obtain the faster rate.

Two types of controllers are discussed:

1. The proportional type which operates on accumulated time error.

2. The floating type which operates on instantaneous frequency.

Once again, the operating companies are not interested in their fundamental differences but are concerned in the results of these controllers operating on the system. Either type will do a good job as long as the system frequency, time error, or tie line, and station loads are not permitted to drift beyond the allowable limits of the operating company. If these limits are exceeded, the controller will have distinct disadvantages. The operation of a controller outside of the limits set up by the operating company is academic, because during this period the operator removes the automatic control from service and uses manual control to restore conditions to normal.

The installation of the correct type of automatic control, on an interconnected system consisting of generating stations and tie lines of varying capacities, will result in a narrower frequency variation, a smaller time error, a better utilization of the tie-feeder capacity, a reduction in the load swings on a station, and a lower maintenance cost in the boiler plant.

C. Concordia, H. S. Shott, and C. N. Weygandt: The object of our paper was to determine the possibilities and limitations of tie-line controllers when an attempt is made to get the most out of them, on the assumption that the tie-line controller is the limiting factor, that is, that boiler equipments and so on, are more than adequate. However, we are in entire agreement with Mr. Wild that the rates of response thus found to be optimum are in general much higher than would be necessary or desirable on the more usual large interconnected system, and with Mr. McCormack that, if such high rates of response are actually used, it may be found that the response of the boiler and its equipment will be the limiting factor. This paper represents a second step in the complete analysis of a controlled power system, the first step being the analysis of speed governors[1] presented a short time ago, and the third step possibly being a more detailed consideration of boiler performance. The boiler and turbine performance have already been discussed in the companion paper.[2]

Supplementary Control of Prime-Mover Speed Governors

Discussion and authors' closure of paper 42-73 by S. B. Crary and J. B. McClure, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April section, pages 209–14.

P. B. Juhnke (Commonwealth Edison Company, Chicago, Ill.): The paper presented at this session by Messrs. Crary and McClure is evidence of decided progress in a field in which, until comparatively recently, wrong notions and concepts were rampant, because thorough scientific analysis had not touched it before. I and many other operating men concerned with this subject were victims of conclusions only partly founded in the facts observed. We made observations and misinterpreted them. Observations were frequently made in connection with the loss of generating capacity, with effects expressed only in frequency variations in a downward direction, and contained in the formula: one per cent loss in generating capacity carries with it a drop in frequency of $^1/_{10}$ cycle, and vice versa. In reality, there was another effect, completely lost sight of for some time, presumably due to the all-absorbing interest which had attached itself to frequency and its maintenance as a principal factor in the operation of interconnected systems. Repeated inconsistencies in our observations and the results reported by New York in the preceding winter convention prevailed on us to make further investigations. And then we began a series of tests to definitely determine the merits of our previous conclusions. We isolated certain sections of our system to simplify the tests, the sections ranging between 60,000 and 100,000 kw. The load on them was totalized on one meter, the voltage was held constant, and then the effects of the variability of the load with frequency, through a range of four cycles, was observed. In this manner we obtained evidence that our previous conclusions were 500 per cent high, or only about 20 per cent right. The conclusions drawn from these tests may be laid down in the formula: $^1/_{10}$ per cent variation in frequency is attended by not more than 0.2 per cent variation in system load. How could we harmonize with this the observation, made over and over, that $^1/_{10}$-cycle variation in frequency was accompanied by one per cent variation in load? We searched and found that every such loss in generating capacity was attended by voltage reduction —not large, but enough so that 80 per cent of the change in generation, which took place whenever the entire interconnected system lost one of its large units, had to be allocated to this cause.

To more definitely corroborate this, we very recently conducted voltage tests to determine the precise dimension of the effect of

voltage variation on the system load. During these tests all automatic circuit regulators were taken out of service and the system voltage varied approximately five per cent. We then found that on a system load of 1,720,000 kw this variation in voltage produced a load change of approximately 70,000 kw, or four per cent, giving a ratio of 0.8 per cent load change for one per cent of voltage change.

Messrs. Crary and McClure's paper may evoke some difference of opinion as to methods and detail, whether the governor should be depended upon in conjunction with controllers equipped with time bias only for speed regulation, or with frequency and time bias. It is one of those subjects on which a difference of opinion may be warranted. We of the Chicago group lean to the belief that a controller based on tie line with frequency and time bias is the *ne plus ultra*, as a time bias alone is somewhat slow of response, whereas frequency bias is practically instantaneous in restorative efforts.

Henry Kreisinger (Combustion Engineering Company, New York, N. Y.): In the design of steam generating equipment for rapidly changing load the following factors should be given consideration:

The response of combustion control in supplying fuel and air to the furnace in proportion to the steam demand. This includes the response of the pressure fan supplying air to the furnace, and the induced draft fan moving the products of combustion through the steam generating unit.

The availability of fuel supply for immediate use with large and rapid increase in load. With gas and fuel oil response is obtained in 5 to 15 seconds, with pulverized coal 15 seconds to two minutes depending on the magnitude of the load increase.

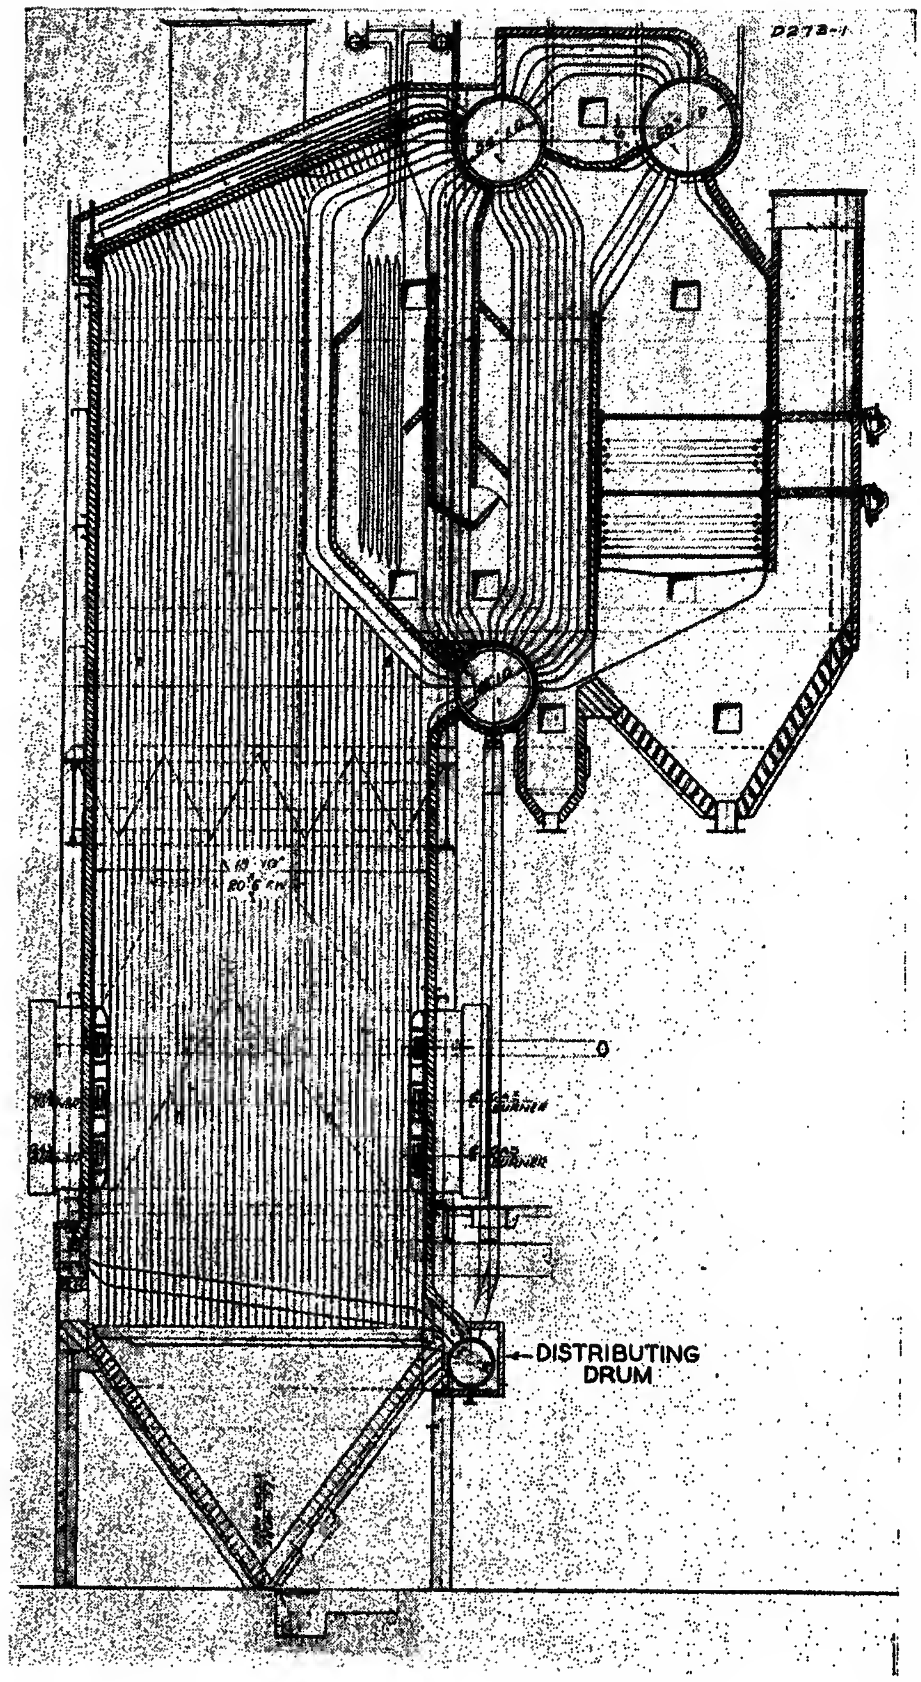
The repeating mechanical stresses imposed on the fan structure with large and rapid changes in load.

The repeating temperature stresses to which the metal of the heat absorbing surfaces is subjected.

The combustion control might be made so responsive that the fuel and air supplied to the furnace could be doubled in five seconds. The fans would have to handle twice the weight of air and gases against much higher pressure, and severe mechanical stresses would be imposed on the fans and the motors. The speed of the rotating parts could not be stabilized in such a short period of time; the speed would slow down and then speed up, and these changes in speed would be reflected in the draft in the furnace and puffy fire. The burning of twice the amount of fuel would result in twice the rate of heat transfer by the heating surfaces, which would require twice the temperature difference between the water in the boiler and the furnace side layers of metal forming the heat-absorbing surfaces. For high steam pressures the metal of the heating surfaces must be made thick, and this increased thickness results in proportionately higher temperature of the furnace side layers of the metal. Doubling the temperature difference causes large changes in the temperature of the furnace side layers of the metal which imposes severe temperature stresses in the metal. Such stresses when periodically repeated result in leaky joints, cracking, and corrosion of the tubes. Thinner tube walls would reduce these temperature stresses, but thinner tube walls would require small diameter tubes which in turn would require forced circulation.

With pulverized coal firing small load increases of about 15 per cent can be taken within about 10 seconds by drawing on the pulverized coal already in suspension within the mill by increasing the air flow through the mill. Most mills are provided with coal classifier which classifies the pulverized coal, allowing the finer coal to pass through to the burners and returning the coarser coal to the mill. Normally the amount of coal circulating through the classifier is five to six times the amount that passes through to the burners. When air flow through the mill is increased, the proportion of coal passing through is increased, and less is returned to the mill. The fineness of the coal going to the burners is only slightly decreased. Increased air flow through the mill also tends to put more coal in suspension, thereby reducing the amount of fines in the coal between the milling surfaces. Inasmuch as the fines have cushioning effect on the process of pulverization, the reduction of the fines in the coal between the milling surfaces tends to increase the rate of pulverization.

Figure 1



At the same time, when the air flow through the mill is increased, the coal feed to the mill is also increased. The rapidity of the response of the coal flow out of the mill to the increase of the coal feed is delayed, because the coal fed to the mill must be dried and pulverized.

The drying of the coal fed to the mill is facilitated by the greater flow of heated air through the mill. The delay in the response of the coal flow out of the mill to the increased feed of coal to the mill varies with the percentage of moisture in the coal. When very wet coal is fed to the mill, the response is apt to be slow, because the wet coal blankets the coal already in the mill, so that the fines are not readily picked up by the air flow. In plants where the coal is apt to be very wet, provision should be made for supplying hotter air to the mill to speed up the drying process. It is the coal already in suspension in the mill air that is immediately available for picking up and holding the load until the increased coal feed raises the rate of pulverization.

With a small drop in load the procedure is reversed, the air flow through the mill and the coal feed is reduced, and this reduction in

turn decreases the amount of coal delivered to the burners.

Small changes in load put moderate duty on steam generating and steam temperature regulation. However, large changes in load impose a severe duty on the equipment and present difficult problems in steam pressure and temperature control.

With large and quick variation of load, it is difficult to follow the demand for steam with fuel and air supply to the furnace, and to vary the draft to move the varying weight of products of combustion through the steam generating unit. Even if such variation in fuel and air supply to the furnace could be obtained, there would be too quick and large variation in furnace temperature, which would cause severe temperature stresses in the metal of the heat-absorbing surfaces. Such stresses would be particularly severe with high pressures, because of the thick metal walls of tubes required for high pressures.

With the conventional natural circulation boiler fired with pulverized coal, the load could be raised from half to full load in about three minutes by doubling the fuel and air supply to the furnace, but this is not usually quick enough for most steel plants. In such plants the large and quick variation in the demand for steam is satisfied partly by varying the fuel and air supply to the furnace, and partly by drawing on the heat storage in the water and the steam space of the boiler. This stored heat is made available for immediate use by a small steam-pressure drop. The steam storage space includes the drums, the superheater, and the pipe line. When more steam is taken out of this steam space than is made by the combustion of the fuel, the pressure drops, and this drop in pressure causes part of the boiler water to flash into steam. The steam formation occurs throughout the body of the boiler water, and inasmuch as the steam has a much greater specific volume than the water, the water level in the steam drum rises. The rise in water level reduces feed water supply, thereby causing the flashing of the water into steam to be accomplished with smaller pressure drop. By the time the water level in the drum is lowered by the evaporation to a point when the feed water regulator would increase the feed to the boiler, the increased combustion rate is catching up with the steam demand or the peak load interval may be over. When the load drops, the pressure starts to rise, and the rise of pressure reduces the ebullition, thus causing further drop of the water level and increase of feed water supply. This increased water supply requires more heat to bring the water to steaming temperature, and this heat requirement gives the combustion control time to reduce the fuel supply to the furnace.

The steam-pressure drop during a large and rapid increase in load depends on the water content in the boiler and the steam space in the steam drums, superheater, and the pipe line. The larger the water content and the steam space, the smaller the steam pressure drop. A bent tube boiler with multiple steam drums of large diameter is best suited for such large and rapid changes in load, because it has large water content and steam space. Each tube is directly connected to one of the steam drums, so that the tubes can be quickly relieved of the excess steam during the peak.

In addition to the pressure drop in the

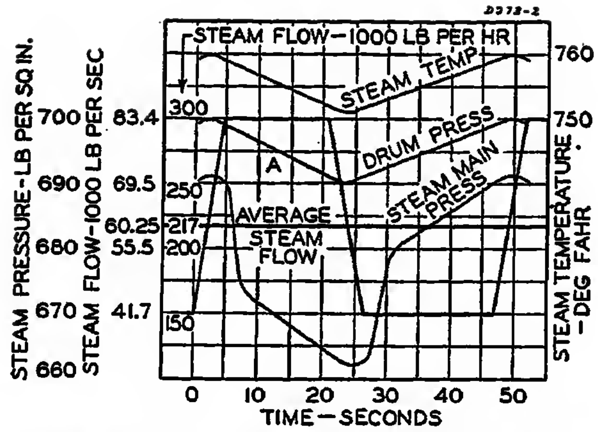


Figure 2. Steam pressure and temperature variation with rapidly changing load

A—Excess steam 432 pounds, six pounds from superheater, six pounds from steam drums, and 420 pounds from heat stored in water and metal

Water volume = 2,200 cubic feet = weight of water = 107,300 pounds

Steam volume in drums = 512 cubic feet

Steam volume in superheater = 230 cubic feet

Weight of metal in boiler = 442,000 pounds

Weight of superheater = 64,000 pounds

Water equivalent of boiler metal = 51,350 pounds

Total water equivalent = 107,300 + 51,350 = 158,650 pounds

steam drum, due to using stored heat in the boiler water for making steam, there is a pressure drop through the superheater and the pipe line. This pressure drop is necessary to make the steam flow and increases approximately as the square of the steam flow. That is, when the steam flow is doubled, the pressure drop is nearly quadrupled. The increase of this pressure drop may be two or three times the pressure drop, due to taking stored heat out of the boiler water.

The residual heat in the furnace is stored heat which works against good pressure and steam temperature control. The heat is stored during the peak load when it should be used for producing steam and is released during the low load period when no extra steam is needed. Therefore, the residual heat should be reduced to minimum by proper furnace design. Refractories and slag accumulations in the furnace should be avoided. The furnace should be completely water-cooled with dry bottom.

The steam generated at the peak loads with the heat stored in the boiler must be superheated with the heat stored in the metal of the superheater. Increased flow of steam through the superheater tubes increases the rate of heat transfer from the superheater metal to the steam, with the result that the temperature of the metal drops. The heat released by this drop of metal temperature is available for superheating the steam made with the heat stored in the boiler. When the load is dropped, heat is again stored in the boiler and the superheater. Superheaters of large weight of metal give more nearly constant temperature of steam with variable load.

When the high and low load periods are of comparatively long duration, the storage of heat in the boiler and superheater gives the combustion control time to catch up with the steam demands. When the periods are of short duration, the stored heat may take care of the load variation, and the fuel may be burned at constant rate. The latter case can be illustrated by the following specific example:

A steam-generating unit is to supply steam for rapidly varying load. The steam demand rises from 150,000 pounds in five seconds to 300,000 pounds per hour; it stays at this peak for 16 seconds and then drops in five seconds to 150,000 pounds where it stays for 21 seconds. This load cycle is repeated every 47 seconds. The unit is to be fired with blast-furnace gas, with pulverized coal as supplementary fuel.

It is obvious that combustion control could not follow such large and quick variation. Even if it were possible to supply fuel and air to the furnace at such varying rate, it would not be good engineering to operate the unit in such a manner, because of the severe temperature and mechanical stresses imposed on the furnace and boiler heating surfaces and the fan equipment.

The unit selected for this load is shown in Figure 1 of this discussion. It consists of a three-drum bent-tube boiler with an additional small drum for distribution of water to the furnace walls. The two top drums are 54 and 60 inches in diameter; the water drum is 48 inches, and the distributing drum 27 inches in diameter. The furnace is completely water-cooled. The following are the principal data bearing on the pressure and temperature regulation:

Operating drum pressure.......	700 psi
Steam temperature............	760 Fahrenheit
Boiler water volume..........	2,200 cubic feet
Weight of boiler water at operating pressure................	107,300 pounds
Steam volume in drums and steam tubes................	512 cubic feet
Weight of metal in boiler.......	442,000 pounds
Water equivalent of metal in boiler......................	51,350 pounds
Total water equivalent.........	158,650 pounds
Weight of superheater.........	65,000 pounds

The operation of the unit is illustrated in Figure 2 of this discussion, which is a chart showing load, steam temperature, and pressure variation with time. The abscissae is time in seconds. The ordinates are steam flow (the zigzag line), the steam temperature (the top curve), drum pressure (second curve from top), and steam main pressure (the lowest curve).

Fuel is supplied to the furnace at constant rate to generate 217,000 pounds of steam per hour, or 60.25 pounds per second, as shown by the horizontal line passing through this flow point on the scale. The area above this horizontal line and below the zigzag line of the peak load represents the quantity of steam made with the stored heat in the boiler, which is 432 pounds. It is also equal to the area below the constant-heat supply line and above steam-flow line during the low load period which represents the heat put in storage. The variation in steam temperature is nine degrees and is likely to be two or three degrees less, because of the increased rate of heat transfer from the metal of the superheater to the steam which has not been included in its determination.

The drum pressure drop is 10 pounds and is likely to be smaller, because the feed water supply will be reduced during the peak load and increased during the low load period. The effect of this variation of feed water supply has not been included in the determination of the pressure drop.

The variation of the pressure drop through the superheater and the steam main is the largest and is difficult to reduce. If the resistance through the superheater is made too

low, the distribution of steam over the superheater may be uneven at low loads.

Earle Wild (Commonwealth Edison Company, Chicago, Ill.): The authors' conclusions in the first paper, excepting conclusion 2, confirm the opinions now held by the majority of operators in the largest interconnection in the country. Governors have been found by test to be the essential device for controlling the speed. In most of the turbines they were found to be active and sensitive, although the per cent regulation left considerable to be desired, especially in some of the newer and larger turbines. The governors very definitely determine the width of the frequency band. Changes in load demand with frequency and changes with voltage were found to be real, but of so much smaller magnitude that the effect of governor action is the only major factor in instantaneous speed control. As pointed out in the first conclusion, with good governors the rate of response of the frequency controlling stations can be much slower, since the error will integrate at a slower rate and correction can also be made at the source of the frequency error.

After recognizing the merits of the governor and the need for improvement in governors, its limitations must also be recognized. The three things that a governor will not do are:

Restore frequency to the tolerance band.
Correct time errors.
Allocate loads in the most economical manner.

These functions must be left to the supplementary controllers. This leads to another aspect of the problem, which has hardly been touched upon in any of the governor or related papers written in the last two years. In the large interconnection there is a load-control problem, which is entirely separate from the speed-control problem, and the importance of which has not been fully appreciated. In any local region of this large interconnection there will be dozens and perhaps hundreds of load changes in which there are no corresponding frequency changes, as contrasted with an occasional load change which is accompanied by a corresponding frequency change. Theoretically, if tie lines are unlimited in capacity, these hundred load changes could be ignored, and only the one which is accompanied by a frequency change corrected, but the fact remains that tie lines are limited in capacity, and no economical justification exists in the majority of cases for increasing their capacity or transferring load to other stations. The load-control problem must, therefore, be met, and this is best done through tie line controllers supplementing the governor action and using the tie-line bias principle, as correctly recognized by Messrs. Crary and McClure.

The periods of abnormal frequency in the large interconnection are caused by a number of local regions neglecting their load control problems at the same time. They are caused by such factors as system operators incorrectly prognosticating the system load, turbines or boilers being brought in too late for the load, the human element ignoring obvious indications of incorrect generation, inadequate telemeters with which to guide the operators. When a series of these maloperations cascade together, a gradual frequency change results, several times the width of the normal frequency departures, and considerably beyond the range of the frequency controlling stations. These occurrences are most severe during periods of rapid load change, when probably 90 per cent of the governors are being reset every few minutes to meet local load changes. Ordinary concepts of governor regulation during these periods are meaningless, because of this frequent resetting of the governors. In other words, if a governor calls for a three per cent load increase due to low frequency, while the operator is making a six per cent increase to meet local load demands, it is hardly expected that the operator would know he should make a nine per cent load increase in order to satisfy the governor. When the frequency was corrected finally, the operator would have to make an additional three per cent increase, in the interim not satisfying the low frequency requirements and increasing after the frequency is normal. This example of inadequacy of governors could be ideally handled with a supplementary tie-line controller. The major problem, then, is not what is the per cent regulation and the sensitivity of the governors, but why were so many turbines and boilers incorrectly loaded at the same time in widely scattered regions of the interconnection? The conclusion which has been reached, after each study of this problem, is that a wider application of supplementary controllers in local regions is needed, and it is very gratifying that the summary of Messrs. Crary and McClure bears out this opinion.

The major contribution of the Chicago area to this problem the past year has been the utilization of the tie-line controller impulses to vary the load of the three large variable load stations simultaneously. The burden of regulation on each one has become almost insignificant, while the deviations of the tie line from schedule are extremely rare, except in response to governor action during frequency changes. This confirms an earlier conclusion that a large part of the difficulty in regulating load and frequency comes from cross regulation between stations within any one group, and that the meeting of one per cent load change per minute is relatively easy. This experience is being extended to two other groups in this interconnection.

G. B. Warren (General Electric Company, Schenectady, N. Y.): The general question of what rate of change in temperature or what rate of change in load a turbine can stand is one of great complexity depending upon the conditions for which the turbine was designed, its capacity, its revolutions per minute, and the initial pressure and temperature at which the machine is operating. The change in initial temperature and change in load are related, since, even at constant initial temperature, changes in load bring about changes in internal temperature in the turbine, which may be exaggerated by the changes in initial temperature occurring simultaneously as a result of boiler conditions.

In a machine such as a turbine, through which steam is passing, the cross section of all parts cannot of necessity be made the same in relation to their surfaces in contact with the steam, and, hence, some parts are heated or cooled faster than others. This gives rise to changes in clearances and sets up strains and stresses, the magnitudes of which are a function of both the amount and the rapidity of the temperature change. This, in turn, may be a function of the rate and magnitude of the load change as well as the initial temperature change.

While exact data on the detrimental effect of these factors on turbines are not available, we have made careful efforts to ascertain from the operating people whether turbines subjected to varying loads require more maintenance than turbines subjected to more constant loads. There does not seem to be any great evidence to indicate that this is so, but in a few isolated cases turbines subjected to great changes in temperature and many washings without careful control of the temperature have appeared to require increased maintenance.

As a result of a careful survey recently made by a group of turbine designers in the General Electric Company, the following conclusions were reached:

A plus or minus 75-degree-Fahrenheit change in internal temperature, either sudden or cyclical around a mean temperature, will not cause serious strains or clearance changes. These variations in internal temperature may be caused by variation in load or initial temperature or both. However, the maximum temperature reached must not exceed the contract limits both as to duration and intensity.

With constant initial temperature, a 75-degree-Fahrenheit change in internal temperature generally corresponds to a change of load of approximately plus or minus 25 per cent of the load at which the turbine is operating.

When Messrs. Crary and McClure asked us for a statement of this situation, our preliminary investigation indicated that the 75-degree-Fahrenheit change corresponded to a change of about 15 per cent of rated flow. A more careful study indicates that a more accurate statement would be 25 per cent of the load or flow at which the turbine is operating. For two-thirds load this is not far from the statement in the paper.

The question of whether greater rates of change in temperature or load can be taken without increased maintenance is not so easily determined. The answer depends upon the size of the machine, the pressure for which it is designed and, hence, the thickness of the parts, whether the machine is an 1,800-rpm machine with a large diameter or a 3,600-rpm machine with a smaller diameter, and whether it is of single- or double-shell construction, and also whether or not it is a fixed back-pressure machine or a condensing machine. In general, the sensitivity of a machine to such changes in internal temperature decreases in the following order:

1. 1,800-rpm single-shell machines.
2. 3,600-rpm single-shell machines.
3. 1,800-rpm double-shell machines.
4. 3,600-rpm double-shell machines.

Condensing machines have a greater internal temperature variation for a given load change than noncondensing machines operating at a fixed and fairly high back pressure, and smaller turbines can probably stand a greater rate of temperature change than larger turbines, other conditions being comparable.

An effort is made to design all turbines so that in cases of necessity they can drop all load instantaneously without damage, or pick up full load from no load as fast as dry steam can be supplied.

Except when special circumstances alter the situation, we know that the most sensitive of the above machines have safely withstood the temperature changes incident to a sudden increase from zero to full load or of a sudden loss of full load. We do not know how many times in the life of a machine it can be safely put through such drastic changes in temperature without increased maintenance being required. In the case of temperature changes in excess of 75 degrees Fahrenheit, it would appear desirable to allow some time for the change to take place. Except under emergency conditions internal temperature changes should probably not exceed 75 degrees Fahrenheit suddenly plus five degrees Fahrenheit per minute for class 1 machines above, and for all other classes should not exceed 75 degrees Fahrenheit suddenly plus 10 degrees Fahrenheit per minute. Thus, an internal temperature change of 200 degrees Fahrenheit (whether from a load change or initial temperature change or a combination of both) should not take place in class 1 machines above in less than $(200-75)/5$ degrees $=25$ minutes. 200 degrees Fahrenheit internal temperature change corresponds to a change in load from about 50 per cent to full rated load, and twice this change will correspond to a swing throughout the full rated load. The conclusions which one would reach with respect to large changes of load from the above principles and simple calculations are not far from the 30 to 60 minutes suggested in the paper for a 100 per cent change in flow.

The above rules are intended to cover general cases. Some machines are particularly sensitive to temperature or load changes, in so far as temporary increases in vibration are concerned, and must, until such conditions are rectified, be accorded special consideration. Specific machines for especially high initial pressures or other peculiar operating conditions may also be exceptions.

These rules do not apply to changes in temperature, incidental to washing solids from the internal parts of turbines where water may be present in the steam with resulting increased heat content and conductivity of the steam, and resultant need for slower temperature changes and for which special instructions have been issued.

F. G. Sandstrom (Consolidated Edison Company of New York, Inc., New York, N. Y.): The morning rate of load growth of the entire Consolidated Edison Company load averages approximately 0.4 per cent per minute. On some stations this rate averages 0.5 per cent per minute. However, for short periods of about 10 minutes this rate may be as high as 2.0 per cent per minute at a station.

When our supplementary controllers were first installed, the rate of load change of the controller was high enough to take care of the short-time load changes. The steam group soon objected to this high rate of pickup because of the increased maintenance costs, objections to smoke and fly, has possibility of blowing a hole in the fuel bed, inability of maintaining steam pressure and so forth. The supplementary controllers are now adjusted for a rate of load change of approximately $1^1/_2$ per cent per minute which the steam group feel is allowable on stoker-fired boilers.

As a result of our experience, we feel that the present supplementary controllers are fast enough. If they are used with too fast a rate of load change, the frequency and load-swing problems are not solved, and an additional problem may be created for the steam men.

The over-all governor response on our system is from 11 to 17 per cent, or several times the optimum rate quoted in the paper by S. B. Crary and J. B. McClure. There is nothing wrong with their theory that the smaller the regulation rate, the smaller will be the frequency swings. However, we are not concerned with frequency swings but are concerned by the load swings accompanying the frequency swings. These load swings are usually caused by the governors on the generators making up a deficit or an excess of generation on the system. If the system suddenly becomes short 50 megawatts, the load swings on the tie feeders and generating stations will be about the same, whether all the generators have 12 per cent regulation or 6 per cent regulation.

We have found that the cause of the load swings is usually incorrect anticipation of the change in the actual consumed load, or manual adjustments on turbine governors that tend to force the frequency away from 60 cycles. On the Consolidated Edison system load swings have been reduced considerably by furnishing the station operators with a synchroscope connected between a standard frequency and the system frequency. The standard frequency at each station is the Bell Telephone standard. The station operators pick up load when the frequency is low and drop load when the frequency is high.

On our system the stations are connected by relatively low capacity ties. An automatic supplementary controller that works on instantaneous frequency or time error would have to be constantly supervised by the operators in order to prevent overloading the tie lines and maintain the economy load schedule. Consequently, on a system similar to ours we feel that the tie-line bias control appears to be most suitable, because it supervises the tie-line loads and allows all stations so controlled to contribute to any large load changes that might occur. Then the station where the load change occurred can slowly at a controlled rate pick up the total load change in the area.

J. E. McCormack (Consolidated Edison Company of New York, Inc., New York, N. Y.): The conclusion of Messrs. Crary and McClure that absolutely flat frequency, zero time error and flat tie-line load are unnecessarily severe limitations may lead to the belief that a close approach to these conditions is desirable. I would like to point out that to approximate these aims, the controlling station or stations would have to withstand rapid load changes of a very high percentage of the station capacity. It appears to me that it is more desirable to let the frequency, time, or tie load drift in order to spread the load change over the entire system, so that the change on any station would be a small percentage of its capacity.

Automatic controllers cannot be expected to do all of the regulating, as the operator must make many manual adjustments. Machines must be started and loaded quickly to their minimum load, the regulating range on the regulating machine must be maintained, and the load has to be distributed between machines for economy reasons. The phase angle between bus sections must be maintained within allowable limits in stations supplying network load. To make these manual changes intelligently, the operator should have a knowledge of the response of the system and be provided with suitable instruments.

We have found a common frequency reference in all major stations to be useful when making manual load changes. A standard frequency is wired to the major stations where a synchroscope is connected between the standard and the system frequency. The synchroscope, being a very sensitive indicator of system frequency, is used by the operator as a guide in making manual load changes only at a time when they tend to restore system frequency to 60 cycles. Load increases are made when the frequency is low, and load decreases are made when the frequency is high.

Experiments have been made using a frequency standard transmitted by radio for comparing the system frequency by means of a stroboscopic image at each station. This method will be an economical way of obtaining a common frequency standard at the generating stations on a widespread system.

The trend toward larger interconnections made it imperative to have a thorough understanding of the effect of changes in load, voltage, and frequency on our system, in order to obtain the most advantages from the interconnection. The first consideration should be to obtain data for each system, which would require making tests allowing one of these three variables to depart from normal, while the other two are maintained normal. The carefully controlled departures of the system conditions from normal to obtain this vital information will result in a better understanding of system operation. The information will aid in obtaining the maximum utilization of the generation and tie lines, as well as aid in restoring conditions to normal in times of an emergency.

When this information is available, the next and most important job is to place the information into the hands of the operating force in the individual plants. Any steps taken to give the operators a better understanding of the importance of performing their operations correctly will produce surprising results in the improvement of system operation.

As an example, I discussed with our system operators the possibilities of a stroboscope using a radio signal for a common frequency standard. Two weeks later one of these men produced a working model of the idea. More important than obtaining this working model, the system operating group have become very interested in obtaining a better understanding of the frequency control problem. The operating men want to do a good job but are often prevented, because the problem has not been presented to them properly.

S. B. Crary and J. B. McClure: The authors wish to express their appreciation for the discussion on this paper. This subject is an important one to both operators and manufacturers, and their combined viewpoints should broaden their understanding of it.

Mr. Juhnke has cited an interesting series of tests on sections of his system to determine the relative effects of voltage and frequency variations on system load. His results check those previously obtained by Mr. J. E. McCormack, namely, that the system load is much more sensitive to voltage variations than it is to frequency variations. It is recognized that these results are peculiar to their respective systems and cannot be generally applied to all systems. Mr. Juhnke's point regarding the use of supplementary time bias in addition to frequency bias is well taken. We did not mention time bias in our paper, since it is ordinarily applied at such a slow rate that it may be added without difficulty. However, it is a valuable addition to automatic frequency and tie-line bias control.

Mr. Kreisinger's discussion of the factors involved in the design and performance of steam-generating equipment will be of particular interest to many electrical engineers who are not so familiar with the mechanical engineers' problems associated with governor performance and supplementary control on a system. We also appreciate his description of a boiler which is so designed as to be able to handle rapidly fluctuating loads. However, from our discussions with the operating groups, the older steam-generating equipments, in many cases, have distinct limitations in this respect.

Mr. McCormack's emphasis on allowing some leeway in the control of frequency, time error, and tie-line load is very much to the point. We had hoped that our conclusions were clear in this respect, particularly for the benefit of groups just embarking on this area of control. Other groups have been through the experience of attempting to force the control of frequency, time, and tie-lines to the limit of perfection and have invariably concluded that the intelligent solution is necessarily a compromise among the several requirements which must be considered in the complete operation of an interconnected system. His reference to the possibility of using a radio-transmitted common master frequency over the entire system indicates that manually controlled stations soon will be able to make their adjustment so as to always help rather than aggravate the over-all picture.

Mr. Sandstrom has cited rates of transfer on their automatic stations which are interesting, and to some who have not had experience with automatic control, and to others whose systems are relatively rough, these rates will appear surprisingly low. Again, this cannot be taken as a general answer, and every system will have individual characteristics in this respect. We concur with his conclusion that relative generator and tie-line loadings will be practically the same for a system equipped with 12 per cent governors as for one with 6 per cent governors. As soon as the operating philosophy recognizes that frequency departure is not important, then it is not so important to have the composite governor regulation at the optimum value. We merely tried to point out that governor as well as supplementary controller characteristics are important factors in determining the regulated frequency characteristic. We emphasized the optimum governor regulation, hoping that that viewpoint would be helpful to some who are advocating operation of their systems with governors having appreciably narrower regulation than at present, in establishing a lower limit of regulation below which no net gain would be obtained.

Mr. Wild mentioned their recent practice of extending the tie-line controller impulses to several stations simultaneously. The benefits of distributed control are so apparent that we can expect the number of regulating units to increase steadily.

The comments of Messrs. McCormack, Sandstrom and Wild on the importance of proper co-ordination of all manual control and the benefits to be derived from educational effort will be of particular interest to other operating companies. Manual control will always be present to some degree, and thorough appreciation of the problem and the objectives is essential to those assisting on manual control. Proper instruments are also essential, and, as the needs are recognized, improved instruments will be made available.

Mr. Warren and his associates assisted us in arriving at the statements made in the paper regarding rates of load transfer on the newer higher-temperature high-pressure steam turbines. We are pleased to have Mr. Warren outline in more detail the factors which influence the performance of a turbine under fluctuating load conditions.

PCC Car Operating Results in Pittsburgh

Discussion of paper 42-52 by W. J. Clardy, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April section, pages 214–17.

H. G. Moore (General Electric Company, Erie, Pa.): Mr. Clardy, in his paper, has shown in great detail the economic advantages of modernization of street railway service by the use of PCC cars in Pittsburgh. This confirms by data, and adds to the list of universally favorable reports on the successful operation of really modern street cars in other cities.

For example, the first PCC car installation was in Brooklyn. Four lines equipped increased their revenue by 15, 24, 26, and 33 per cent in a period when other lines had decreasing revenues of one to five per cent. Schedule speeds were also increased 13 and 14 per cent on two lines where PCC cars are used exclusively.

Other figures, at random, may also be cited. In Chicago, riding increased approximately 12 per cent over the balance of the system, and schedule speeds were increased eight to ten per cent. In Baltimore, revenue increased eight per cent, and maintenance was reduced. In Los Angeles it has been estimated that the increased patronage provides increased receipts of $3,000 per car annually on one line, and $4,000 per car annually on another line. Washington reported somewhat increased schedule speeds in spite of operating on lines with older cars, 22 to 37 per cent decrease in platform expenses; 15 to 30 per cent decrease in accidents and 30 to 49 per cent reduction in maintenance costs. Philadelphia increased revenue 16 per cent and schedule speed 15 per cent.

While all of these figures compare operation of modern PCC cars with older types of cars, it should also be kept in mind that PCC cars compare even more favorably with other types of vehicles sometimes proposed for handling heavy-density surface traffic. I would refer to a paper[1] presented at the winter convention four years ago by Mr. C. M. Davis outlining the particular fields of public transit served best by one or another type of vehicle.

The principal governing factor is the traffic density, or the number of passengers to be carried per unit time in the direction of maximum movement. For the heaviest type of service, the rapid-transit system operating over private right of way under ground or overhead has no competition in handling 100,000 to 180,000 passengers per hour on two tracks, one express and one local. On the surface, the street car cannot be excelled in the range of 6,000 to 12,000 passengers per hour.

In low-density traffic such as that permitting the use of 40 passenger vehicles with headways of 15 minutes or more (approximately 240 passengers per hour) an advantage can probably be shown for the use of gas busses. But even here, electric transmission with either a gas or Diesel engine may be economically desirable, particularly in frequent stop service.

Between the fields best served by gas busses on one hand and street cars on the other, there is a large field in the vicinity of 2,500 passengers per hour which usually can be best served by trolley coaches.

We may conclude, therefore, that where such facts as Mr. Clardy presents relative to the PCC car are obtained and fairly used in the selection of transit vehicles, the inevitable decision must be in favor of some form of electric drive for transporting more than three quarters of the millions of pe ple who daily use public transportation services.

1. APPLICATION OF MODERN ELECTRIC VEHICLES TO URBAN TRANSPORTATION, C. M. Davis. AIEE TRANSACTIONS, volume 57, 1938, January section, pages 57–60.

Modern Electrical Equipment for Industrial Diesel-Electric Locomotives

Discussion and author's closure of paper 42-50 by Lanier Greer, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April Section, pages 229–32.

Robert W. Barrell (General Electric Company, Erie, Pa.): Here are some facts illustrating exactly how the modern electrical equipment described by Mr. Greer's paper together with the modern engine very greatly affected the industrial Diesel-electric locomotive within a short period of time.

In 1935 a 65-ton locomotive power plant consisted of a single 300-horsepower 550-

rpm Diesel engine and generator with auxiliary generator. In 1940 there became available for such a locomotive a power-plant unit consisting of a 190-horsepower 1,800-rpm Diesel engine and a generator developed especially for the purpose. This new engine-generator set was exactly one such as described in this paper. Two of the new sets were used in place of the former single set.

The interesting facts in comparing the new locomotive with the old are shown in Table I.

Table I

	Per Cent
Increase in net horsepower at the wheels	19
Decrease in total engine cost	71
Decrease in total generator cost	38
Decrease in total cost of power plant alone	65
Net decrease in power plant cost when applied to locomotive	61

The net decrease when applied to locomotive is less than the decrease in the total cost of power plant alone, because it was necessary to maintain the locomotive weight at 65 tons. Hence, steel ballast was added to offset the decrease in power plant weight, and the ballast cost has been deducted from the saving.

Now the power plant cost in the old locomotive represented 43 per cent of the total locomotive cost. Hence, it is to be noted that modernization of just the power plant alone brought about a cost reduction of 26 per cent in the over-all locomotive cost. And this was accomplished while improving performance by an increase of 19 per cent in the net power.

The paper mentions several advantages of the modern traction motor with double reduction gearing. From a locomotive builder's viewpoint, one great advantage of such a motor is its flexibility in adapting it to several sizes of locomotives. This is well-illustrated by a motor now in use which is actually being applied to as many as six sizes of locomotives, ranging from 25 to 70 tons. One, two, or four motors are used on a locomotive, depending on the weight. Also, any one of several gear ratios may be selected.

It is very apparent, therefore, that such a motor makes possible a high degree of standardization resulting in many benefits. Not only is there a standardization of the motor and items of control equipment, but also many mechanical parts, such as wheels, axles, and motor suspensions, can be standardized to a large degree.

Apropos to the subject of this paper, some mention can be made of the generator and motor-control equipment for modern industrial Diesel-electric locomotives. Such equipment, while a much smaller portion of the locomotive, nevertheless has played its part in bringing about cost reduction, simplification, and standardization.

One control item, the reverser, can be cited specifically as an illustration. There has been developed a direct-operated type of motor reverser, radically different in design, much simpler and lower in cost than former conventional types of reversers, which has proved to be a complete success for single-motor and two-motor industrial locomotives. An appreciable saving, simplification, and standardization were thus realized over the conventional electropneumatically operated reverser with its master controller.

As stated in this paper concerning the propulsion equipment, it can likewise be said of the control equipment that new materials and methods have been developed and adopted, which have made it possible to reduce weight and cost and, at the same time improve the quality of the product.

An interesting improvement recently incorporated in this type of modern generator, briefly referred to in Mr. Greer's paper, is the engine cranking feature. It is still a common practice to use separate automotive-type geared starting motors with high-speed Diesel engines, but it now has been proved that a cranking winding can be added to the generator with the important three-fold result of reduction in over-all cost, increase in reliability, and simplification.

The idea of using the generator as a cranking motor is old and formerly commonplace. Its application to the modern high-speed equipment is a splendid example of the efforts to produce for industrial Diesel-electric locomotives machinery of the simplest and most rugged design.

Along this same line of thought concerning the development of simple and rugged Diesel-electric equipment for industrial locomotives, it here seems in order to amplify the description of and give facts about the generator excitation and engine control scheme.

A Diesel engine is inherently a constant-speed, constant-power machine. The combination of traction generators and traction motors on a locomotive is not. Thus, the fundamental problem concerning the electrical equipment on a Diesel-electric locomotive is to devise for this combination of dissimilar machines the most suitable scheme for utilizing the power of the engine.

On slow-speed industrial switching locomotives it is obvious that perfect utilization of the engine can be sacrificed in favor of simplicity, ruggedness, and good accelerating characteristics. The excitation scheme described by Mr. Greer does exactly this. Without the use of complicated rotating devices, speed or torque-control schemes, or special windings or separate exciters, a practical method of engine utilization and good locomotive acceleration is accomplished.

This method employs the inherent speed-torque characteristics of a Diesel engine together with the inherent characteristics of a simple shunt generator with but the minor modification of a small amount of separate excitation from the standard cranking battery. The price paid for this extremely simple scheme is very small in terms of loss of power utilization.

Actually the figures on the two commonest industrial locomotive engine sizes are as follows:

At normal operating generator temperature the maximum reduction in engine speed when operating on the full-throttle torque curve results in 10 per cent reduction in power on one engine and $7^1/_2$ per cent reduction on the other. However, this maximum power reduction occurs at but one point in the full power utilization range. The actual integrated power reduction realized over only the utilization range is less than 5 per cent for the one and 3 per cent for the other. Since it is not necessary for the utilization to cover the entire speed-tractive effort range of these locomotives, the true integrated power reduction values realized at the wheels are found to be less than 4 per cent and $2^1/_2$ per cent respectively.

Therefore, it can be said for these industrial Diesel-electric locomotives that the maximum power available at the wheels is but $2^1/_2$ to 4 per cent less than it would be were a perfect power utilization scheme employed. But it should be observed that this reduction applies only to the possible maximum power obtainable at full throttle. Now in the usual industrial switching service, full throttle is used for but a small fraction of the work, hence the net result of this power reduction when measured in terms of work done is negligible. Surely, this simple and rugged design of modern electrical equipment for industrial Diesel-electric locomotives is well justified.

Lanier Greer: Mr. Barrell's discussion has brought out the fact that the modern electrical equipment for industrial Diesel-electric locomotives has reduced greatly the cost of equipment for these locomotives. Also the mention of ballast being added implies that the weight of the equipment has been reduced. This is a fact and can best be illustrated by comparing the new high-speed equipment with the old low-speed equipment.

In the traction generator this weight-saving can be measured in total pounds of material used per engine horsepower. The modern high-speed generator weighs only 8 to 10 pounds per horsepower against 20 to 21 pounds per horsepower for the old low-speed generator.

For industrial switching, tractive effort is of prime importance. Therefore the continuous tractive effort rating per pound of material used is a measure of weight saving in the traction motor and gearing. The modern high-speed traction motor with double-reduction gearing has a continuous rating of 2.2 pounds tractive effort per pound of material used in the combined motor and gear unit. The older type of traction motor with single-reduction gearing had a continuous rating of only 0.9 pound tractive effort per pound of material used in the combined motor and gearing.

These figures show weight savings of more than two to one when measured by actual ability to do work. Savings of material are always important and are especially so at this time, as all materials used in this equipment are of strategic value to our national security.

Facilities for the Supply of Kilowatts and Kilovars

Discussion and author's closure of paper 42-53 by H. K. Sels and Theodore Seely, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 249–55.

J. W. Butler (General Electric Company, Schenectady, N. Y.): The authors have called particular attention, in conclusion 1, to the effect that the data, on which the study was made, should not form the basis of a generalization, but apply only to the Public Service System. In order that this be further emphasized, and in an attempt to speculate in the general case to allow a generalization, I offer this discussion.

In Figure 3 of the paper the authors give data indicating the annual kilovar load duration requirements of their system. A curve of this general shape can be taken as typical of most systems. With such a kilovar requirement, one may ask: "What is the most economical way of supplying this requirement consistent with good operating practice?"

For purposes of discussion this kilovar requirement will be divided into three sections, as given in Figure 1.

Unregulated Reactive

The major portion of the system base reactive requirement can be supplied by unswitched capacitors. The maximum amount of this type of reactive source that can be used depends primarily on:

1. The light-load voltage conditions in load areas.
2. The system-stability margins during light load.

The light-load voltage problem in the load areas can be sufficiently controlled by judiciously locating capacitors so that this limitation can be sufficiently far removed to the background to bring the other factor to the front. For instance, the closer to the generation the capacitors are placed, the lower will be the voltage rise, and if this problem presents itself, unswitched banks can even be placed on substation busses of four kilovolts or higher for supplying base kilovar requirements.

The next important consideration is, therefore, one of stability. One can readily visualize that if unswitched capacitors are installed in sufficient quantities to require generators to run underexcited during certain periods, instability may arise. Therefore, it is not generally considered good practice to so operate unless intelligent generator voltage regulators are employed. We can, therefore, tentatively set as an upper limit that value of unswitched capacitors which allows the generators to operate at 1.0 power factor during light-load periods. Whether this value can be practically obtained depends upon two factors: transient and steady-state stability.

Transient stability can be very critical to fault-clearing times, for a given kilowatt load and excitation on the generators, and so it follows that if transient stability is a limiting factor, faster switching times allow more unswitched capacitors to be used for the same stability margins. On the other hand, if steady-state stability is the limiting factor, the use of generator voltage regulators will materially increase this type of stability, allowing again more unswitched capacitors to be used for the same stability margins.

Thus, it is seen that with modern relaying and breaker times, and with intelligent generator voltage regulators, this base, or

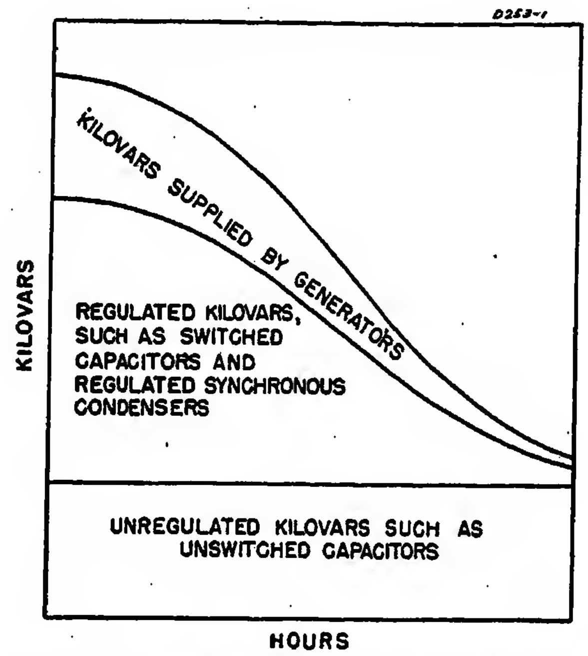

Figure 1. Representative annual kilovar-load duration curve

firm system reactive requirement can for all practical puposes be completely supplied by unswitched capacitors. In fact, it may under certain conditions be economical to more than supply this requirement, but this discussion will not go into that refined phase of the problem.

Kilovars Supplied by Generators

At high-operating power factors it is generally accepted that generators can carry reactive economically. The actual amount that can be carried by the generators in a particular case depends upon the particular generator design and the value and amount of reserve kilowatt capacity, and so, for the sake of discussion, the line of demarcation between the reactive supplied by generators and the regulated reactive will be only approximately located.

Regulated Kilovar Supply

It is in this center region—the regulated reactive requirement—that all engineers are particularly interested, and this is the region in which they will be more so in the future.

I quote from the last paragraph of the section of the paper labeled "Kilovar Supply."

"... After the limit of static capacitors is reached, if additional reactive capacity cannot be provided economically in new generators or maintained in existing generators because of the value of their kilowatt output, synchronous condensers offer a quick and economic way in which kilowatt generation can be obtained to meet unexpected demands. The higher over-all cost of large synchronous condensers may be partly offset by the convenience of their operation and their stabilizing effects ...."

I am concerned as to how the so-called "limit of static capacitors"—as apparently defined in this paper—was arrived at. It is appreciated that the authors' reasoning—and hence their conclusion—in respect to the static capacitor, was made on the basis of the *unswitched* capacitor. But it is not known what factors were responsible in this instance for ruling out the switched capacitor, and so my general findings in this respect will be outlined with the thought that possibly I have overlooked pertinent factors obtaining in the actual operating system, which oversight may be responsible for my arriving at a conclusion somewhat different from the authors.

Let us first consider the economic picture. I have made an economic analysis of the switched capacitor versus the synchronous condenser, based on known factors that can be reasonably evaluated in dollars and cents. Other intangible operating factors will also be discussed. In this analysis, the annual charge for each equipment was determined, and the type of equipment "proving in" was obviously the one having the lower annual charge.

As the equipment losses are the most important factor in such a comparison—where either the condenser or capacitor can fulfill the system requirements—they will be given careful consideration. The fixed, or no-load losses of a synchronous condenser are about 50 per cent of its full-load losses, the remaining loss varying approximately as the square of the load, with full-load losses being from two to three per cent. The losses in a capacitor are a constant, being one third of one per cent of the connected capacity. From this one can see that the total kilowatt-hour loss consumed by the condenser for a given kilovolt-ampere-hour requirement, is a function of the load pattern, while in a capacitor it is independent of the load pattern. Therefore, to make a fair comparison, this must be taken into consideration. So the data in Figure 2 were prepared from standard listed information.

In calculating which equipment would

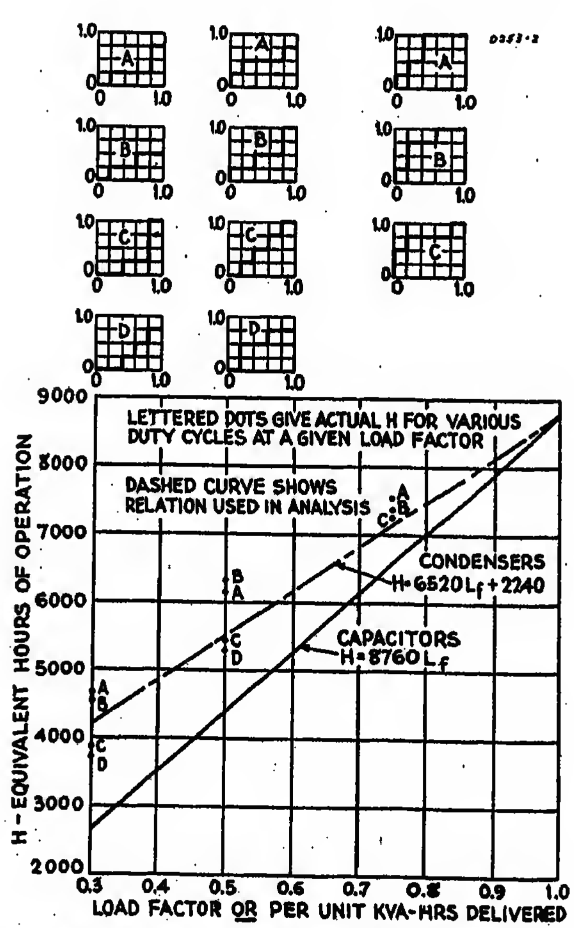

Figure 2. Relation between equivalent hours and load factor L_f under various assumed duty cycles for capacitors and synchronous condensers

ıave the lowest annual charge, the following ›asic assumptions were made:

. Per-unit annual carrying charge on equipment ıvestment taken as 0.125.

. Annual energy charges on losses figured for ata given in Figure 2, for various load factors.

. Demand charge—per-unit annual carrying harge for use of system investment taken as 0.125.

. Maintenance and operating charges are taken s equal for each.

)n this basis were calculated the data ›lotted in Figure 3, which show the eco- .omic dividing line between 5,000-kva syn- hronous condensers and capacitors as a ınction of energy charge in mils per ilowatt-hour, kilovar load factor, and in- talled cost difference, for two conditions, amely:

. No evaluation on demand.

. Capitalized demand charge of $100 per kilo- att.

In equipments of 5,000-kw capacity, a beral cost differential can be taken as 2 per kilovolt-ampere. On this basis, these alculations show that capacitors prove in, no demand charge is levied against the eak losses, and only 2.5 mils per kilowatt- our is made for energy losses, providing the ilovar load factor is not less than 0.3. ince 2.5 mils for energy—and a 0.30 load ıctor—are conservative figures, it indicates ıat capacitors in large banks switched for roviding regulated reactive are relatively ıw-priced reactive generators. This, of ɔurse, is in substantial agreement with the ıthors' first conclusion listed under the :ction "Kilovar Supply," except I believe ıey were speaking of the unswitched ıpacitor, close to the load.

Now to consider the differences in system ɔeration obtaining when using switched ıpacitors or condensers for the regulated :active supply.

1. *System Stability.* If a system is designed ıd operated in accordance with well-established inciples utilizing modern relaying and switching :uipments, the transient-stability problem can be sentially narrowed down and isolated to those ses involving *electrically long lines* and *hydrogen- ating stations.* (This excludes the developments sociated with high-speed, three-phase and one- ıase reclosing for single-circuit lines.) The instal- tion of 5,000-kva synchronous condensers is made by and large—in subtransmission and distribution eas which are electrically remote from hydro- nerators and long lines. Even adjacent to long ıes and hydrogenerators, the character of the con- nser in having electrical and mechanical inertia, ɜults in only a second order effect on stability.

2. *Voltage Stabilization.* I feel that the field the smaller synchronous condenser is practically ıited to those cases imposing a difficult regulating ɔ, such as found in substations feeding shovel ads, arc furnaces, and so forth. Under these nditions, the capacitor aggravates the voltage sturbance, if unswitched, and if switched, its itching equipment cannot follow the voltage anges anyway, so for this use it is ruled out. ıd the synchronous condenser in providing voltage ıbilization in this instance holds a strong position system design.

Summarizing—I feel the use of the ıitched capacitor as a regulated reactive urce will be used more and more in the ture, when engineers have accurately ıdied their system requirements as have ese authors, and when more experience s been obtained with the switched ca- citor. And as indicated in the paper, as ıll as in my discussion, each system needs be studied as a *complete unit,* making it cessary that the distribution engineers,

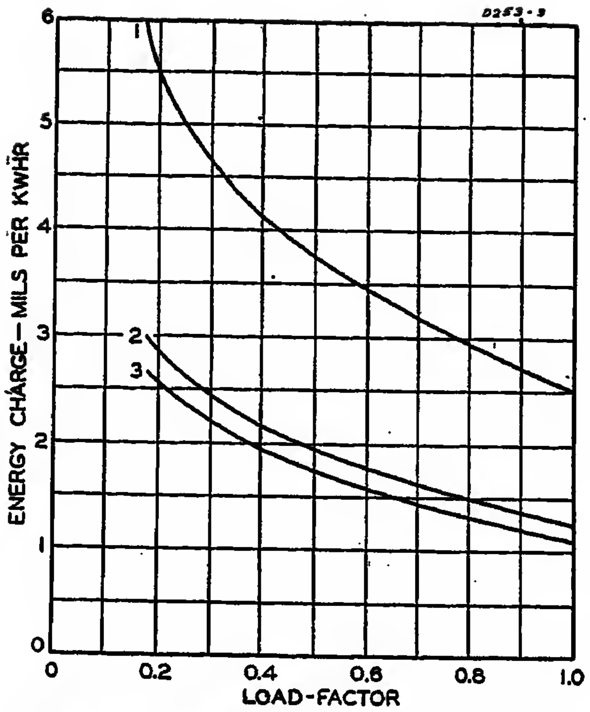

Figure 3. Curves showing economic dividing line between the application of synchronous condensers and capacitors rated 5,000 kva

Capacitors are more economical in regions above each line. Cost difference is capacitors minus condensers

Curve	Cost Difference	Demand Evaluation
1	$4 per kva	0
2	$2 per kva	0
3	$4 per kva	$100 per kw

who have been the large user of capacitors so far, fully co-operate with the generation and transmission engineers in designing a system to meet its requirements, namely that of supplying the two commodities, kilowatts and kilovars.

G. S. Lunge (General Electric Company, Schenectady, N. Y.): It is interesting to note the increasing attention that is being given to reactive power (kilovar) dispatching. Although kilowatt load dispatching is taken for granted in modern utility systems, it is only in relatively recent years that reactive power has been similarly treated from an operating standpoint.[1]

From the manufacturers' standpoint an interesting by-product of this trend is the increasing use of varmeters (reactive kilovolt-ampere meters) for indicating and recording the flow of reactive power. A varmeter gives complete information regarding the reactive power flow, without resorting to any calculations, whereas a power-factor meter reading is of little significance unless considered in combination with the associated wattmeter reading. From an instrument-accuracy standpoint, the use of varmeters is worthy of encouragement. The varmeter is essentially built like a wattmeter and measures the quantity with a high degree of precision, regardless of the load. On the other hand, the power-factor meter, which measures the angle between current and potential, has a high degree of precision only when the load is above one fifth of its current rating. Except for application to synchronous motors, it appears that, in the future, power-factor meters will be used only rarely.

Although the use of telemetered readings of kilowatts has become quite common as an aid to power dispatching, such installations seldom include provision for telemetered readings of reactive power (kilovars). Nevertheless, this paper shows that for maximum utilization of the system facilities, it is essential that the reactive power dispatching be handled as thoroughly as the active power dispatching. The simplest and most effective means for giving the dispatcher a continuous picture of the reactive power flow in the system is to provide telemeter recording receivers in front of him to show:

1. The reactive power output of each major station or substation containing sources of reactive power.

2. The grand total of such readings.

3. The reactive power flow in each tie line interconnecting with neighboring systems.

In certain cases, a few additional kilovar readings from key transmission circuits inside the system itself will be helpful in making maximum utilization of the carrying capacity of those circuits.

When wire line channels are used for telemetering purposes, provision of a reactive power reading in addition to an active power (kilowatt) reading ordinarily doubles the expense of providing such facilities. However, when audio-frequency-modulated carrier channels are used, it is possible to use the same carrier channel for two simultaneous readings, so that the principal additional expense involved in adding the kilovar reading is merely that of the telemeter transmitter and receiver for reactive power (kilovars).

When the carrier channel is of such a nature that it cannot be used without further expense for the transmission of more than one telemeter reading at a time, it is entirely possible to change the telemeter-transmitter potential connections at regular intervals, say, every ten minutes, from wattmeter connection to varmeter connection and vice versa. When the associated (single) receiving instrument is of recording type, there is no difficulty in distinguishing the two records from each other on the same chart, except in the case of tie lines, in which case the use of separate kilowatt- and kilovar-recording instruments is highly desirable because of possible overlapping of the record.

1. Operating Aspects of Reactive Power, J. Allen Johnson. AIEE Transactions, volume 52, 1933, pages 752-7.

S. B. Crary (General Electric Company, Schenectady, N. Y.): The recommendations listed in the paper by Messrs. Sels and Seely for the improvement in system protection will be recognized as being generally consistent with results obtained from studies made of other systems.

There is a question in regard to the stability calculations on which a little more detailed explanation would be appreciated. The statement is made: "The studies show that the phase-angle displacement is much more dependent on the turbine power output than on the generator power factor." This statement would seem to apply for stable transient operation through a severe fault but would not apply for the case of

steady-state pull-out under the condition of carrying a high kilowatt load or a suddenly increased kilowatt load with low excitation. This latter condition has been considered an equally important consideration as a possible limitation for the application of unswitched shunt capacitors to a power system as the transient stability. In fact, this is a more important limitation than the transient case when quick relaying and switching are used. Accordingly, if quick switching and relaying are used with generator voltage regulators, it becomes possible to increase further the stability limitation toward the steady-state case and therefore to allow for a greater ratio between fixed and variable corrective reactive kilovolt-ampere from a stability standpoint. In this connection, also, I would like to ask the authors what is meant in the same paragraph by "pull-out angle." Is this steady-state pull-out angle or transient fictitious pull-out angle, and how is it determined?

E. F. Dissmeyer (The Commonwealth and Southern Corporation, Jackson, Mich.): Mr. Sels and Mr. Seely have clearly outlined the more important factors which should be considered in connection with determining the ability of a power supply system. An accurate knowledge of the operating limitations of kilowatt- and kilovar-producing equipment is of course essential.

The increasing of power-factor and kilowatt ratings of generators will, of course, result in a reduction in their ability to provide reactive kilovolt-ampere load. It will be found, however, that although many machines are operated at kilowatt loads considerably in excess of their name-plate ratings, they can still provide substantial quantities of reactive kilovolt-amperes.

The excitation requirements at kilowatt loads in excess of the generator rating and at high power factor are usually considerably less than those for name-plate kilowatts and power factor. Therefore, from the standpoint of rotor heating, appreciable reactive kilovolt-amperes is available from a machine which is already carrying a kilowatt load equal to its kilovolt-ampere rating. For many machines, especially those operated at 3,600 rpm, the temperature rise of the stator will be increased only slightly.

For example, a 3,600-rpm, 20,000-kilowatt, 25,000-kva, 0.8 power-factor generator can be operated at 25,000 kilowatts and at 0.9 power factor without increasing the temperature rise of the rotor and with only 110 per cent rated amperes in the stator. Since generators are designed so that they may be operated at 95 per cent rated voltage without excessive heating, the 10 per cent increase in stator current actually represents a five per cent increase in what might be considered a normal operating current. In a 3,600-rpm generator the stator I^2R loss is extremely small compared to the total losses in the machine, and it will be found that this increase in stator amperes will affect the temperature rise of the stator only a slight amount.

In view of the fact that overload operation of machines may be required only during peak load periods or under emergency conditions when other generating units are out of service, it would appear that this type of operation should not cause any noticeable effect upon the life of a generator. In fact, there may be many cases where the rotor as well as the stator might be operated at overloads for rather long lengths of time without seriously affecting the reliability or the life of the unit.

H. K. Sels: With respect to Mr. Lunge's suggestions on the desirability of using telemetering for both kilowatts and kilovars, consideration must be given to the fact that summation of distributed switchable and nonswitchable static capacitors installed throughout the system is impossible, and, therefore, the net kilovar load is indeterminable to a considerable extent. Likewise, where a considerable number of small generating plants feed into a system, the net kilowatt load is not simultaneously available.

In attempting to reach the upper limit of unswitched capacitors which allows the generators to operate at unity power factor during light load as suggested by Mr. Butler, the total generator load power factor probably cannot exceed 95 per cent without certain generators having to operate at unity or leading power factors. However, in general, it is agreed that faster switching times and the use of generator voltage regulators will allow a greater use of unswitched capacitors at light load. With respect to the selection of synchronous condensers in preference to switched capacitors, this question has not been exhausted. The low installation cost of this first group of synchronous condensers in existing buildings was competitive with the cost of switched capacitors located at substations. A portion of the cost of the greater losses in synchronous condensers could be credited to building heating. The voltage-stabilizing characteristics of a synchronous condenser, as compared to a capacitor, came in for some consideration. The initial installation of synchronous condensers offered the possibility of later using the lagging capacity of the machines to regulate the installation of additional unswitched capacitors near their terminals. Some of these may be pertinent factors which Mr. Butler has overlooked. Nevertheless his contribution of a criterion on which to determine the proper proportion of different forms of kilovar supply is welcomed.

The proper proportion of switchable and nonswitchable static condensers, synchronous condensers, and kilovar loading on generators is largely an economic problem, including all factors of capital, operating, and maintenance costs. However, the problem of unstable voltage regulation which may be obtained under all conditions with the use of too much switchable and nonswitchable static condenser capacity must not be overlooked.

In regard to the relative importance of transient and steady-state stability discussed by Mr. Crary, all of the stability studies made to determine the proper kilowatt and kilovar loading of individual generators were based on the transient pull-out angle calculated from a regular a-c network analyzer set up since the steady-state pull-out of the closely coupled Public Service system has not appeared to be a problem. However, it is possible that steady-state conditions should be considered further in the light of Mr. Crary's comments.

As Mr. Dissmeyer points out, there is some temporary overload capacity in most generating units and these so-called short-time proved overload ratings are known, but to use them some sacrifice must be made in stability margins. Undoubtedly, these ratings will be used in extraordinary emergencies, but somewhere the last straw that breaks the camel's back, such as broken blading, is reached, and these ratings cannot be considered as determining the normal system capacity. The use of autotransformers and higher generated voltage firms up these ratings to a considerable extent from the standpoint of thermal and stability limitations. It is believed that full account has been taken of these overloads by planning for only 10 per cent reserve capacity, the lowest in the country, and if these emergency ratings were included in the balance sheet of load and capacity, reserves would probably need to be boosted to as much as 15 per cent. Therefore, no over-all net gain would be effected.

Progress in Design of Electrical Equipment for Large Diesel-Electric Locomotives

Discussion and author's closure of paper 42-23 by G. F. Smith, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, March section, pages 130–1.

R. Tom Sawyer (American Locomotive Company, New York, N. Y.): Mr. Gerald Smith's paper was an excellent paper. We have needed such a paper for some time to sum up the progress in the design of electrical equipment used on Diesel locomotives.

In the early days when the first Diesel-electric locomotives were built, traction motors designed for street cars or other uses were placed under the Diesel-electric locomotive. The insulation was poor, and the ratings very low. Today the traction motor is especially designed for Diesel-electric locomotive service and especially designed for the particular class of service utilized. Today, practically every piece of electrical equipment of the Diesel-electric locomotive is especially designed for its particular service—certainly a very marked step in the advancement of the Diesel-electric locomotive.

I should like to elaborate on Mr. Smith's paragraph on overloading capacity. We must agree that the traction motor of the Diesel-electric locomotive is still the vulnerable spot when it comes to overloading the locomotive. Tonnage ratings are based upon two factors.

1. The rating should be of the proper size in order to maintain the schedule.
2. The rating should stay within the limitations of the traction motors to prevent them from overheating.

For example, the American Locomotive Company and the General Electric Com-

pany have one survey department which calculates the performance of their Diesel-electric locomotives and thereby sets a tonnage rating of these locomotives for any given profile. Frequently these calculations have been checked with actual service conditions and have been found to be extremely close. When it is possible to calculate so closely, we find it advisable to not leave any leeway; that is, we expect the railroads to operate the locomotives at the tonnage rating given.

In Mr. Gerald Smith's conclusion he states that a freight locomotive may have twice as many traction motors as a passenger locomotive. This, of course, is generally the case; however, a passenger locomotive geared for 120 miles an hour can be converted into a freight locomotive and made to handle twice the tonnage simply by changing the gearing to 60 miles an hour. The New Haven Railroad is a good example; in this case the locomotives are geared for 80 miles per hour and handle both passenger and high-speed freight service.

G. F. Smith: It may be desirable to explain in detail why more motors are sometimes used on freight locomotives than on passenger locomotives. A 4,500-engine-horsepower locomotive geared for maximum of 80 miles per hour, with worn wheels, for operation on roads with 0.4 per cent (compensated) prevailing upgrades could haul 750-ton trailing load of light passenger cars at balancing speed of approximately 70 to 75 miles per hour, or 1,200 tons of heavy passenger cars at between 60 and 65 miles per hour, or 4,000 tons of freight trains at approximately 25 miles per hour. Such a locomotive would be very useful for passenger and freight service in rolling country with light grades.

If the number of motors is doubled, the locomotive weight would be increased by approximately 40 to 50 tons, and it could also haul freight trains of 4,000 tons on one per cent grades and 2,000 tons on 2.2 per cent grades at approximately half speed.

Doubling the number of motors without change in gear ratio permits operation of passenger and freight trains over a wider range of grades with corresponding reduced speeds on the heavy grades.

A Fast Circuit Breaker

Discussion and author's closure of paper 42-38 by D. I. Bohn and Otto Jensen, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, March section, pages 165–8.

O. K. Marti (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): As a rectifier engineer, I feel greatly indebted to the two authors who were instrumental in developing a new breaker device for protecting mercury-arc rectifier systems.

In 1938 the Allis-Chalmers Manufacturing Company put into operation, at the Alcoa plant of the Aluminum Company of America, ten mercury-arc rectifier units, consisting of twenty 12-anode, 4,580-ampere tanks. These units were protected by standard oil circuit breakers on the primary side, and by high-speed d-c cathode breakers. After a few months of operation extensive tests were carried out to verify the computed characteristics of the circuit and the estimated currents obtained during possible short circuits and backfires. The tests confirmed our computations and also the fact, which was pointed out in the paper, that the increase in current takes place at the rate of over 5,000,000 amperes per second. In spite of the fact that the cathode breakers were able to limit the current in about half a cycle, the current during disturbances would sometimes exceed 50,000 amperes, and, in consequence, greatly stressing all the equipment connected to the system. Shortly after these tests were completed, the customer decided to enlarge this station to double capacity, but it was felt after analyzing the test data, that this high concentration of power should make it necessary to improve the protective means still further.

An investigation was started by our company, along the line of using grid blocking for further protection, and at the same time by Mr. Bohn of the Aluminum Company of America, to develop an anode breaker to be connected between the transformer and the rectifier. It was found that by means of grid protection, the internal short-circuit current in the rectifier, flowing during a backfire (see Figure 2 of the paper) could be interrupted in about one-sixth of a cycle. However, it was found difficult to increase the speed of the large-capacity cathode breaker, which during a backfire has to interrupt the current feeding from the parallel connected units into the faulty anode. In spite of the fact that at that time no suitable d-c breaker was available which could be used as an element of the anode breaker it was decided to develop such a breaker and introduce it into the anode circuits.

Furthermore, it was deemed advisable to equip the rectifier units for this new expansion with high-speed blocking by means of grids, and, in order to reduce the number of breaker elements, to use anode reactors in connection with a six-phase rectifier transformer. The application of anode breakers, and grid-blocking devices as used in this new station, designated as number 4, can be best seen from the paper entitled "Alcoa Rectifier Installations" by Mr. J. E. Housley and Mr. H. Winograd presented at the AIEE Southern District meeting in New Orleans, December 3, 1941.

It can be seen from Figure 2 that as each element of the breaker opens, the anodes are prevented one by one from firing and from feeding into the faulty anode. The protective action of this breaker is, therefore, similar to that action of the grid-blocking device by means of which, as in the first scheme, the anodes are prevented one by one from firing as soon as the grid is made negative. It can, therefore, be seen that both protective devices support each other in the clearing of disturbances which may be very advisable for some installations.

I would like briefly to enumerate some of the points which had to be taken into account when designing this new type of breaker and which are based on experiments made in the first installation referred to above. This will show that we do not here have a 600-volt d-c breaker, as superficial consideration may lead us to believe. From Figure 2 it can be seen that during operation between some of the anodes, a potential double the secondary phase voltage appears, and, therefore, the insulation between poles had to be designed for a voltage of 2,300 volts peak in order to take care of the increase in voltage in the interphase transformer during operation with grid voltage control.

Furthermore, when designing this breaker it had to be taken into account that during normal operation, the current may reach a maximum value of 2,500 amperes in about one fifteenth of a cycle and will drop to zero approximately at the same rate after one third of a cycle. During disturbances, the breaker was supposed to interrupt in about one cycle so that the current could not exceed 50,000 amperes, although it was estimated that the inductance of the circuit would be about one quarter of a millihenry. The tests also showed that such a breaker had to be able to interrupt the above current following a forward current of the magnitude of 25,000 amperes, and that during such interruptions a voltage of 3,000 volts was sometimes exceeded. This voltage had to be taken into account when the breaker was being designed, the reignition of the arc being borne in mind. The maximum interrupting time was set not to exceed one cycle, and it will be seen from Figure 11 that this value was reduced to 0.64 cycle, after further improvements were incorporated by the authors.

We feel, therefore, that a great step forward was made not only in the art of circuit interruption, but still more so in perfecting the protection of rectification systems for large blocks of power.

C. H. Black (General Electric Company, Philadelphia, Pa.) and **Lysle W. Morton** (General Electric Company, Schenectady, N. Y.): This paper is particularly significant to operators of rectifiers and to rectifier application and design engineers. The authors are to be complimented on the paper which treats of the development and design details of an ultrahigh-speed air circuit breaker.

As the rectifier art progressed during the past twenty years, the need for high-speed interrupting devices in the anode circuits gradually became apparent to many of the engineers interested in rectifiers. Desultory attempts were made to solve the problem from time to time, using then available medium-speed or semihigh-speed circuit breakers. However, these did not meet the requirements fully, and it became evident that what was needed was a high-speed multipole breaker equipment designed especially for use with mercury-arc rectifiers.

Some of the general specifications that such a breaker should meet may be listed as follows:

1. The individual poles must be trip-free.

2. Tripping action should be essentially for reverse current. The first and only always completely reliable evidence of occurrence of arc back in the circuit of a rectifier equipment is the reversal of current in the anode connections. Hence a polarized form of reverse-current trip is necessary to distinguish arc-back current from forward overcurrent.

3. High-speed current interruption should be provided both from the standpoint of time required to start reducing the overcurrent and time required to extinguish the arc. This requirement is dictated by several factors. When rectifiers are connected to the same d-c bus with other rectifiers or conversion apparatus, not only do other anodes of the affected rectifier feed reverse current into the faulted anode, but all of the other equipment connected to the bus may contribute current of high magnitude. The value of this current is limited only by the copper resistances of the circuits and the short-circuit impedances of the contributing equipment. For this reason, the rapidly increasing current must be interrupted before damage occurs to apparatus, and before it gets out of hand in magnitude.

In order to provide continuity of operation in larger installations, where several conversion units operate in parallel, the interrupting action should be fast enough to prevent associated equipment from going out of service due to overcurrent, and also prevent "sympathetic" or "simultaneous" arc backs on other rectifiers due to the short-circuit imposed. In many cases, two rectifiers are fed from a single transformer, and the anode circuit breaker, if its action is fast enough, may eliminate the faulty rectifier so quickly that the other rectifier may remain in service. These operational advantages may be obtained if high-speed anode breakers are used, by adjusting overcurrent devices associated with the a-c and d-c switchgear to obtain the proper selectivity.

4. Adequate insulation must be provided between the individual poles of the multipole circuit breakers to take care of the well-known voltages which occur in rectifier transformer circuits.

5. The complete multipole circuit-breaker equipment with its operating mechanism should be simple in construction and require minimum space. It should be so reliable in operation that it does not complicate or increase maintenance of the over-all rectifier installation.

The company with which we are associated is so thoroughly convinced of the real need for and advantages of high-speed anode circuit breakers that we have made available apparatus of this sort. Particularly, for rectifiers whose voltages are above 300, we regularly advocate and apply this type of high-speed switchgear.

One important fact, which we believe should be kept in mind, should be stated here. That is, high-speed switchgear in the anode circuits must not be considered a substitute for adequate a-c switchgear or other protective d-c switchgear. Arc backs are not the only faults which may be encountered with these equipments. In common with all other electrical apparatus, high-quality full-capacity a-c switches are still just as necessary to protect for such things as transformer ground faults, as ever. It is also just as necessary to provide d-c switchgear to protect for overloads and d-c system faults as ever.

D. I. Bohn: Mr. Morton's comments, in which he gave very complete specifications of the requirements of this type of device, need no further enlargement.

With reference to the last paragraph of his comment regarding the desirability of installing a full capacity a-c switch ahead of the rectifier transformer, this is largely a matter of opinion involving type of load, seriousness of infrequent short-time interruptions, and other angles which are essentially economic.

It, therefore, presents a problem apart from the rectifier and associated equipment, this protection being complete with the anode and cathode breakers themselves.

The particular scheme outlined in this paper furnishes adequate protection against transformer ground faults as well as overloads on the d-c system.

High-Capacity Circuit-Breaker Testing Station

Discussion and author's closure of paper 42-26 by J. B. MacNeill and W. B. Batten, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 49–53.

J. R. North (The Commonwealth and Southern Corporation, Jackson, Mich.): We agree wholeheartedly with the authors that methods of testing which merely approximate the breaker rating have very definite limitations. Our experience also has indicated that it is not always satisfactory to extrapolate interrupting data taken at less than rating to determine the full rating.

Circuit breakers may be considered essentially as current-interrupting devices, and it seems particularly important that interrupting devices be tested up to at least their full rating, especially interrupting devices which have a high-ampere interrupting rating. We feel very strongly that the selection and application of circuit-interrupting devices should be made only on the basis of authentic interrupting test data, which clearly demonstrate the ability of the devices to interrupt the duty expected at the actual operating service voltage.

We have been privileged to witness interrupting tests which demonstrated that the interrupting devices as designed and built easily met their rating, and this was subsequently substantiated by actual operating experience. On the other hand, several serious cases of trouble have resulted with devices which had not been adequately tested. For example, it was planned to modernize a group of breakers, and the design of the modernized parts was based on extrapolated data. Interrupting tests on a sample breaker at the proposed service voltage showed the performance to be unsatisfactory and prompted several important design changes. These tests thus proved very advantageous to both the manufacturer and the purchaser.

In another case, breakers which were to be used on service voltage considerably below their rated voltage were found on test to be inadequate to interrupt the higher short-circuit currents at the lower service voltage, although tests at the breaker rating had indicated satisfactory performance. Design changes were made which resulted in satisfactory operation at the lower service voltage and improved operation over the entire application range.

Comprehensive field tests and operating experience are invaluable supplements to factory tests; however, the number of tests which can be made in the field is generally very limited as compared to the number of tests which can be made in a factory test laboratory. Furthermore, in analyzing operating experience it must be remembered that circuit-interrupting devices are generally applied on the basis of short-circuit duty which it is expected will exist in the future, with adequate allowance for system development and growth. Thus for several years after installation a circuit breaker may not be called upon to interrupt currents anywhere near its rating, and the experience indication may therefore be of little value.

J. D. Wood (Roller-Smith Company, Bethlehem, Pa.): I wish to discuss the paper presented by Messrs. MacNeill and Batten describing the additions to their short-circuit testing station making possible the testing of high-capacity circuit interrupters.

Many of us can remember the time when manufacturers had no testing facilities, and design data were accumulated from experience on devices which were installed or an occasional short-circuit test conducted by a utility. These data were sketchy and conflicting, because they were collected under uncontrolled conditions, and the progress of the art was necessarily slow.

With the advent of permanent short-circuit testing facilities by manufacturers has come a period of rapid development. The advance in design and construction of modern circuit breakers is progress of which the engineers of this country can justly be proud.

The high-capacity station described in this paper will be found very useful, not only when testing larger breakers, but also in testing small breakers under conditions comparable with large concentrations of power, as found in present-day utility practice. It should be expected that these testing facilities will result in still further improvements in the apparatus offered for sale.

I would like to take just a moment to describe to you another type of testing station which has been built by one of the smaller manufacturing companies—Roller-Smith. It differs from previous practice in that it is designed to use power directly from a high-capacity bus on a utility property and is adapted for the testing of medium-size circuit interrupters. It is a permanent installation, entirely owned by the manufacturer and operated entirely under his supervision (Figure 1). As will be seen from Figure 1, the station takes power at 66,000 volts over a line approximately a quarter of a mile long, from a high-powered bus in a centralized switching station. With this arrangement voltage is maintained at a high value on the primary of the test transformer. Transformers are provided to step the voltage down to the desired test voltage. A backup breaker is provided to clear all faults, should any trouble develop in the device under test. Reactors with taps are provided to limit the short-circuit current to the desired value. Each of these is in a

Figure 1

separate room, and a third room is provided as a test compartment. A separate building is provided for the oscillograph and other important recording and control devices sufficiently removed to provide safety for all operating personnel.

This station provides testing facilities from 300 volts to 23,000 volts, and up to 250,000 kva. A detailed description has been published in *Electrical World* (January 3, 1942).

I think the advantages of this testing station, located as it is, to subject breakers to the conditions usually found in an actual installation and to do it with a very economical setup, will be apparent to all of you. This station has just recently been completed, and something over 100 short-circuit tests have been made. The equipment for measuring transient voltage conditions is not yet completed. It can be expected that the station, operated in the future, will provide much interesting, useful data.

W. F. Skeats (General Electric Company, Philadelphia, Pa.): Messrs. MacNeill and Batten have done an excellent job of providing in somewhat limited space for a large number and variety of the tests associated with the development of circuit breakers.

Most important among these is the short-circuit testing of circuit breakers approximately to full interrupting capacity. It is unquestionably desirable to be able to determine in the laboratory the interrupting capacity both of conventional circuit breakers and of breakers of new types. This can be done, as Messrs. MacNeill and Batten have done it, by providing sufficient generating capacity to make the test on a conventional circuit. It can also be done with somewhat less generating capacity by the use of a dual power supply, one part of which supplies high current for application during the arcing period, while the other part supplies the recovery transient and the sustained normal frequency voltage. This procedure has been described before the Institute in two previous papers, the discussion of which is quoted as a reference by Messrs. MacNeill and Batten, and further experience with it is mentioned in one of the papers presented earlier this morning.

These papers have shown that the circuits can be switched with sufficient speed and accuracy to realize a transient-recovery voltage rate of several thousand volts per microsecond. Such recovery rates have been read from the oscillogram on both oil and air-blast circuit breakers.

Theoretically, there is some modification of the current wave form as it approaches final zero. But, practically, with most modern breakers, an effective increase of several fold in the capacity of the testing plant can be obtained with a modification which is hardly perceptible. Furthermore, the tests' results may be read from the oscillogram in such a way that any error lies on the side of extra severity of the test, so that the net result is an increase in the breaker's margin of safety. Confirmation of this is given in the three comparisons cited in this morning's paper, which show the synthetic test to be at least as severe as the conventional circuit.

The performance of this circuit is illustrated by the oscillogram shown in Figure 2 of this discussion. In the early part of the film a rather low voltage is shown on the voltage trace, corresponding to the open-circuit voltage of the high-current circuit. This drops to zero when the short circuit is initiated, but, upon interruption, it rises to approximately double its initial value, corresponding to the voltage of the high-voltage circuit, and superimposed upon this is a recovery transient which rises almost to double the instantaneous normal frequency recovery voltage at the time of interruption. It will be observed also that the current wave is not perceptibly distorted.

This circuit has been employed to good advantage in a number of important developments, and its use is expected to continue on the increase.

H. A. P. Langstaff (West Penn Power Company, Philadelphia, Pa.): The authors' description of the high-capacity circuit-breaker testing station at East Pittsburgh seems quite brief and limited to one who has seen the equipment in actual operation. Comparing this with the facilities and surroundings of the Wilmerding tests certainly shows the progress of the Westinghouse organization. Everything pertaining to this testing station seems to be about the last word and this removes practically all of the doubt in an operating man's mind as to the present-day ratings. In discussing this installation with members of our organization, none of us seems to have any suggestions or additional ideas which should be embodied in such a station. The results obtained give the operating men a great deal more confidence in the equipment; in fact, we believe that breakers today are gradually approaching the rating as I outlined at the time of the Wilmerding tests; namely, the standby rating or one such that the operator may stand by the breaker when operating at maximum rating.

W. S. Edsall (Allis-Chalmers Manufacturing Company, Boston, Mass.): In reference to the paper by Messrs. Strang and Skeats on field tests on high-capacity air-blast station-type circuit breakers, and also that by MacNeill and Batten on high-capacity circuit-breaker test stations, it is my opinion that the industry is now faced with the need of a more precise definition of circuit-interrupting factors and conditions, such as it faced almost 25 years ago. Then the famous Hewlett, Mahoney, and Burnham paper delivered here in February 1918, set up the methods of calculating short circuits to enable proper application of circuit breakers for interrupting duty. It pointed out, however, that there were many variables such as transient-recovery voltages and system conditions which could not be taken into account by a general formula, without making all designs so costly as to be economically prohibitive for general use.

Now we have interrupting-capacity testing stations and have a better grasp of these same variables of transient-recovery voltages and system conditions than we had 25 years ago, but the probability of adverse effects from these conditions is greater today, because of the much higher concentration of power to be handled.

The paper by Messrs. Strang and Skeats advocates the single-phase synthetic method

of interrupting tests on circuit breakers, while MacNeill and Batten are satisfied with nothing less than a three-phase full-capacity test. Actually, the one great difference between these methods is a question as to the severity of circuit conditions such as transient-recovery voltage. Up to date there is no exact definition or yardstick of transient-recovery voltage against which a commercial circuit breaker must perform on interrupting tests.

In considering plans for extension of our own interrupting testing laboratory, we feel the need of a specification to tell just what we must test for, so far as rate of recovery voltage rise is concerned. It seems that a common basis of test standards and methods must be arrived at. Perhaps as a preliminary step, the best thing to do would be for the General Electric engineers to take their air-blast circuit breaker and test it in the Westinghouse company's laboratory, with the Westinghouse standards of measurement, and for the Westinghouse Company to do the same with their breaker, with the General Electric Company's standards of measurements. I might also add that we might also contribute to such an exchange of breaker and laboratories. The results, I am sure, would make a most fascinating Institute paper, and would give data to establish a sound basis of circuit-breaker testing and application.

J. B. MacNeill: The writers of this paper wish to thank those who have discussed the project, several of whom have visited the laboratory and witnessed tests therein.

A high-power laboratory such as described in this paper requires, in addition to a large first cost, a considerable maintenance and operating expense and occupies space that would be valuable for other purposes. The Westinghouse Company in providing these facilities believes that the investment is justified by improved switchgear and similar electrical equipment resulting from the laboratory operation.

Until the industry grew to a point where this expensive equipment could be absorbed in reasonable costs, it was necessary to rely on occasional tests on operating systems. This was not a satisfactory arrangement for several reasons:

1. Tests could only be made in small numbers and when system conditions provided a minimum of hazard to connected machinery and personnel.
2. The design of circuit-interrupting devices was incomplete, and development tests in large numbers rather than proving tests were required.
3. Available short-circuit concentrations were below the requirements of a growing industry.

The most comprehensive set of field tests ever made on an operating system were those on the Consolidated Gas, Electric Light, and Power Company lines at Baltimore during 1920 and 1921. A total of 200 short circuits in capacities up to 500,000 kva was made on approximately ten different types and sizes of circuit breakers. The cost to manufacturers and operating companies of running the tests probably was not less than $150,000, and the results in improved apparatus were considerable.

Looking back at these tests we realize that the results were in some cases extrapolated incorrectly to meet other conditions for which data were not available. To illustrate: These field tests were all at 25 cycles, and certain conclusions were drawn regarding 60-cycle operation, which were inaccurate. Again, the tests were at 13,000 volts, and subsequent work extrapolated the results to 25 kv with rather disastrous consequences. Again, restored voltage transients were in most cases relatively low and resulted in inaccurate findings.

However, these tests marked a great advance over previous data and the 1,500,000-kva breakers at Hell Gate and other large stations supplied during the 1920's were a result of this work. They have given satisfactory service, and the Hell Gate breakers today are operating without essential change from the time they were installed in 1921.

In contrast today we can under some conditions make 100 tests in an eight-hour shift. Large numbers of tests are necessary, since the variety of conditions which arise with transient troubles on a power system is very great, and the switches must be good for all. On one difficult design we made 3,000 short-circuit tests. This took a period of months, but we were analyzing what went on during $1^1/_2$ cycles while the breaker operated. The total elapsed time we were studying then for the whole 3,000 tests was only a minute and a quarter.

This explains why the laboratory described in this paper has already been subjected to over 100,000 tests. On the other hand, all the high-power switchgear tests made on all the operating systems in the country over the 20-year period from 1920 to 1940 probably did not exceed 1,500. We see then that the development of modern switchgear is quite impossible without this expensive and rugged tool called "a high-power laboratory."

But you may say: "Even if you have a Laboratory, why does it need to be so large?" The answer is found in the requirements actually being placed before us today for switchgear performance. One customer is changing existing breakers to 3,500,000 kva. Another has just split his system in two to keep within a limitation of 2,500,000 kva.; shortly, he will need larger capacity. A third is now operating with bad voltage regulation, because his switching capacity will not permit adding ties to his system which would increase the interrupting duty. In the not too distant future 3,500,000 kva will be necessary at our more important transmission voltages rather generally. The laboratory here described is the most adequate one in the world to meet these requirements.

Field Tests on High-Capacity Station Circuit Breakers

Discussion of paper 42-12 by H. D. Braley, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 31–5.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): We are all impressed, I am sure, with the magnitude of the undertaking related by Mr. Braley in shorting the Hellgate Bus with 294,000 kva on the test stub and tied in with the rest of Hellgate through Waterside and Niagara-Hudson. This is by far the greatest concentration of power for such purpose ever put together at 13 kv for a field test.

Previous circuit-breaker tests at station voltage have given 25,000 to 30,000 amperes. New York got 65,000 amperes in the arc on one shot. However, the Baltimore tests in 1920, giving 25,000 amperes, resulted in the circuit-breaker design now in use at Hellgate, and these breakers have been satisfactory. It seems reasonable then to assume that these later tests should provide data on which adequate designs for the future can be based.

The paper itself makes clear the precautions taken before the tests and relates certain incidents which show the necessity for care in such a project.

The phraseology is excellent in places and carries plenty of meaning to those of us who have witnessed field tests over a period of years—"The psychological effect of the flash and the accompanying sound effect, in connection with the arc in the test breaker, undoubtedly lent some emphasis to the need for more caution." This could hardly be improved upon. As to the advisability of field tests on circuit breakers, there may be a difference of opinion in some cases. Practically all such tests so far have been worth-while in the development of the art, certainly the Hellgate tests described by Mr. Braley resulted in desirable improvement which, otherwise, might not have been so promptly made. However, as currents increase, the stresses between bus runs, and so on, go up at the current square, and the possibility of damage also increases. Perhaps then it is not reasonable to expect tests on utility systems much beyond those here related.

A particularly valuable type of field testing during the last two or three years has been the work done at 220 kv, some of which has been described to the Institute. There are certain phenomena connected with extremely high-voltage switching such as arc prestriking, restriking tendencies, and characteristics of charging current opening, which are not present in lower-voltage work, and some of which cannot be simulated exactly in laboratories at this time. The knowledge of these factors gained recently in field tests at 220 kv has been a most valuable contribution of that close co-operation between designer and user which is so much in evidence in these papers you are here considering.

W. R. Brownlee (The Commonwealth and Southern Corporation, Jackson, Mich.): The thorough advance planning by those familiar with the details of design, application, construction, and operation, unquestionably played a major part in the success of the short-circuit tests described by the author. Aside from the principal objective of the tests, the discovery of weak points in the system protection, which had unquestionably escaped detection after adequate low-voltage tests, was probably of sufficient value to justify making them.

Careful planning of short-circuit tests[1] reduces the risk of damage to sound equipment to a negligible value. Unforeseen defects disclosed during short-circuit tests

are not likely to cause serious system trouble, since a high concentration of specially trained personnel will be on guard at many points. The same unforeseen difficulty, if allowed to persist until an accidental system fault occurs, may result in serious service and equipment troubles.

Material gains are usually associated with appreciable risks, but the very low ratio of risk and benefit which is obtained with short-circuit tests is not so widely appreciated as it deserves. The results of many short-circuit tests made in the past were not published, probably for reasons other than those concerned with the technique and value of the test procedure. It is suggested that the appropriate AIEE subcommittee might wish to compile an informal list (from the information which may be readily collected) of short-circuit tests performed during the past few years, giving names of companies, dates, and a brief statement of the nature of the tests.

R. L. Webb (Consolidated Edison Company of New York, Inc., New York, N. Y.): With reference to the paper by Mr. Braley describing the setup for field tests on a 15-kv indoor air-blast circuit breaker, it may be of interest to know what recovery voltages were maintained.

Mr. Braley has described the circuit connections in detail. It will be noted that the breaker test house had to be located at a position where it was necessary to use two three-conductor lead-covered cables in parallel for the main test circuit. Each cable was approximately 600 feet long. Also, this connection contained no lumped reactance near the test breaker, since it was desired to obtain the highest short-circuit current that could be provided with the available capacity.

The circuit constants, particularly the cable capacitance, were such that only low recovery-voltage rates could be expected.

Table I of this discussion shows the current in the first phase to open, the approximate short-circuit kilvolt-amperes on a three-phase basis, the calculated recovery-voltage rate and the recovery-voltage rate obtained during the tests with the cathode-ray oscillograph. These are given for the 1941 tests only, though the values obtained in 1940 were of the same order of magnitude. The recovery voltages on all the tests were lower than those expected in an application of these breakers at Sherman Creek station. At this location the feeder breaker recovery-voltage rate has been calculated to have a maximum value of 2,400 volts per microsecond, on 500 megavolt-ampere breakers.

The maximum recovery-voltage rate expected on 1,500-megavolt-ampere and 2,500-megavolt-ampere main bus and bus-tie breakers, in the same station, is indicated by calculation to be 4,600 volts per microsecond. We, of course, expect that the breakers will handle these recovery rates.

The main test circuits were set up a second time, with no voltage applied, to permit the General Electric Company to apply low voltage tests with their recovery voltage analyzer.[1]

We are informed the results agree substantially with the cathode-ray oscillograph records obtained on the actual tests.

Field Tests on High-Capacity Air-Blast Station-Type Circuit Breakers

Discussion and authors' closure of paper 42-30 by H. E. Strang and W. F. Skeats, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 100–04.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Messrs. Strang and Skeats outline very well the actual development in the factory and field of a large compressed-air breaker. The design is neat and compact and lends itself well to station layout. The tests referred to are up to the rating of 1,500,000 kva under discussion.

Since breakers of the same type of 2,500,000 kva are being installed shortly in New York, a statement of the bearing of this work on the higher rating would be of interest to designers and users.

The authors discuss the synthetic method at some length as corroborating the results of field tests. Since this method was made public several years ago, I assume it was available before the first series of Hellgate tests. Is this a reasonable assumption, and if so was it used before these tests?

A fair statement of the limitation of the synthetic circuit is made by Strang and Skeats. They dispose of these limitations rather too briefly however. The interpretation of test results referred to in the paper detracts from the value of the device as a demonstration of ratings. Again, Figure 4 of the paper on recovery voltage transients shows three curves, none of which exceeds at any point the normal open circuit voltage. Are we to understand that this is typical of the synthetic circuit?

On the breaker design itself, which in general is an excellent physical structure, one major consideration is the tortuous air path. The compressed air starts on top of the structure, proceeds through relatively small tubes to the interrupters, changes here from vertical flow to generally horizontal flow, and then at the exhaust changes again to vertical flow. This results in loss of air efficiency against a straight air-flow device and no doubt is the reason that recourse has been taken to 250 pounds pressure. It has been found possible to retain the 150 pounds pressure tentatively agreed to by the industry for indoor applications by an improved design of the air passages so that the lower pressure is adequate. A discussion by the authors of this point would be appreciated.

L. R. Ludwig (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors of this paper have devoted considerable attention to methods of circuit-breaker testing, particularly with respect to compressed-air breakers. These devices are comparatively new to American engineers, and consequently special interrupting tests have more than the usual importance in proving the interrupting adequacy of compressed-air designs.

Long time study of the problem of circuit interruption has proved that, to establish the interrupting ability of a particular circuit breaker, the following sequence of breaker and circuit action must be satisfactorily completed:

1. The breaker contacts must part and form an arc.
2. The current in this arc must be equal to the current interrupting rating.
3. Immediately following current zero, recovery voltage must be applied across the breaker contacts as a function of time. The rate of application of recovery voltage must at least equal that of the actual service circuit as modified by the conduction of the breaker itself after current zero.
4. During the application of recovery voltage, the conduction current in the breaker must not be limited by the inadequacy of the test circuit.

The methods of testing the breakers described by the authors are,

1. Tests in the field.
2. Tests using a synthetic circuit of presumably equal severity.

The field tests as described in the paper, "Field Tests on High-Capacity Station-Type Breakers" by H. D. Braley, were made with the breaker set up in a special sandbag structure in the yard so that approximately 600 feet of cable were used to connect the breaker to the station bus. It is recognized, of course, that this type of test setup was essential for safety. Unfortunately, however, the effect of this cable is to greatly modify the circuit voltage-recovery rates in favor of the breaker. Therefore, it appears that the previously mentioned condition 3 for demonstrating interrupting ability is not necessarily met. For example, in actual installation of a 1,500,000-kva breaker a reactor is often used adjacent to it, and the circuit recovery-voltage rate may reach 12,000 volts per microsecond. Even without the reactor the recovery-voltage

rate as determined by the generators may reach 3,000 volts per microsecond and possess sufficient energy so that the damping effect of the circuit breaker is negligible. With the breaker and circuit set as described, however, calculations indicate that the circuit voltage-recovery rate would be only 400 volts per microsecond. This is so very different from the rate if the breaker were actually installed in its own cell that one must raise the question seriously as to the complete proof of the breaker performance for all types of circuits.

I would like to ask the authors if they have cathode-ray oscillograms and voltage-recovery rates of the field test conditions and what values of recovery voltage were obtained.

We have deliberately modified circuit recovery-voltage conditions while testing compressed-air breakers and have found considerably more difficulty in building the breaker to satisfactorily interrupt circuits having high recovery-voltage rates.

The synthetic method of testing is a difficult one to control when attempting to meet the four conditions required to prove adequate interrupting ability. Equivalent voltage-recovery transients can only be established in the synthetic circuit so long as the breaker has not just conducted a high current. We have found that the compressed-air breaker differs quantitatively from other types of interrupters in that

1. It is strongly affected by the rate of rise of recovery voltage.

2. It passes many amperes leakage current following normal current zero.

Therefore, the breaker itself can and does modify the recovery transient originally established by the circuit alone, whether it be real or synthetic. In the real circuit, this modification is simply accepted. However, with the synthetic circuit, which does not have comparable impedance, how is one to judge that the breaker is subjected to the equivalent duty of resisting construction? The authors have offered no criterion for isolating the effect of the circuit on the arc space of the breaker. The leakage current increases greatly with the kilovolt-amperes to be interrupted, and, in consequence, a check of synthetic test methods with laboratory tests at say 500,000 kva does not imply that the methods will also check properly at 1,500,000 kva.

The authors state, with respect to Figure 4 of the paper, that one of the cathode-ray oscillograms—which unfortunately is reproduced without time or voltage scales—indicates a failure of the breaker to interrupt. There is no definite fall of voltage to arc-drop value and associated evidence of a continuous arc in the breaker, however. It may be that the greatly modified recovery-voltage transient is simply the result of large conduction current in the breaker. One cannot be certain. "Failure" may or may not have occurred. But if the circuit had been real, no room for doubt would exist.

The authors refer to interruption, in conjunction with the synthetic test circuit, associated with "high recovery rates." They have given no specific rates, however, and further definite data would be appreciated.

The authors' third conclusion calls attention to the close agreement demonstrated between the factory synthetic test and the field interrupting performance. However, the reasonable question regarding the sufficiency of either set of tests, with respect to recovery voltage, still leaves a great deal to be desired before accepting the check as proof of the breakers' performance.

H. V. Nye (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The paper by Strang and Skeats on a breaker of such similar type, voltage, and capacity is interesting, not only because of the method of testing used, but also because of the differences in arcing time and break distance shown by the two tests. One can hardly be blamed for wondering whether the lower arcing times shown in the latter paper are due to the test method employed, or to the higher air pressure used. Certainly my experience leads me to agree with the statement in this paper that a higher pressure does increase the margin of safety in insuring a consistently short arcing time.

In conclusion, it may be interesting to note that my company is at the present time constructing two outdoor air-blast breakers which will be put in service on a 13,800-volt system requiring an interrupting capacity of 1,000,000 kva, although the breakers are insulated for $34^1/_2$ kv. We all hope that the operating experience with the large capacity air-blast breakers described in these papers will bear out the promise of the laboratory tests which have produced them, and warrant a more general acceptance of the compressed-air breaker.

Joseph Slepian (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In spite of the scarcity with which actual test data are given in this paper, some interesting conclusions can be drawn as to the properties of arcs near current zero in actual circuit breakers, and as to the value of the proposed so-called synthetic tests. Concerning the synthetic tests, a conclusion completely opposite to that of the authors' conclusion 3 should be arrived at.

The idea behind synthetic tests is that after current zero the arcing space presents predominantly dielectric properties and only needs to be given a dielectric strength test at sufficiently high voltage to prove its adequacy for bearing normal circuit voltage. The arc space after current zero, however, differs from usual insulating materials in that just before current zero it has been carrying heavy current and has had a very high conductivity. One certainly should expect, therefore, that just after current zero there might still be some conductivity left, and therefore, in carrying out a synthetic test one should be sure that the dielectric-strength testing means has sufficient capacity to really impress voltage on the space in spite of the dielectric leakage current. Everybody knows that an ordinary "shooting box" cannot test leaky insulation.

This point, along with other points of equal importance which are not being repeated in this discussion, has been raised before and was met with the statement that in the circuit breakers being tested by the advocates of the synthetic test, because of a displacement principle, the arc space was occupied by fresh insulating material which had practically zero conductivity or leakage, right up to its dielectric failure point.

But now, we have presented in this paper actual experimental information as leakage resistance of the arc space af rent zero in an actual circuit breaker displacement principle type.

For, by a lucky chance, the circui while not at all a test on the inter capacity of the breaker, is just the ki circuit which one would devise if one with the research problem of measur leakage resistance of the arc space aft rent zero. With the cathode-ray graph the voltage impressed on the ar by the test circuit is determined; fr the voltage drop on the series resist the test circuit and, therefore, the supplied by the test circuit become and with voltage and current in space known, its resistance is determi

So we look at Figure 4 of the pap particularly curve *C* with great in This is said to be for "breaker fa This conclusion is not justified. T space as the oscillogram shows, is qui to bear full voltage as fast as the syn circuit is able to supply it. If it rep the failure of anything, it is the failu cause of insufficient capacity, of th thetic circuit to give an adequate diel breakdown test on the arc space. does very nicely give us information leakage resistance of the arc space current zero. It shows that under t cumstance of that test, and where, the the breaker was operating satisfactori conventional circuit, presumably on t placement principle, the arc space re begins by being small compared to the resistance of the test circuit and be large compared to this resistance only three divisions on the time scale are The authors do not give us this time but I guess that the time involved is hundred microseconds!

Now the series resistance of the te cuit, according to the data given i paper, was varied from 300 ohms to ohms. Hence we conclude that th space resistance was of this order of m tude for a length of time after curren corresponding to three divisions of the scale of Figure 4.

But this contradicts the displace principle!

In Figure 5, the "border-line-syn tests" curve marks only the limits o sensitivity of the synthetic circuit for m uring the resistance of the arc space gives no information whatsoever, o capacity of the breaker for clearing a con tional circuit.

W. S. Edsall: See discussion, page 407

H. E. Strang and W. F. Skeats: The cussion of this paper divides itself in into two parts: that concerning the bre itself, and that primarily concerned wit synthetic testing circuit. That regar the breaker will be considered first.

As Mr. Ludwig calculates, the rec rate in the field tests was comparatively Supplementary tests have been made, ever, with very much higher recovery

Mr. MacNeill asks about the signific of the field tests with reference to the 2, 000-kva breaker. In the course of a dev ment such as this, many tests are made dependently varying such factors as

sure, recovery rate, contact speed, shape, number, and location of barriers and coolers, and so forth. When the design of the 1,500,000-kva breaker was arrived at, it was subjected to a large number of synthetic tests to determine its performance under controlled conditions. After the field tests were completed, these results were compared with the factory test results under similar conditions, and it was found that the field performance, if anything, was slightly better than would have been expected, based on the synthetic test background.

The close agreement between the full-capacity field tests and the synthetic tests under similar conditions up to the 1,500,000-kva duty established beyond doubt the validity of this method of testing. The results of the synthetic tests are interpreted at their face value with the knowledge that the test procedure is at least as severe as service conditions and may result in a slightly increased factor of safety.

With this benchmark established, the development of the 2,500,000-kva breaker proceeded on the same basis. As was to be expected, an increase in duty of 67 per cent required some changes in design before satisfactory results were obtained, but the basic principle of determining performance applies to this rating as well as to the smaller sizes.

Before accepting the advantages which the configuration of this breaker gives in station arrangement and design, a careful study was made of the effect, if any, of the so-called "tortuous air paths" leading from the air tank to the contacts and from there to the exhaust. Vague references are frequently made to the effect that bends or restrictions in air passages introduce losses, so that the problem remained one of determining the magnitude of such losses. Obviously they must be confined to two kinds, both of which are susceptible of measurement.

(a) Loss of pressure.
(b) Loss of time.

Figure 1 of this discussion shows schematically the principal functional parts of such an air-blast breaker system: the tank, blast valve, pipe, manifold, and chutes. The chart shows results of actual measurements of pressure at various parts along this system. The lower curve was taken with an early design of blast valve, and shows over 40 per cent drop in the valve itself, compared with about 8 per cent in the "tortuous paths." An improved blast valve gave results shown in the upper curve. The drop across the valve itself is greatly reduced but remains about twice the drop through all the rest of the system. Blast valves are an essential part of any air-blast breaker system, and their design must be such as to reduce this drop to a minimum. However, actual tests have proved conclusively that the drop in pressure resulting from the bends in the air paths is negligible.

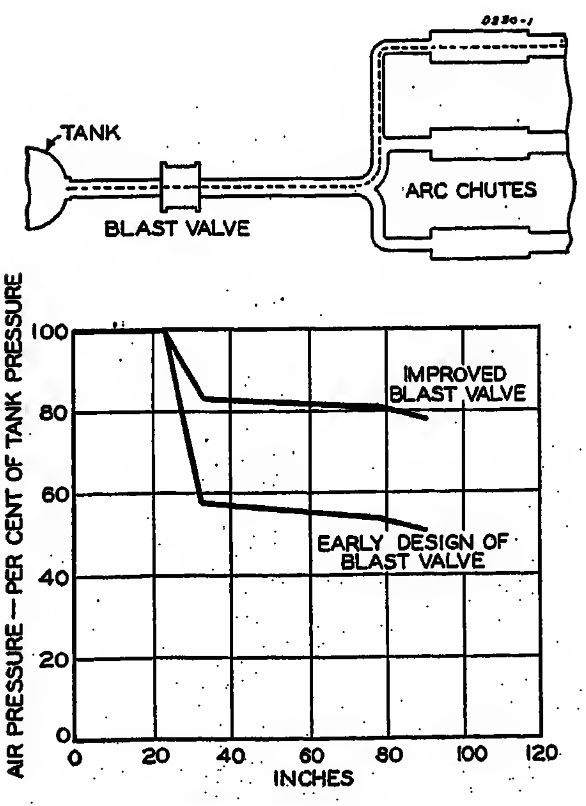

Figure 1. Pressure losses in blast valve and piping

Figure 2 of this discussion also portrays schematically the principal functional parts, in this case plotted to a time scale. From the blast valve on to the right, reference to the scale below will indicate the time at which normal working air pressure arrives at the various parts. Something in the order of two cycles from the time the trip coil is energized is required in this particular breaker for the blast valve to fully open. Less than a half cycle later full air pressure has arrived at the arcing contacts, after having travelled down the backpipe and along the "tortuous paths" through the header to the contacts. Blade travel is indicated at the right and shows that over a cycle later the contacts part, drawing the arc. In other words, full working air pressure has been available at the contacts in this design for a full cycle before the arc is started.

From such a study, based on actual measurements and not on surmises or speculations, it has been proved that this arrangement is not responsible for any substantial losses either in pressure or time, and that compared with the outstanding advantages which it affords in the way of simple and flexible terminal arrangements, such losses as do occur are unimportant.

A large part of the criticism of the synthetic circuit is based on the effect of leakage current after the final current zero. Up to a certain point the analysis on which this criticism is based is sound. The authors, too, have observed leakage conduction after current zero, and certainly this will affect the recovery transient. Certainly also the resulting difference between the ideal circuit recovery transient and the test transient actually realized will be greater with the relatively high impedance circuit which supplies the recovery voltage in the synthetic circuit which was used than in the low impedance circuit corresponding to field duty at equivalent kilovolt-amperes and recovery rate.

The authors agree, therefore, that it may be very misleading with the circuit shown in the paper to determine the ideal circuit recovery rate for the synthetic circuit, then make tests and, if the tests are successful, assume that the breaker will clear satisfactorily a field circuit with the same kilovolt-amperes and recovery rate. Because of the unsoundness of this procedure, the authors have shunned it, relying instead only upon recovery transients actually observed on the cathode-ray oscillogram taken at the time of the test. Comparing these with unmodified circuit recovery transients to be anticipated in the field is a very much more reliable procedure. It is based on the following logic: Suppose that upon interruption of a given current, a certain test recovery-voltage transient has been obtained on a synthetic laboratory test and recorded on the oscillogram. Now suppose the breaker on which this transient was obtained is to be applied in the field at the same current and on a circuit incapable of producing a recovery-voltage transient which exceeds at any time the test transient recorded on the oscillogram in the laboratory. The application of this circuit recovery transient can certainly generate in the arc path no more heat due to leakage current than is generated by the leakage current accompanying the test transient. The arc path will, therefore, gain dielectric strength at least as rapidly under the field conditions as under the laboratory conditions and, hence, will interrupt just as successfully.

Mr. Ludwig states that there is no definite fall of voltage in curve "C" of Figure 4 of the paper, which represents a breaker failure on the synthetic circuit. Apparently he has overlooked the substantially vertical line dropping practically to zero from the "A" and "B" curves about one millimeter to the right of the voltage axis. This is a part of the "C" curve and is the definite fall which Mr. Ludwig could not find.

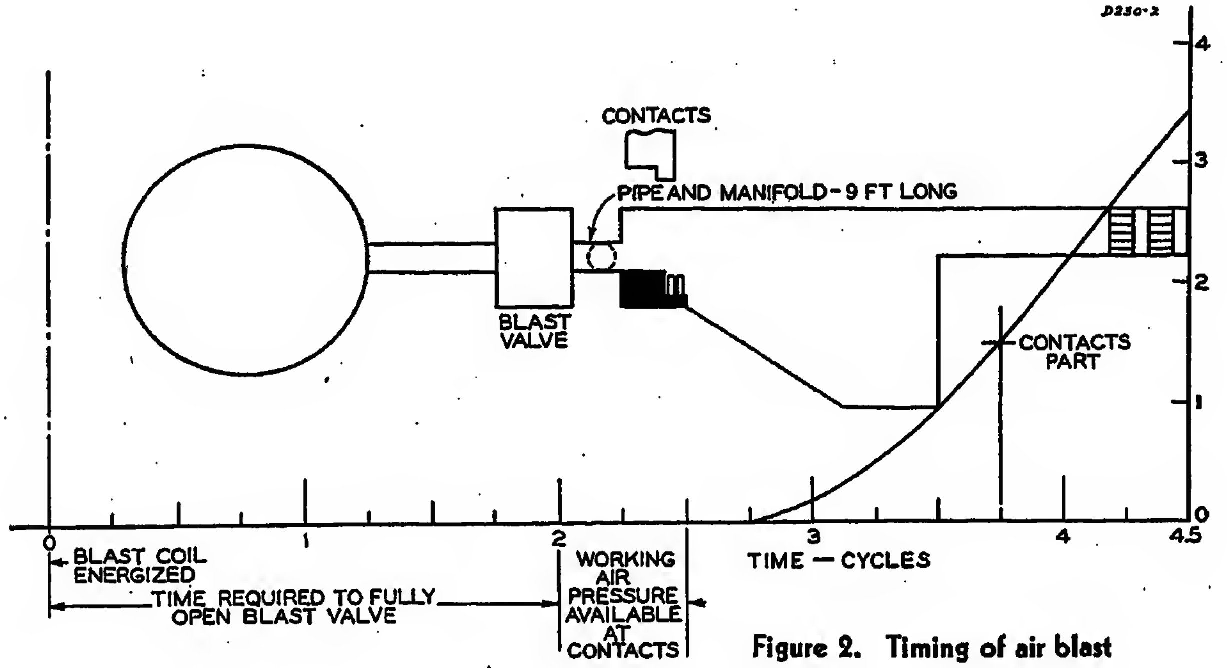

Figure 2. Timing of air blast

Figure 3. Recovery transient obtained on synthetic circuit showing overshoot to 2.7 times normal

Even if this definite fall and the rise preceding it were not present, however, curve "*C*" would be considered to represent a breaker failure. Admittedly it represents ability to clear against the very low rate of rise corresponding to the curve itself, with due consideration for its low as well as its high points. It might even represent ability to clear against a circuit recovery-voltage transient a little more severe than is represented by curve "*C*" itself. But that is hardly of interest when the breaker must clear against much more severe recovery transients, and the dangers in assuming more have been quite emphatically pointed out by Mr. Ludwig and Dr. Slepian themselves.

With reference to the question about synthetic tests before the first group of field tests, attention is drawn to the statement in the paper that alterations were inadvertently made in the arcing chamber of the breaker just prior to the field tests and after the synthetic tests at the factory. Under these circumstances, any comparison of the field tests with tests made in the factory would obviously have little significance.

One of the attractive features of the synthetic testing scheme is the flexibility with reference to the recovery-voltage transient that results from separating the high-current circuit and the recovery-voltage circuit. Among other things, this makes possible overshoots not only up to twice the instantaneous value of the normal frequency wave, the highest ordinarily encountered in the field, but far beyond in case that should be required. Figure 3 of this discussion shows an oscillogram on which the overshoot reaches 2.7 times the instantaneous normal frequency value.

It is believed that the synthetic testing procedure will find a field of great usefulness both in proof tests on circuit breakers and, as Dr. Slepian has suggested, in telling us more of the fundamental properties of an arc.

Field Tests and Performance of a High-Speed 138-Kv Air-Blast Circuit Breaker

Discussion and authors' closure of paper 42-9 by Philip Sporn and H. E. Strang, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 1–6.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The Sporn–Strang paper makes an important contribution to our American literature on high-speed oilless circuit interrupters. The double-break form of device tested should be entirely adequate for the ratings discussed and, in fact, the complication of a two-break device seems hardly necessary in view of previously published work. The development under discussion here was presented with limited test values by Rankin and Bennett at the last winter convention, and the present paper supplements the previous one by a considerable increase in test kilovolt-amperes.

However, at the last winter convention Ludwig and Baker presented a paper on a single-break compressed-air breaker which had been tested to 8,900 amperes with 132 kv impressed across the single interrupter and with high rates of recovery voltage. Since this value represents kilovolt-amperes considerably beyond that given by Sporn and Strang, one wonders if the additional complication of two breaks is justified.

The review of circuit-breaker development given in the early part of this paper is of interest, as it shows the considerable effort on the part of one operating company to advance switchgear design. Equally important work was conducted at somewhat earlier dates on other properties. Thus the AIEE paper by Baker and Wilcox presented in January 1930 dealt with field tests with 66 kv across a single-pole unit that uniformly gave two cycles or less of arcing, and, when equipped with a mechanism of normal speed, would give less than eight cycles of breaker operating time. Further results of field tests reported by L. W. Dyer in *Electrical World* for April 19, 1930, gave additional data on the Duquesne Light Company system tests of October 12, 1929, and included tests on the Alabama Power system up to 1,170,000 kva at 110 kv with arcing time well below eight-cycle breaker levels.

An especially important contribution was the Plymouth meeting tests on the Philadelphia Electric Company system of November 1929 in which eight-cycle breaker time was met on 220 kv.

These relatively early tests, including those referred to in the Sporn-Strang paper, have in the past been lifesavers in determining the adequacy of interrupting devices. Of late years, however, field tests have been relatively infrequent, as manufacturers' laboratories have demonstrated their ability to handle the test situation. In fact several important utilities who have been approached on the subject of field tests have not felt the hazard to their systems was justified.

The writer is of the opinion that in some respects factory tests against adequate power form a more difficult basis of approval than do field tests. For instance, the Ludwig-Baker paper reported circuit transient-recovery voltage rates as high as 3,420 volts per microsecond. We know of no field location where similar recovery rates have been had on circuit-breaker tests at high voltage.

The two methods of conducting interrupting tests both have advantages. The factory test can be made conveniently without hazard to a large operating system and in a minimum of time. The field tests on the other hand have a large value in operating experience gained during the tests, which points out possible weaknesses in operating setups under fault conditions as well as demonstrating the device on test. Therefore, for many of us the discussion of system effects given by Sporn and Strang is of particular interest and is conclusive evidence of the desirability of high-speed switching for heavy power concentrations.

B. M. Jones (Duquesne Light Company, Pittsburgh, Pa.): I am sure that all of us are glad to see the progress and development of air-blast breakers, for none of us wants to use oil in electrical equipment, particularly in circuit breakers.

We have used it, it is true, and are still using it, but we just don't want oil circuit breakers.

The paper by Sporn and Strang covers the disadvantage of oil circuit breakers in a very clear and complete manner, and no repetition is necessary.

The data presented in this paper, as well as in the associated papers at this technical session, certainly give encouraged hope that the *great day* is nearing when we can buy at a reasonable price circuit breakers without oil for *all our requirements*.

We utility people want them, the steel mills, mines, and industrial plants want them, and the manufacturers want to build them; and all of us in the electrical business have an investment problem in writing off our oil circuit breaker and associated investments, and manufacturing plant therefore.

I would like to emphasize very strongly the need for continuing with the development of these breakers without oil and would like to show one slide, Figure 1, portraying the unsatisfactory performance of oil circuit breakers during tests to destruction, just to impress upon you the possibilities of a great catastrophe that might result from the use of oil circuit breakers, particularly beyond their capacity.

This Figure 1 shows a picture of an oil circuit breaker being tested to destruction. This oil throw with its accompanying fire and smoke was several hundred feet high and quite wide, as you can readily see. Such an explosion in an operating station would be intolerable.

There were many types and makes of breakers tested by our company about 15 years ago, and this entire test program covered duties up to 500,000 kva at 24 kv. This test program was arranged and carried through quite satisfactorily, even in spite of these spectacular explosions, and the breakers were tested below, at, and beyond their capacities to determine their performance.

I might say, as all of you familiar with oil circuit breakers will realize, that such breakers are not on the market now and you couldn't buy them if you tried. I doubt if any of you have breakers similar

Figure 1. Fire and explosion resulting from breaker failing to interrupt a heavy short circuit

to these (I am not going to tell you what they are), for they have undoubtedly been fixed up so that they are really oil circuit breakers now.

The photo just illustrates something that might happen as a result of an oil circuit breaker attempting to interrupt larger and larger duties due to the system behind them growing. Even with the very best of maintenance and attention, an oil breaker is something we just don't want to keep around.

While these comments are referred to Mr. Sporn's paper, they apply equally to the companion papers on circuit breakers presented at this meeting.

W. S. Edsall (Allis-Chalmers Manufacturing Company, Boston, Mass.): Four years ago the company with which I am connected conducted its first commercial witness interrupting-capacity tests on a 15,000-volt, 250,000-kva air-blast circuit breaker. Three years ago, we made the first installation of a 15-kv, 500,000-kva air-blast circuit breaker. At that time we advocated compressed air for power circuit breakers. Then we were alone in our recommendations of the air-blast principle. Now we have a lot of good company, as is evidenced by the papers presented here today. I congratulate the engineers who have presented papers here at this session on the air-blast circuit breaker they have produced. While the different designs have much merit, the outstanding fact is that we manufacturers are all seemingly in agreement that the air-blast principle is safe, sound, practical, and efficient, as is amply demonstrated by the laboratory and field tests presented today, and by the thousands of interrupting tests made in our own laboratories. It seems we were also in agreement that compressed air is the only medium other than oil which can be applied over a wide scope of interrupting and voltage ratings. Air-blast breakers as manufactured by ourselves and by foreign manufacturers with whom we have been associated for many years are in operation today in this country and in Canada, extending from 100,000 kva at 2,300 volts indoors, up to 2,500,000 kva at 220,000 volts outdoors.

We think that the Sporn and Strang paper on field tests on the 138-kv air-blast circuit breaker is of particular interest, because it is a summation of one manufacturer's efforts to reduce arcing and reclosing time to a minimum. We appreciate the courage with which the American Gas and Electric Company's engineers faced the matter of making interrupting and reclosing tests of such magnitude, upon a system carrying important loads. The tests indicate the ability of the air-blast breaker to do substantially the same job as the oil circuit breakers of equivalent rating. However, the interrupting time of the breaker described seems quite long. In the outdoor air-blast circuit breakers of our associated companies before referred to and now operating in Canada, the 138-kv and the 220-kv breakers now in operation have interrupting times in the order of $3^1/_2$ cycles. This compares to five cycles for the breakers described in the paper by Sporn and Strang. Also, on the 220,000-volt breaker having interrupting time of approximately $3^1/_2$ cycles the reclosing times can be set to be quite low, that is, in the neighborhood of 12 cycles. Reclosing may be done on the single-pole basis if desired, and as has been reported in other discussions before the Institute, reclosing tests on a single-phase basis were conducted by our associated companies some years ago.

A further advantage of the breaker of which I am speaking is that reclosing is not done on exterior isolator contacts with the consequent brilliant visible display, but rather is accomplished within an interrupting chamber under 225-pound pressure. This eliminates the visual display and the possible hazard of attempting to reclose in normal atmospheric pressure by isolator contacts moving comparatively slowly and making circuit in the open air.

The authors' statement that it took 30 years to develop a five-cycle, high-voltage oil circuit breaker, but that the same accomplishment was achieved in two years in the air-blast circuit breaker draws our attention. It is felt that it would be well to acknowledge that several of us manufacturers had resident or visiting engineers in Europe, where these high-voltage air-blast circuit breakers were first developed, and that each one's designs are largely based upon European experience. However, as we have shown in our own case, the European experience and actual practice on many high-voltage breakers already installed in Europe, and in Canada give interrupting speeds not of five cycles, but of three to four cycles.

E. W. Knapp (The Shawinigan Water and Power Company, Montreal, Que., Canada): The authors state that, "the success of this development on 138 kv points encouragingly to the prospect of development at higher voltages, such as 230 kv or even higher." The Shawinigan Water and Power Company have in service at this time two different designs of air-blast circuit breaker operating on a 220-kv system. This company has been interested in the development of this type of circuit breaker for some years and has on a number of occasions made available sections of their power system for primary tests.

One air-blast circuit breaker now in service is quite similar to the 138-kv design discussed in the paper. It is rated as follows:

Voltage rating	220 kv
Current rating	400 amperes
Rupturing capacity	2,000,000 kva
Closing Time	17 cycles (60-cycle basis)
Opening time (contacts part)	$3^1/_2$ to $4^1/_2$ cycles
Arcing time	0.5–1.0 cycle
Air pressure	250 pounds per square inch

Automatic reclosing, single-pole or three-pole

Satisfactory primary tests have been conducted on this unit with one phase to ground, with and without the automatic reclosing feature in service, up to approximately 100,000 kva at 245 kv and up to approximately 1,000,000 kva at 220 kv.

It is noted that the 138-kv air-blast circuit breaker operates on an air pressure of 350 pounds per square inch, as against 250 pounds for the 220-kv air-blast circuit breaker. Have the authors tested the 138-kv unit at pressures below 350 pounds, and may we assume that operating at pressures above 250 pounds on this particular design does materially increase the rupturing capacity or produce other advantages?

The second type 220-kv air-blast circuit breaker now in service on the Shawinigan Water and Power Company system is rated as follows:

Voltage rating	220 kv
Current rating	600 amperes
Rupturing capacity	2,000,000 kva
Closing time	15 cycles (60-cycle basis)
Opening time (contacts part)	$3^1/_2$ cycles
Arcing time	one-half cycle
Air pressure	115 pounds per square inch

Not arranged for automatic reclosing

This design uses the cross-blast principle and is somewhat similar in operation to the type described by L. R. Ludwig, H. M. Wilcox, and B. P. Baker.

A series of primary tests was conducted on this type during the development stage which resulted in a considerable modification of the original design. The unit now in service has been tested on the power system to approximately 900,000 kva at 220 kv. Although the tests appeared to indicate satisfactory performance at the specified ratings, there has been insufficient operating experience to insure satisfactory service under all conditions.

During the primary and secondary tests on air-blast circuit breakers on the Shawinigan Water and Power Company system, a number of conditions were noted which might be of interest. This applies particularly to outdoor service in the rather severe climatic conditions of Canada.

Air-drying facilities and convenient supervision of the same is important.

Special attention may need to be paid to the problem of condensation.

Using the correct materials is important, not only for satisfactory operation, but also for weathering. Machined parts must be carefully chosen and adjusted to prevent sticking under extreme variations of temperature. Air pressures from 100 to 350 pounds per square inch are being used. It would be very desirable to standardize on a closer range of pressures.

Philip Sporn and H. E. Strang: It is true, as Mr. MacNeill has stated in his discussion, that improvements in manufacturers' laboratories have increased their ability to handle the testing of circuit breakers. On the other hand, it is our impression that field testing of circuit breakers has not fallen off either in frequency or importance in later years; also some very important utilities have in late years become very much converted to the value if not the necessity of making occasional field tests on their own systems. It is still true, of course, that many other important utilities are not now and never have been willing to subject their systems to staged interrupting capacity tests.

Notwithstanding our gratification on the good results obtained from the test on the air-blast circuit breaker, it is our belief that Mr. Jones has passed sentence rashly and altogether too severely on the oil circuit breaker, considering the present state of development and experience with both oil and air. Without discounting the encouraging and promising results obtained with air, it is still true that the modern oil circuit breaker is doing an outstanding job. Oil fires of anything like the nature indicated by Mr. Jones' photograph are extremely rare for really modern breakers when subjected to duties within their ratings. As a matter of fact, Mr. Jones' discussion lends support to the feeling which has been maintained for some time that factory tests and field tests supplement each other, and each have an important and distinct place in the development of circuit breakers. During the same general test program which Mr. Jones has described, and with the same setup and operating conditions, one breaker equipped with up-to-date arc-control devices which had been developed with the aid of factory test equipment was tested. It successfully passed these tests without any such disturbance as shown in the photograph.

As Mr. Knapp has suggested, the industry undoubtedly should standardize on such matters as air pressure in due time. Development tests which have so far been made have indicated that within certain limits interrupting performance improves with an increase in air pressure. Future designs may make possible the same kind of performance with lower pressures, but, for the time being, it does not appear advisable for the industry to standardize on this factor, since it might result in a handicap rather than a benefit. Pressures of 250 or 350 pounds per square inch are not difficult nor costly to obtain or maintain and represent an economical way of building an increased factor of safety into a line of air-blast circuit breakers.

There is no particular mystery about the design problems in connection with making available a satisfactory air supply. There is no reason to suspect that a straightforward engineering approach with a thorough check of each step will fail to produce results here. At least four years ago an indoor air-blast breaker was mounted in an unheated outdoor switchhouse, together with the necessary compressor and control facilities, and installed during a whole winter in northern Canada. Experience gained during that time has been of great assistance in the design of satisfactory equipment of this kind.

Mr. Edsall has rather jumped at conclusions in assuming that the successful performance reported for outdoor air-blast breakers and high-capacity indoor breakers naturally means that this principle may be extended over the entire range of circuit-breaker ratings. For duty below 500,000 kva, self-contained magnetic-type breakers have been in regular use for several years, and their popularity is steadily gaining.

The test results submitted with this paper include all of the tests which were made in the field without exception. This report was made for the purpose of clearly and completely defining the present state of the art as far as this particular development is concerned. If Mr. Edsall has available results of other tests which show faster operation on some other type of breaker, it is hoped that in the interests of providing the industry with all available information, he will make a similar complete disclosure of all the factors concerning such tests.

As Mr. Edsall has pointed out, our statement in which it was inferred that the entire air-blast circuit breaker development had been accomplished in only two years is not quite correct when interpreted in that way. The authors' comparison of the 30 years of oil circuit-breaker development work to a development of only two years with the air-blast circuit breaker was made primarily with regard to the particular circuit breaker and manufacturer under discussion. However, as pointed out by Mr. Edsall, the statement was probably misleading, particularly if interpreted to include all of the development work done on air-blast circuit breakers. We, therefore, wish to acknowledge the excellent work which has been done over a considerably longer period by other manufacturers including Mr. Edsall's company.

Both Mr. Edsall and Mr. MacNeill have brought up the question of the influence of transient recovery voltage rates on circuit-breaker tests, and Mr. Edsall has suggested that some rule or yardstick covering transient recovery voltage should be set up for testing purposes. While the severity of recovery voltage conditions is important, the bulk of evidence which we have been able to gather to date, with respect to the operation of modern types of circuit interrupters, seems to indicate that these breakers are capable of handling the highest rates that have been encountered. In both field and laboratory tests on modern types of breakers, where conditions have been controlled to obtain both high and low recovery rates, the actual effect on performance as measured by arcing time, appears to be relatively small. For example, in the tests listed in this paper, the recovery voltage rate was varied from less than 200 volts per microsecond, to approximately 2,000 volts per microsecond without any marked change in breaker performance. Furthermore, in connection with a recent survey of voltage recovery rates on power systems, it was found impossible, although an attempt was made, to obtain any definite correlation between recovery rates and breaker distress by studying actual operating records. This does not mean that there have not been any known instances where breakers, particularly of older plain-break designs, have been in trouble under conditions of known high rates of recovery voltage on other systems not included in this survey. It does, however, bear out the general conclusion that most modern breakers are capable of doing their job, regardless of the severity of recovery rate conditions.

In view of all of this, we are not of the opinion that there is anything to be gained by attempting at this time to standardize recovery rate values for circuit-breaker testing. While it is true that voltage recovery rates constitute one of the important factors to be taken into account in the design of circuit breakers, most of the known results to date seem to indicate that this has been done successfully, even for the highest rates encountered. As for a criterion as to what rates may be encountered, the results of the above-mentioned survey of voltage recovery rates made by the Association of Edison Illuminating Companies has already been made available to the circuit-breaker manufacturers, and certainly should constitute a fairly reliable guide for future developments in circuit-breaker design.

A 2,500,000-Kva Compressed-Air Powerhouse Breaker

Discussion and authors' closure of paper 42-41 by L. R. Ludwig, H. M. Wilcox, and B. P. Baker, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 235–41.

R. M. Bennett (General Electric Company, Philadelphia, Pa.): This excellent paper presents a remarkable description of the factors entering into the design of a cross-blast interrupter.

It is of particular interest to note, that although two groups of designers have both employed air-directed across the arc, their solutions to the same problem constitute radically different interrupting devices.

As the authors have stated the problem, and I quote, "A 60,000-ampere arc in an arc chute two inches wide will liberate sufficient gas from the splitters to cause the flow of gas to reverse a distance of six inches against a driving pressure of 150 pounds per square inch." In order to handle these large volumes of gas the authors have placed the arc, as indicated by the sketch on the left in Figure 1, at a point where the throat is very wide, so wide in fact that the operating pressure of the breaker, which is 150 pounds per square inch, can drive away the large volumes of gas that are produced by extremely high currents.

The 15-kv air-blast breaker described by Mr. Braley and Messrs. Strang and Skeats, however, interrupts a 60,000-ampere arc, not in a two-inch throat, but in one approximately half this wide. Air flow through this narrow throat is maintained by a radically different method. As shown in the sketch at the right (Figure 1), an orifice is placed upstream from the arc chute and acts as a flow stabilizing means. In the other view the arc chute would appear to diverge rapidly on the inside, and the orifice configuration would be more apparent. Upstream from the orifice the air pressure is very high since it comes from a

storage tank at 250 pounds per square inch. Downstream from the orifice in the region of the arc the pressure is normally very much lower. This positive difference of pressure directly back of the arc chute maintains the flow of air under the most extreme current conditions, because, in order to stop the flow, the pressure in the throat would have to rise to the pressure back of the orifice. The drop in pressure at the orifice also acts as an effective blocking means to prevent particles of metal and carbon from being driven backward where they might impair the insulating properties of the incoming air line.

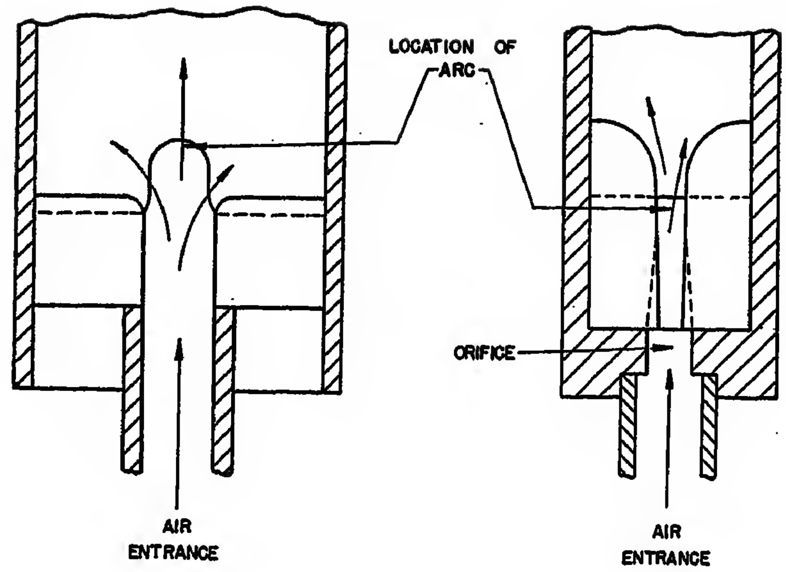
Under light current conditions, the interruption problem is quite different. The air pressure and velocity required to produce satisfactory interruption is entirely a function of voltage and rate of rise of recovery voltage and depends not at all upon the width of the throat. It is this fact that explains the significant differences between the interrupters. Both of the above designs must maintain virtually the same normal or no-load air pressure at the arc in order to interrupt light currents. But the interrupter shown on the right in Figure 1 employs much smaller air passages than the one at the left, with the inevitable consequence that it consumes substantially less air, in spite of the fact that the air in the tank is at higher pressure. In brief, the interrupter shown at the left permits much of the air to by-pass the arc, while the one at the right with its narrow channel forces air to flow through and across the arc stream.

This fact is reflected throughout the design of the two breakers, in the size of the arc chutes, in the air storage and compressor systems, and, incidentally, in the acoustic shock that results during interruption. The design described by the authors employs three blast valves and very short supply tubes in order economically to deliver large volumes of air to the interrupter. The one at the right employs a single blast valve and supply pipe together with a manifold to deliver air to the three arc chutes. It is this fact that permits the small over-all size and the extreme flexibility of terminal connections that are possible with the latter design.

With reference to the "reversal of flow a distance of six inches," the authors state: "If the rate of rise of recovery voltage of the circuit is slow, the stalled flow will have time to recover velocity, and dielectric will be restored. However, if the recovery rate is fast, the space below the splitters will remain clogged too long, and reignition will result." No matter what theory of operation applies, it must be evident that interruption cannot take place while the interrupter chamber contains incandescent gas. Yet the authors state that this gas is removed after the recovery voltage has started to rise.

What is more remarkable, the removal of six inches of gas, which must be accomplished at least before the recovery voltage reaches its peak value, would require a velocity of air flow of some 5,900 feet per second, or say six times the velocity of sound. This is true if the recovery voltage rises at the relatively slow rate of 500 volts per microsecond. At 5,000 volts per microsecond, it would require a velocity of 59,000 feet per second. It is to be presumed, therefore, that the arc chutes are not so badly clogged with hot gases as the authors believe, and that the majority of hot gas is removed before the current zero.

Figure 1. Arc chutes for air-blast circuit breakers



H. V. Nye (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The group of papers submitted this morning on air-blast breakers of large interrupting capacity, both at 15 kv and 138 kv, is very interesting, as demonstrating the claim made in one of these papers that compressed air seems the only practical interrupting medium, except oil, for use on a line of breakers from small to large capacity and throughout the commercial range of operating voltages. This is the conclusion reached several years ago by the engineers of the company with whom I am associated and explains why our developments along the line of oilless breakers have been along the line of the air-blast type.

Some six years ago my company built and tested an outdoor air-blast breaker at 37,000 volts across a single-pole unit. Even with this experimental breaker, operating speeds were very satisfactory, the average time from trip to arc extinction running in the neighborhood of two cycles. Our tests at that time, however, indicated that a great deal of work needed to be done to make the mechanical design of the breaker and its associated parts sufficiently rugged and reliable to make it commercially practicable. Since that time we, as well as other manufacturers, have been working toward the development of thoroughly satisfactory designs. The papers here presented are a good indication that this work has produced results, and it is now practicable to build air-blast breakers for the more usual breaker ratings.

The test results given in the paper by Messrs. Ludwig, Wilcox and Baker are valuable, not only because of the high capacities in kilovolt-amperes interrupted, but also in the wide range of currents and recovery voltages employed. They show a consistency in performance under varying conditions of load and recovery voltage which I think is typical of the compressed-air type of breaker. On the commercial breakers which we are now building up to 500,000 kva we have repeatedly demonstrated this consistency in performance.

On studying this paper I noticed the statement "that the breaker never failed to clear the circuit when the contacts were more than a fraction of an inch apart." As the tabulated data all show a separation of contacts at interruption of anywhere from 1.1 to 3.8 inches on the three-phase tests for the last phase to clear, I would be interested in having the authors explain as to just what meaning they intended to convey by this statement.

In the notes under Table III a statement is made that 58 consecutive tests, as outlined in the tables given, were made without any maintenance on the breaker. This is a record of performance which I think should be particularly mentioned. As an illustration of the fact that smaller types of air-blast breakers are also capable of repeated operations under interrupting duty, I would cite a series of tests recently run on one of our 150,000-kva five-kilovolt air-blast breakers. This unit was rated for a maximum interrupting amperes of 37,500. A series of 97 close–open short-circuit tests was run on this breaker with 25 per cent of the shots at each of the following values—10,000 amperes, 20,000 amperes, 30,000 amperes, and 40,000 amperes. There was no maintenance on the breaker during these tests, and at the end the breaker was in operating condition and capable of taking further shots.

H. A. P. Langstaff (West Penn Power Company, Philadelphia, Pa.): The authors have presented an excellent story on a new development which should prove of great value to the industry. A great deal of theoretical and practical principles have been applied to this compressed-air breaker.

High-capacity and quite complete factory tests, simulating operating conditions, have materially assisted in proving the breaker capable of meeting its guarantees; yet we must apply these breakers in our powerhouse laboratory where any remaining deficiencies will be developed, resulting from factory assembly and so forth.

Comparing the functioning of this compressed-air breaker with that of the ordinary oil circuit breaker and the functioning medium, namely, air versus d-c control voltage, I raise the following question. The tripping of an electrically operated oil circuit breaker has a guaranteed range of 90 to 140 volts, but in the majority of cases it will trip at a much lower value than 90 volts. Its rupturing capacity is not thereby affected, whereas in the case of the compressed-air breaker, it may trip on low pressure, but this, in turn, materially affects its rupturing capacity. I understand control circuits are arranged such that the breaker is now allowed to trip if

the air pressure drops below a certain value.

In the paper the authors state that: Enlarging the throat of the arc chute or increasing the air pressure will obviously improve conditions; however, both result in an increased air consumption for a nominal gain in interrupting ability.

Since the kilovolt-ampere interrupting capacity is a function of pounds air pressure at certain opening of the arc chute, how much would the interrupting capacity be affected if the air pressure was reduced from 150 pounds to say 100 pounds or to 75 pounds provided the opening of the arc chute was the same?

Would a 1,000,000 and a 2,500,000-kva breaker of the same voltage rating have the same arc chute and opening? I am thinking of standardization.

R. A. Hentz (Philadelphia Electric Company, Philadelphia, Pa.): This paper describes another stepping stone in the commendable progress that the circuit-breaker designers have made in the march toward adequate oilless switchgear, starting some 15 years ago when the company with which the authors are associated first produced commercially the Westinghouse air De-ion breaker.

The tests described are the first, so far as I am aware, where 2,500,000-kva has been delivered by a laboratory for testing a circuit breaker with the ability to repeat such a severe test as often as desired by those in charge of the test.

One shortcoming is apparent; one, however, that it may be impractical to overcome. These heavy short-circuit tests were made at circuit voltage-recovery rates, but a small fraction of the 12,000 volts per microsecond that may be expected in large generating stations. Such high recovery rates were obtained, but at kilovolt amperes only a fraction of the breaker's rating. Of course, the testing engineer must choose between "his cake or his penny" as the reactor which gives the high-voltage recovery rates cuts down the short-circuit kilovolt amperes. The third from last test given on Table III shows high-current and high-voltage recovery rate occur in what appears to be a more severe combination than any other test recorded. Is it just a coincidence that the arcing time is relatively low?

While the above paragraph points out that the tests do not duplicate the maximum conditions that may be met in certain large generating stations, I wish to pay high tribute to the fact that these tests, so far as I know, approach nearer to such conditions than any other laboratory or field tests ever made.

Progress made in the design of the air-blast circuit breaker gives comfortable assurance that as interrupters they may be relied upon to do what is expected of them, but, if any uneasiness still lurks in the user's mind on that score, it should be offset by the realization that any failure that may remotely occur will not be accompanied by a fire which could spread the damage far beyond the immediate confines of the circuit involved, a consideration of value at any time, but particularly when the possibility of bombings hangs over us.

The description of the compressed-air system in section IV indicates that care and forethought has been given to this important element, and it is well that this has been done, for it is in the air system that most of the troubles may be expected. This is the place where a major number of minor difficulties have already been found in several air-blast breakers already in commercial operation.

L. R. Ludwig, H. M. Wilcox, and B. P. Baker: Mr. Nye has made reference to experimental work and limited use of compressed air in this country for a period of about six years. Compressed-air breakers have, of course, been used in Europe for 12 years or more, and this, naturally, raises the question as to why this form of breaker has not been made commercially available at an earlier date in America. The European breakers have not been called upon to have the high interrupting kilovolt-amperes required for indoor breakers in American practice. This has led to European constructions of the nozzle type, which in general seem to possess a current limitation of the order of 25,000 to 30,000 amperes. At 13 kv this restricts the rating of the breaker to approximately 750,000 kva. In order to extend these limitations, it has been necessary for American designers to develop entirely different forms of interrupters. The cross-blast type, which is capable of reaching 2,500,000 kva, represents a satisfactory answer, but until this type of improvement was made, application of compressed-air breakers in this country was necessarily limited.

Mr. Nye points out that the tabulated data show that the contact separation at the time of interruption reached as much as 3.8 inches and questions this in view of the statement that the breaker never failed to clear the circuit when the contacts were more than a fraction of an inch apart. Detailed examination of the procedure during interruption quickly indicates, however, that these data are not inconsistent. For example, the contacts may part and form an arc just prior to a normal current zero. At the time of the current zero the contacts may be separated only three-eighths inch, and interruption will not take place. Because of the high mechanical opening speed, the contacts can then be 3.8 inches apart at the time of the next current zero. Clearly, the interruption can only take place at normal current zeros. An examination of the data with this point in mind does lead to the conclusion that the breaker always interrupted at the first current zero after the contacts were more than a fraction of an inch apart.

Mr. Bennett has contrasted the interrupting action in two forms of cross-blast compressed-air breakers. With reference to his sketches, it should be considered that the one at the left represents the arc chamber of a 2,500,000-kva breaker, whereas the one at the right shows the arc chamber of a 1,500,000-kva device. Naturally, the 2,500,000-kva arc chamber is wider.

When small currents are being interrupted in the chamber at the left, the air is so directed that it flows straight across the arc and does not diffuse toward the sides, as indicated by the arrows. When large currents are interrupted, the pressure in the region of the arc core (which is central with respect to the arc chamber) develops high counter pressure. During the portion of the half cycle when this counter pressure is sufficient, the air stream is then diverted sidewise as shown by the arrows. The effective action of the air stream at this time is to remove the extraneous ionized gases as they are formed and prevent them from "backing up" into the throat. As current zero is approached, the diversion of the air stream sidewise ceases, and the actual interruption near current zero is quite similar for both high and low currents.

This explanation should make clear the way in which the arc chamber recovers dielectric strength after current zero. It is seen that there is no need to remove six inches of ionized gas after the current zero, since this is done by properly diverting the air stream prior to current zero.

The fourth paragraph of the second section of the paper and Mr. Bennett's remarks in his last two paragraphs refer to the type of arc chamber in which there is no side diversion of the air stream. Mr. Bennett points out that velocities of 5,900 feet per second would be required for interruption, if ionized gas "backs up" six inches. Actually, interruption would probably not occur. The problem can be solved by the use of higher air pressure (250 pounds), which should prevent ionized gases from "backing up" six inches. The authors' solution, however, of "diverting" arc products, permits operation with only 150 pounds pressure.

In the design of the two breakers, the arc chute sizes are reasonably comparable for the same kilovolt-ampere rating. Furthermore, the quantity of air used in cubic feet per interruption, based on atmospheric pressure, is very nearly the same. The air is, however, used in an entirely different manner. The use of mechanically operated blast valves makes it possible to closely time the opening and closing of these devices, so that the duration of the air flow can be made quite short. Therefore, the quantity of air when it is flowing can be made high. The interrupting ability of the compressed-air breaker seems to depend upon the rate of air flow, and, naturally, the higher this rate, the greater the margin of safety. The air-storage tanks in the compressor system can obviously be made of different sizes, but the larger equipment has the advantage of providing the greater number of operations.

Mr. Langstaff has inquired relative to the kilovolt-ampere interrupting capacity of the breaker at lower air pressures. The designs, in general, are based on satisfactory interruption of full kilovolt-ampere rating, starting with tank pressures of 100 to 125 pounds per square inch. The nominal pressure used is 150 pounds. Since the drop in pressure does not exceed 25 pounds per operation, two complete operations are possible without supplying any additional air from the compressor equipment. It has been found that designing on this basis has not handicapped the size and cost of the breaker, because the curve of interrupting capacity versus tank pressure is comparatively flat in the range of 100 to 150 pounds with the type of design used.

Mr. Langstaff has further inquired regarding breakers of various kilovolt-ampere rating for the same voltage service. The arc chute width, the diameter of the blast valve, and the diameter of the air-supply

tube are all increased progressively, as the kilovolt-ampere rating is increased. This means, of course, that greater quantities of air are used for interrupting the higher kilovolt-ampere capacities. Pressure is held constant, however, for all kilovolt-ampere ratings, and the design factors are worked out in such a way that standardization should not be a difficult problem.

Mr. Hentz has pointed out that it is difficult to simultaneously obtain high kilovolt-ampere interrupting tests and extremely high recovery voltage rates. As he has stated, we believe the tests shown in Table III of the paper, in which 53,000 amperes were interrupted with a circuit voltage recovery rate of 7,100 volts per microsecond, are the most severe tests ever made. The variation in arc time shown in the entire table is the result

1. Of contacts parting at various points in the half cycle.

2. Of the erosion of the first two splitter plates as the result of the large number of tests previously made on the arc chamber.

Therefore, the short interrupting time of the particular test referred to is to a large extent probability.

Mr. Hentz has pointed out that these tests still do not appear to reach the voltage recovery rates and currents which can be obtained in the field. In this connection, attention is called to the statement in the paper that, "All three of these circuit conditions represent double-frequency transients, but, in the second and third oscillograms, the higher frequency is so greatly damped by the conduction current of the breaker following current zero that little trace of the oscillation appears in the recovery-voltage transient recorded by the oscillograph." This damping out of the higher frequency component indicates that, if the circuit is modified in an attempt to further increase the recovery voltage rate, no actual increase will result, and the interrupting requirements placed on the breaker will not be made essentially more severe than they were during this particular test. If the current is increased, complete damping takes place at lower recovery rates, and, in view of these considerations, it is believed that the tests actually shown do indicate the ability of the breaker to withstand the highest recovery rates which may be encountered, up to full kilovolt-ampere capacity.

Acoustics and the Quiet Train Ride

Discussion and author's closure of paper 42-56 by William A. Jack, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, pages 382–92.

F. C. Lindvall (California Institute of Technology, Pasadena, Calif.): In the development of the new pendulum-type suspension which is incorporated in three passenger cars just put in service on the Santa Fe, Burlington, and Great Northern, the problem of acoustical treatment was given particular consideration. Mounting of the car body on a truck in this new suspension system described in February 1942, *Railway Mechanical Engineer*, permits the use of liberal amounts of rubber in all connections between the truck and car body. This rubber can be operated with quite large static deflections so that transmission of truck noise into the car body through attachments is greatly reduced over what is possible in standard equipment in which the body weight is concentrated at the truck center plates.

Preliminary measurements with two experimental cars showed that the noise level in the vicinity of the trucks was far higher than at other points outside the car body. Consequently particular care was taken with floor acoustical treatment. Calculations made by Dr. V. O. Knudsen showed that a substantial reduction in transmitted noise, about five decibels, could be made by treating the under side of the car in the vicinity of the trucks with absorptive material exposed toward the truck. The theory behind this suggestion is that the intensity of sound in the space bounded by the car floor and the ground can be minimized by preventing sound reflection at the under side of the car. The transmission loss through the floor itself is not much affected by the presence of the exposed acoustical material, but the intensity of sound at the under side of the car is substantially lower than it would be if a hard surface were used under the floor exposed to the truck which is the sound source. Road tests showed that the material known as Airacoustic was mechanically suitable for use under the car floor. Behind this material is a stainless steel sheet which seals the floor heat insulation against moisture penetration.

The car floor is a fairly rigid plywood slab uniformly supported on sponge rubber pads. The floor static deflection is small, but the rubber support is helpful in reducing the transmission of high-frequency disturbances. Comparative tests made with these new cars coupled in with standard modern lightweight equipment indicate a noise level of eight to ten decibels below that of the standard equipment. In the new cars not enough attention was given to acoustical treatment of the air-conditioning system with the result that the noise level, though it be low, is due largely to air noises.

Walter C. Keys (United States Rubber Company, Detroit, Mich.): Apparently noise vibrations travel through rubber and steel to an extent represented by the inverse of the velocities of sound through the two media. In steel, sound travels some 30,000 feet per second; in rubber of 50-durometer hardness (comparable to rubber heels), the velocity is 210 feet per second.

Mr. Jack indicates, in the section entitled "Vibration Isolation," that a bonded rubber isolator used in shear was less efficient than another using a controlled spring in combination with rubber. Experience with the millions of bonded rubber mountings used in modern automobiles indicates that bonded rubber mountings, when properly designed and applied, provide the most practical and efficient known means for isolating both vibration and transmitted noise.

We have a record of an installation of rubber at the center bearing of a six-wheeled truck having performed satisfactorily for 12 years. This is perhaps unusually long service but it illustrates the possibilities where stresses in the rubber are kept low. Insulation at center bearings, side bearings, truck pedestals, draft gears, stems, buffers, pantagraph supports, brake linkage, and so on, are essential to the quiet ride in railroad passenger cars. In addition, all auxiliary equipment such as blowers, motors, and so on should be adequately insulated.

It is well-known that vibrations of any frequency require a definite minimum flexibility to be adequately isolated. Some materials which have been extensively used cannot provide adequate deflections; hence, their value consists chiefly in interrupting metallic continuity.

The writer has too often been disturbed at night by people talking outside of a standing car; this indicates that the "enclosure" effect of the car body could be improved which would lower the noise level within the car.

The remarkable quieting effect of several inches of light snow is well-known. It is hoped that this beneficial effect can be approached or equaled by the use of some inexpensive product which may be easily applied.

A material known as Permacell, capable of sustaining moderate loads for long periods of time could be used as a support for an inner body which could be non-metallically joined to the outer body. The writer believes that such an assembly can be designed and that it could provide one of several means for reducing the interior noise level.

William A. Jack: Mr. Keys' remarks on the successful use of rubber in several forms are very heartening. The quiet train ride will be obtained by designers, working in conjunction with such experts who know the proper uses of their materials and, in this way, include them in an early stage in the planning at the several points where acoustical experience indicates the noise problems can be attacked. The velocity of sound, as the discussion points out is much lower in rubber than in steel. This fact, in itself however, is not believed responsible for the usefulness of rubber to the acoustical engineer. The velocity of sound in a medium is a function of its elasticity and its density. If the attenuation of energy per unit length were the same, and if the same amounts of energy were introduced into each material, a rubber rod would deliver just as much energy to its far end as would a steel rod, although it would do it more slowly. However, the attenuation of energy per unit length is greater in rubber, and more of the vibrational energy is converted to heat. Furthermore, it is difficult to get large amounts of vibrational energy into rubber in the first place. Pieces of compliant material provide isolation when placed under the feet of a compressor, for example as brought out in the paper. The feet of the machine at the higher-frequency components vibrate much as they did when rigidly mounted. Rubber yields under these small-amplitude high-frequency oscillations in such a way that much of the energy is reflected, not absorbed. The author agrees that if energy does get in the

rubber, most of it will be converted into heat before it travels far.

Professor Lindvall's remarks on the application of acoustical principles in the pendulum-type suspension cars are interesting, and the author certainly agrees with the steps taken. The complaint about the air-conditioning system might not have been noticed if the other disturbances had not been so well-reduced. It seems that there is always some smaller noise hiding behind a larger one. Perhaps the conditioning system, in question, has a sufficient run of duct so that Airacoustic may be installed to reduce this noise. As sometimes happens, the trouble may be an air-rush sound from the grilles. This is too far along for the acoustical engineer to be of much help, and the problem lies in the field of redesign.

A New Instrument for Recording Transient Phenomena

Discussion and author's closure of paper 42-57 by S. J. Begun, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April section, pages 175–7.

E. A. Blomquist (Consolidated Edison Company of New York, Inc., New York, N. Y.): We investigated briefly the possibility of using a magnetic tape recorder for recording transients last August. We found that satisfactory reproduction at 60 cycles was not possible on the outfit we had, which was designed for sound recording. We did no further work on it but referred the matter to the manufacturer.

Mr. Begun's method of getting around the difficulty of recording the low frequencies is very ingenious. I would like to ask what accuracy can be expected from the device, and also how well it will hold its calibration over periods of time.

In applying this device to the recording of power-system transients, it would be desirable to obtain records up to several seconds. As I see it, this would preclude the use of a cathode-ray oscilloscope for viewing the record, due to the limited screen size and the limitations of the persistency of the screen. However, I see no reason why the record could not be taken off on a magnetic oscillograph. I would like to ask Mr. Begun if the recording and reproducing heads and tapes are sufficiently uniform so that a tape containing a record could be taken to the laboratory and there transcribed onto a film using a different head from that with which the record was made. If this were possible, recorders could be set up at various points on the power system, and when a fault condition occurred, the tapes could be removed and brought to the laboratory for transcription.

Another question that comes to mind is the possibility of obtaining more than one record on a tape. In power system studies, six to nine records are usually needed. Possibly this could be done by widening the tape and staggering the recording and reproducing heads.

It seems to me that this method of recording has decided possibilities in the field of power-system measurements, although further development may be necessary before it is practical.

S. J. Begun: It is very gratifying to hear that Mr. Blomquist feels that this method of recording transients has some possibilities in the field of power system measurements. As a matter of fact, during the development stages of the transient analyzer, this application was kept in mind.

The difficulties in recording low frequencies, to which Mr. Blomquist referred, are not surprising, but by the use of the carrier frequency method, very satisfactory results are obtained.

With regard to the problem of how to make the transient visible, the immediate observation, by means of an oscilloscope, is, in very many cases, desirable; but where this cannot be done, because of the length of record required, there is no reason why the signal should not be supplied from the tape to a magnetic oscillograph.

From our observations so far, we feel that the tape, as well as the heads, can be made sufficiently uniform so as to assure consistent results. The tape may be recorded on one instrument and reproduced on another without any difficulty. Furthermore, for all practical purposes, the record life is infinite.

Hot-Spot Winding Temperatures in Self-Cooled Oil-Insulated Transformers

Discussion and authors' closure of paper 42-59 by F. J. Vogel and Paul Narbutovskih, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, March section, pages 133–6.

H. L. Prescott (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): In this paper, the authors have presented some interesting data which add considerably to our knowledge of the variation of gradient and temperature rise with load. The application of these data to operating practices for transformers will, as the authors have shown in Figure 7 of the paper, permit a given transformer to carry considerably higher overloads for short times than has previously been allowed. The authors have shown by their example computation of the temperature at 200 per cent load that to compute the permissible overload for a given transformer under varying operating conditions is a long and tedious job and therefore is not a very practical basis for emergency loading of a transformer.

The winding temperature is determined by the sum of the oil temperature and the winding gradient. The temperature of any other conductor placed in oil and carrying current is determined in the same way. The Westinghouse company has developed a relay, which operates on this principle. The operating element of the relay consists of a bimetal conductor through which is circulated a current proportional to the winding current. The gradient between the bimetal and the oil, therefore, has a definite relation to the gradient between the winding and the oil and, by using the data similar to figures 3 and 4 of the paper, the desirable relation can be accurately predetermined. The bimetal is mounted in the same oil as the winding, so that the oil temperature factor which determines the winding temperature also determines the bimetal temperature. The relay, therefore, takes into account all of the factors included in the sample calculation given in the paper and provides a practical means of operating the transformer to take advantage of its inherent overload capacity. By adjusting the relay so as to obtain a proper relation between the bimetal and the winding gradients, the relay is made to automatically allow higher winding temperatures at higher overloads for shorter times in accordance with an approved time and temperature schedule such as, for example, that shown in Figure 7 of the paper. As the transformer approaches this predetermined schedule, the relay automatically operates an alarm signal to warn of approaching danger and later trips the circuit breaker if the predetermined operating limit is reached to prevent transformer burnout.

L. Wetherill (General Electric Company, Pittsfield, Mass.): This discussion is limited to the circulation of oil in self-cooled oil-insulated core-type transformers. There are several possible assumptions which serve to simplify the subject, and, in general, the broader the assumption the less closely calculations agree with tests. Three assumptions which have been used will be discussed.

Case I. The broadest assumption, and one which has proven adequate for many purposes, is that temperature differences within the oil can be neglected. Oil-temperature rise above ambient- and winding-temperature rise above oil can be calculated independently and added. It is particularly helpful in analyzing transient thermal per-

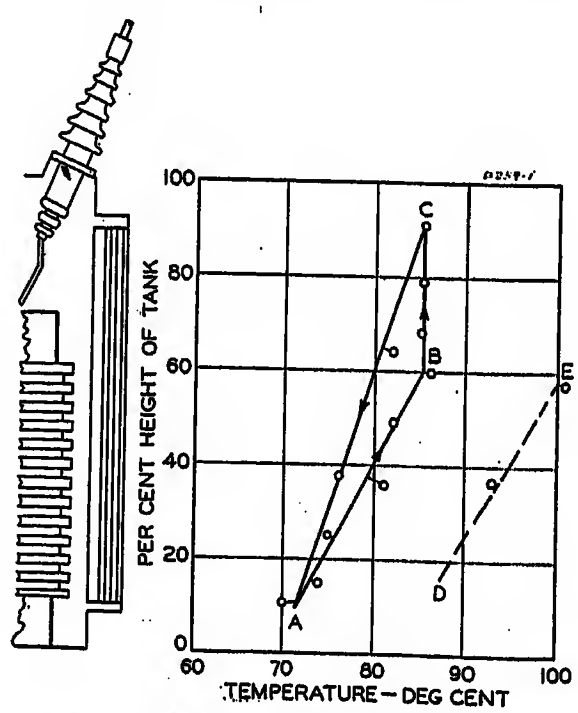


Figure 1. Thermal conditions in 2,500-kva self-cooled transformer

o o o Test points

formance, since the resulting equations may be made identical with those representing transient performance in electrical circuits when current is abruptly changed in a circuit containing resistance and capacitance in parallel.

As a result, we obtain thermal transients with exponential decrement which can be superposed on the steady-state condition. The authors have made use of this procedure in analyzing transient behavior, and this procedure is in fact the most satisfactory which has been described in published literature.

Case II. It has long been known that calculation according to the foregoing procedure may lead to errors. Three such cases are as follows:

(*a*). Transformers in which the core is nearly as high as the tank.

(*b*). Transformers in which there is appreciable loss generated above the top of the core.

(*c*). Transformers undergoing heavy short-time overloads.

To predict with reasonable accuracy the higher temperatures which may result from these conditions, the assumption that temperature differences within the oil can be neglected should be replaced by the more accurate assumption that the core and coils can be represented by a single channel in which heat is absorbed as the oil moves upward, and that the tank cooling surfaces can be represented by a single channel in which heat is dissipated as the oil moves downward.

Figure 1 of this discussion shows ultimate steady-state temperatures observed in the oil of a 2,500-kva transformer at 135 per cent rated load. Starting at A (in Figure 1), the oil moves upward through the windings increasing in temperature at an approximately uniform rate to B. The oil then moves on to C at the top of the tank with no appreciable change in temperature. From C the oil moves down through the cooling tubes, or past the cooling surfaces, decreasing in temperature at an approximately uniform rate, to A; completing the cycle.

The temperature of the copper is shown by the curve DE in Figure 1 as a function of the height above the bottom of the tank. It is assumed that the temperature rise above adjacent oil is the same for all parts of the winding. Actually, this is frequently incorrect on specific transformers, but it serves to illustrate the nature of the phenomenon.

If the watts per square inch of winding surface is low, and the copper is at nearly the same temperature as the adjacent oil, reference to Figure 1 will show that the average copper temperature may well be lower than the top oil temperature. This doubtless accounts for the so-called negative gradients referred to in the paper.

The pressure difference which maintains the continuous circulation of the oil is the weight of the column of downward moving oil minus the weight of the column of upward moving oil. The magnitude of the pressure difference is

$$F=\rho\alpha a$$

where

F = pounds per square inch
ρ = density of oil at 0 degrees centigrade in pounds per cubic inch
α = thermal coefficient of expansion of oil per degree centigrade
a = area of oil circulation curve in inch-degrees centigrade

When, as in Figure 1, the oil circulation curve is approximately triangular the area is

$$a=RH$$

where

R = cyclical temperature range of oil in degrees centigrade (temperature at B minus temperature at A)
H = height of center of gravity of cooling surface above center of gravity of generated loss in inches

If the center of gravity of the generated loss is abnormally elevated, due to a tall core in proportion to the tank, or to appreciable auxiliary losses generated above the top of the core, the circulating force is reduced, the rate of oil circulation is reduced, the cyclical temperature range of the oil is increased, the top oil temperature is increased, and the hottest-copper temperature is increased.

If the resistance to oil circulation is known, it is possible to calculate the cyclical temperature range of the oil. A comparison of such calculations with test results is shown for a number of cases in Figure 2 of this discussion.

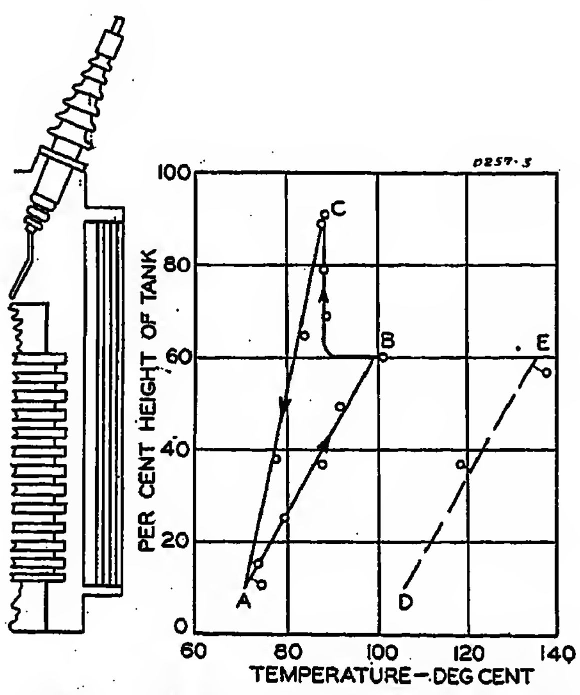

Figure 3. Thermal conditions in 2,500-kva self-cooled transformer

Short-time overload
——— Oil Temperature
— — Copper temperature
o o o Test points

Figure 3 shows data corresponding to Figure 1 for a transformer undergoing short-time overload. Oil moving upward through the transformer winding from A to B rises in temperature and is discharged into the region above the core and coils at a temperature considerably above that of the oil already occupying this region. The streams of hot oil become dispersed and serve to bring about a slow increase in the temperature of the mass of oil between the core and the tank cover. Oil then moves down, from C to A, through the cooling tubes, completing the cycle.

Therefore, temperature of top oil is likely to be misleading when used in determining hot-spot temperature before thermal conditions have become constant. Temperature of oil in the cooling duct adjacent to the coil furnishes a better basis.

Case III. There are conditions for which the assumption of a single oil path is too simple to give results in reasonable agreement with test data. Such cases fall in the following categories:

(*a*). Transformers in which one winding is exposed much more freely to oil than another winding.

(*b*). Transformers in which a part of the heat dissipating surface is exposed much more freely to oil circulation than another part.

For these cases it is necessary to represent the transformer by a network of oil channels. For each oil channel the rate of oil flow is governed by the following equation:

$$P=rG+\rho V(1-\alpha T)-\frac{\rho\alpha M}{105G}$$

where

P = pressure at inlet minus pressure at outlet in pounds per square inch
r = flow resistance of channel in pounds per square inch per gallon per minute
G = flow through channel in gallons per minute
ρ = density of oil at 0 degrees centigrade in pounds per cubic inch
V = height of outlet minus height of inlet in inches
α = thermal coefficient of expansion of oil per degree centigrade
T = temperature of oil entering channel in degrees centigrade
M = moment of loss absorbed or dissipated by oil about horizontal axis through outlet in watt-inches

Performance of a network of channels can be determined from the foregoing equation by a process analogous to the application of Kirchhoff's laws.

Evolution of the concept of thermal behavior of oil in transformers requires creation of new terms. For many years the term "top oil rise" was used as though it were

the only quantity necessary to specify the thermal condition of the oil. In recent years we have added the term "effective oil rise," and we have recognized the distinction between top oil rise and effective oil rise. A thorough analysis of thermal behavior of transformer oil would involve recognition of at least four different oil temperature rises as follows:

(*a*). "Effective dissipating oil rise" is the average rise of the moving oil adjacent to the tank dissipating surfaces. The "effective dissipating oil rise" is the dominant factor in the steady-state thermal performance of oil-insulated self-cooled transformers, and it can be calculated with a high degree of accuracy.

(*b*). "Effective absorbing oil rise" is the average rise of the moving oil adjacent to the coil dissipating surfaces. It is not necessarily the same for all windings. In normal transformers the "effective absorbing oil rise" is not appreciably different from the "effective dissipating oil rise" and they can be frequently assumed equal.

(*c*). "Effective thermal oil rise" is the average rise of all the oil. It determines loss absorbed by the oil under transient conditions.

(*d*). "Top oil rise" is the rise of the mass of hot oil at the top of the transformer.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): This paper is a very timely one and one that is of particular interest to me, because I have spent considerable time during the past year in obtaining data on hot-spot temperatures in oil-immersed transformers. Altogether about 50 heat runs have been made on three different transformer designs, each under a different condition such as self-cooled and forced air-cooled for both ultimate conditions and for short-time heavy overloads.

The authors show in Table I the gradient of "average copper to top oil." This leads, in some cases, to the assumption of negative coil gradients, a condition that cannot exist when the coils are dissipating heat. Average winding rise should, of course, be based over average oil temperature (not over top oil or maximum oil temperature) and hot spots in coils near the top oil should either be based over top oil or adjacent oil temperature.

The authors also show in Figure 6 that the difference in degrees between the hot-spot and the average winding temperature remains constant for loads ranging from 100 to 250 per cent. My tests show that this difference always increased with load, and under some design conditions it increased as the loss raised to a power ranging from 0.7 to 0.8, particularly under short-time overload conditions.

I would like to ask the authors how the losses of the 600-kva transformer were supplied to the oil. If the losses were supplied in a manner that caused the center of heat to change with load with respect to the center of the cooling tubes, this would affect the hot-spot rise over the average winding temperature and could easily account for some of the discrepancies between our results.

The authors used the method of calculating hot-spot temperatures given in my 1930 AIEE paper, "Loading Transformers by Temperature."[1] While not rigorously correct under some conditions, as pointed out by Mr. Wetherill, recent tests show that this is still the most practical method for obtaining reasonably accurate results.

I cannot agree with the statement made by the authors that the results of their tests make it possible to recommend much higher emergency overloads than those given in the American Standards Association Guides for Operation of Transformers. In the first place, they apparently did not use their test data on short-time overloads in their calculations of short-time overloads. In the second place, they used the same method of calculating overloads (as used in calculating the present ASA curves), except for the expedient of not making any correction for increased losses with temperature, since they assumed that the change in oil viscosity counteracted the increased loss. The effect of this however is small—being in the order of three to four per cent of overload values obtained.

The larger overload values proposed in the paper are mostly due to:

1. Using higher temperature limits than those used in calculating the ASA curves as for example 125 degrees centigrade instead of 115 degrees centigrade, for two-hour overloads.

2. Using 61 degrees centigrade hot-spot rise and 50 degrees centigrade top oil rise, instead of 65 degrees centigrade hot-spot rise and 45 degrees centigrade top oil rise as used in preparing the ASA curves. The difference obtained in the overloads when using 11 degrees centigrade, instead of 20 degrees centigrade, hot-spot rise over top oil (at rated load) is quite large.

While there are many small low-voltage transformers that meet the 11-degree hot-spot rise over top oil, there are also many large high-voltage transformers that approach a 20-degree hot-spot rise over top oil at rated load. Therefore, the ASA emergency overload curves were prepared for and apply safely to transformers that have a 20-degree hot-spot rise over top oil temperature.

Using the hot-spot temperature limits given in the paper, although in my opinion somewhat higher limits can probably be used, Table I of this discussion gives the calculated overload values of large high-voltage transformers in comparison with the overload values shown in Figure 7 of the paper apparently intended for small low-voltage transformers.

Table I. Emergency Short-Time Overloads

Time in Hours	Hot-Spot Temperature (Degrees Centigrade)	Times Rated Load Current Following			
		Small Low Voltage		Large High Voltage	
		No Load	Full Load	No Load	Full Load
1/4	140	3.0*	2.35*	2.4	2.0
1/2	135	2.6	2.10	2.20	1.80
1	130	2.25	1.90	1.95	1.65
2	125	1.9	1.71	1.65	1.45
4	120	1.55	1.45	1.4	1.32
8	115	1.33	1.33	1.25	1.23
24	110	1.2	1.2	1.16	1.16

*Values given in paper.

The characteristics applying under rated load conditions are shown in Table II.

Table II

	Small Low Voltage	Large High Voltage
1. Loss ratio	2:1	3:1
2. Top oil rise (degrees centigrade)	50	45
3. Hot-spot rise (degrees centigrade)	61	65
4. Time constant	4	3
5. Ambient (degrees centigrade)	30	30
6. Hot-spot rise over top oil and top oil rise over ambient vary as loss$^{0.8}$		

For intermediate classes of transformers intermediate overloads would of course apply.

It will be noted that the overload values for the large transformers are in general appreciably lower. This shows that different overload values should be used for different classes of transformers.

While I do not claim that one can calculate the exact amount of life taken out of a transformer during an overload period by the eight-degree rule, I feel that it is a useful tool—one that enables us to make progress. This suggests the consideration of even greater overloads than those shown above in cases where interruption of service cannot be allowed.

During the war period there may be cases where it would be advisable to take out of a transformer considerably more life than that used up for the overloads shown in Table I, to prevent a shutdown in a war plant or a station supplying power for war work. In fact a munitions manufacturer recently wished to purchase a spare bank of transformers of *minimum size* to carry the load during a period of one or two weeks in case a saboteur put his present bank out of commission. He was willing to sacrifice 100 per cent of the transformer's life.

I believe, therefore, that it is time for us to start studying the question of allowable overloads that will take out various amounts of the transformer's life. While one user may be willing to sacrifice say only one per cent of life during an emergency period, another user may be willing to sacrifice 10, 25, or 50 per cent and still another as mentioned above may be willing to sacrifice 100 per cent of the transformer's life to prevent a shutdown. Of course, caution would have to be used in applying such overloads to transformers already built, since there may be limitations other than thermal in such units.

1. Loading Transformers by Temperature. V. M. Montsinger. AIEE Transactions, volume 49, 1930, pages 776–90.

H. W. Hartzell (The Commonwealth and Southern Corporation, Jackson, Mich.): This paper has been read with considerable interest, because every contribution to the knowledge of loads that transformers may safely carry is especially valuable at this time when installed equipment may be

called upon during emergencies to serve loads greatly in excess of name-plate ratings.

Continuity of service, prevention of costly shutdowns, and conservation of transformer equipment are some of the items which depend directly upon intelligent transformer application. With many loads growing rapidly and new loads being connected to power systems every day, it would seem that much thought should be given to the overloads that transformers can actually carry under the various conditions of operation.

Table III. Calculated Life for Transformers Operating Continuously at Hot-Spot Temperatures Indicated

Hot-Spot Temperature (Degrees Centigrade)	Calculated Insulation Life (Days)	
	Open Type	Closed Type
140	21	107
135	33	168
130	51	260
125	78	398
120	123	628
115	192	980
110	297	1,520

The authors have presented a table of suggested times and associated hot-spot temperatures which determine emergency overloads that might be applied to a transformer. Although these are of value, the overload ability of a transformer for longer lengths of time is of considerable interest. Momentary overloads occurring during system switching operations would probably be carried without too much regard to the transformer life consumption due to high overloads. The emergency ability of transformers for overloads having a duration of several daily load cycles warrants considerable attention, since under these conditions a substantial amount of transformer life may be consumed.

It would appear that the values given in this paper, although allowing greater loads than the proposed operating guide of transformer standards ASA-C57, may be extremely conservative. To illustrate this point Table III has been made from calculations which follow those of Nichols[1] for open-type transformers and Montsinger[2] for closed-type transformers.

With a hot-spot temperature of 130 degrees centigrade Table III indicates that the total life of the insulation in an open-type transformer would be $51\times24=1{,}224$ hours. If the transformer sustained two hours of operation per year when the hot-spot temperature remained at 130 degrees centigrade, this condition recurring annually for say 30 years, the total operation at this temperature would be 60 hours or $60/1{,}224\times100=4.9$ per cent of the calculated life of an open-type transformer operating at this temperature. For a closed-type transformer the life consumption would be $60/6{,}240\times100=0.97$ per cent, or practically a negligible amount for so many emergency operations. If calculations were made for the transformer insulation life loss during emergency loads limited by the temperatures and times proposed in this paper, since these temperatures would be attained only at the end of the time shown instead of continuing throughout, the loss of life would be much less than that indicated in the above illustration even though the unusually large number of emergency operations during the life of the transformer is considered. It would seem, therefore, that greater loads than those suggested in this paper should be considered for transformer emergency operations.

W. C. Sealey (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The general method of determining permissible overloads outlined in this paper is correct, for it is a method which has been in common use for the past few years. However, the application of the method by the authors contains serious inaccuracies.

Nontypical transformers, having unusually low temperature rises were selected as a source of data. Values of temperature gradient even lower than those shown by these data were assumed and used for calculating allowable overloads. Consequently, the conclusions drawn are not conservative as claimed.

A brief summary of the most serious errors made in this paper follows: The examples in Table I of the paper are not typical standard 55-degree transformers, since all these transformers have temperature rises of less than 35 degrees centigrade. Any transformer user will testify that seldom, if ever, has he had a standard 55-degree power transformer which had a tested temperature rise of less than 35 degrees centigrade. Consequently, the data used as a basis are not data on typical standard transformers, but on transformers which contain more material than standard transformers and are, consequently, more expensive than standard transformers.

Even the data so obtained, however, were not correctly applied, but lower values of gradient between the copper and oil temperatures were assumed than were obtained on these special transformers. In the tabulation of test given in the paper, two of the measured gradients were above eight degrees at full load; these, however, are disregarded and a five-degree gradient is assumed for determining allowable overloads. A similar liberty was taken in determining the hot-spot correction. In the words of the authors, "On the average, the difference between the hottest copper and the average copper was eight degrees." Immediately following, the data are disregarded, and the authors state: "It appears that actual hot-test spot temperatures are in the order of six degrees or less above the average copper temperatures." This figure of six degrees is used in calculating the overloads instead of the eight-degree figure shown by their data.

While these differences are small in degrees, they are large in percentage and, consequently, they make a large error in the values obtained for allowable overloads.

The authors' claim in the conclusion that a more accurate method than previously used for calculating temperature rises has been derived is inaccurate, since the method used has been published before. To name one specific instance, this method was used in the December 1939 issue of the Allis-Chalmers *Electrical Review* in an article entitled "Simple Method of Calculating Transformer Temperature Rise Under Variable Loads."

Because of these fundamental errors, in applying the method, the conclusions reached in the paper are not conservative as claimed.

F. J. Vogel and **Paul Narbutovskih:** Mr. Sealey, in his discussion of our paper, has severely criticized it on the basis of the data furnished and the methods used. Typical of his criticism is his statement that "nontypical transformers having unusually low temperature rises were selected as a source of data." It was not claimed or intended that these were typical of commercial practice, but they were selected because the data for these transformers were available and were used to show that the methods of calculations commonly used are in error. Contrary to Mr. Sealey's further discussion, test data indicate that the conclusions reached in the paper are conservative, and there is a definite possibility that similar values will be recommended for general use.

Mr. Wetherill furnishes some very interesting data in his discussion regarding the thermal behavior of transformers. His analysis of the various cases is good, even though one might wish that the experimental data were given more completely. The fundamental considerations underlying the theory of his first case are essentially in line with those given in the paper. The data given on Figure 2 of the discussion were very interesting to us. The data furnished for transformer *A* seem to be a confirmation of our results. The results given for transformers *B* and *C* do not furnish as good a confirmation, but it is to be noted, that the actual oil temperatures are not given, and so there is no way of comparing the results with the theory outlined in our paper on the effect of viscosity. However, in both cases of transformers *B* and *C*, the variation of the difference between the top oil and the average oil over the range of loads from 100 per cent to 140 per cent load is not over four or five degrees centigrade. It also appears to us that transformers *B* and *C* are not entirely typical. Particularly in the case of transformer *C*, there might be a difference between the average oil and the top oil of nearly 15 degrees at 100 per cent load, and this in turn would lead to the transformer having a hot spot at least 15 degrees above its average temperature, which is not in conformance with the present standards.

In regard to the effect shown on Figure 3 of the discussion it is somewhat difficult to understand why this effect will appear on short-time overloads only. One is likely to encounter this effect when the oil circulation is partially impeded around one of the windings, such as an internal winding of a core-type transformer with a narrow vertical duct. But in this case the effect will appear in varying magnitude at all loads. The difference between the temperature of oil issuing upward from the vertical ducts and the tank oil elsewhere on the same level would be a variable quantity, depending on the magnitude of the load and a change in the oil flow as affected by the pressure difference and the friction head, including the effect

of viscosity. A practical way of taking care of this phenomenon in computing the winding temperatures is to treat it as a component of the hot-spot gradient, although it will not vary quite as much as the 0.8 power of the losses. It may be estimated that this component at 100 per cent load may amount to about three degrees centigrade.

Mr. Montsinger questions the data in Figure 6 of our paper, wherein we showed that the difference between the hot-spot temperature and the average winding temperature remain constant for loads ranging from 100 to 250 per cent. He states that in his tests the difference always increased with load. We have confirmed the results obtained in Figure 6 with tests on a number of other units and feel that Figure 6 is in reasonable agreement with the facts. A small proportion of the losses of the 600-kva transformer was supplied above the coils, but, due to the other tests made, we believe that this had little effect. Further, additional study of the results themselves confirmed this belief. There are some conditions, however, under which this effect will not hold. Two of the simplest of these are:

1. The case where the top coil is more heavily insulated than the coils in the stack.

2. If shielding or other construction details prevent as free coil ventilation in the top coils as in the stack.

However, Mr. Montsinger has made a more serious comment than his remarks regarding the accuracy of the test data. He does not agree that the results of our tests make possible recommending higher emergency overloads than those given in the ASA Guides for Operation of Transformers. We did use our test data in that we showed that many transformers had lower hot spots than had previously been believed or, at least, used in similar calculations. Also, we did show that the increased losses, due to increased copper resistance at higher temperatures, were counteracted by lower gradients and increased oil flow, due to changes in oil viscosity. The fact is that higher temperature limits than those considered in the present Proposed ASA Guide for Operation are given in the paper, and this presentation is in agreement with the papers and discussions of "Temperature Limits Set by Oil and Cellulose Insulation," by Dr. Charles F. Hill, AIEE Transactions, volume 58, 1939, September section, page 484, and "Loading Transformers by Copper Temperature," by Mr. H. V. Putman and Mr. W. M. Dann, AIEE Transactions, volume 58, October section, page 504.

It was not intended that the characteristics given in the paper and used in the calculation of Figure 7 of the paper necessarily applied to all transformers, nor that additional classifications might not be desirable. For this purpose, the authors are prepared to suggest a list of several types of transformers with their respective characteristics. The authors believe, however, that for any of these types, a 20-degree gradient suggested by Mr. Montsinger is high.

Mr. Hartzell's discussion is very interesting to us, since it shows that some operating engineers are also thinking that higher overloads can be carried for emergency service than given in the operating guides in the proposed ASA Standards. We agree that the values proposed in the paper are conservative. We hesitated to go to the extremes, although we may have fundamental data which would indicate possibilities, because

1. It would be a radical departure from past practice.

2. There are other factors involved, such as, contacts, bushings, tap changes, and so forth.

High-Speed Single-Pole Reclosing

Discussion and authors' closure of paper 42-24 by J. J. Trainor, J. E. Hobson, and H. N. Muller, Jr., presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 81–7.

S. B. Crary, L. F. Kennedy, C. A. Woodrow (General Electric Company, Schenectady, N. Y.): The detailed technical information at present available on the problem of high-speed reclosing seems to be well understood. There appears to be no outstanding differences in the results of the stability analyses presented in the Trainor, Hobson, and Muller paper and in our paper. Manufacturers can supply as standard equipment either single-phase or three-phase reclosing breakers. It is agreed there are fields of application for both.

However, there does appear to be a difference of opinion in the interpretation of the technical data. This difference is in the extent of the field of application for single-phase reclosing breakers as compared with three-phase reclosing breakers.

In most stability studies double line-to-ground faults and three-phase faults have been used as a basis for determining the stability of the system. It would appear, if all at possible, that faults involving more than one phase should continue to be the criterion for reliable power delivery. This philosophy of system design, if continued, would result in the emphasis being placed on high speed of clearing, with possible shorter deionization times, rather than on the development of single-phase slower speed reclosing systems for single line-to-ground faults only.

If this approach is followed, reclosing will become much more beneficial to the over-all performance of the system and give it a more important place in system protection, since it would generally allow for successful operation through even the most severe faults rather than only line-to-ground faults.

J. Trainor (Public Service Company of Indiana, Inc., Indianapolis, Ind.): The transmission system of Public Service Company of Indiana, Inc., as it now exists, contains 1,837 miles of 33-kv line, 796 miles of 66-kv line, and 409 miles of 138-kv line, with 120 additional miles of 138-kv line under construction and 45 additional miles planned for immediate construction. When the expansion of the 138-kv system was undertaken, careful consideration was given to the available means for improved operation. The importance of these lines as major links in the interconnection of the systems of Louisville Gas and Electric Company, Cincinnati Gas and Electric Company, American Gas and Electric Company, and Northern Indiana Public Service Company and Public Service Company of Indiana, Inc., makes it necessary that their operation be of the best. For example, our load in the Newcastle area is 25,000 kw, but the duty on the Lenore–Newcastle line has reached 65,000 kw during power transfers for Cincinnati Gas and Electric Company and Indianapolis Power and Light Company to the system of American Gas and Electric Company.

Because of existing insulation levels, ground-fault neutralizers could not be applied to the system with reasonable cost. We have watched the operation of three-pole reclosing on neighboring systems in Indiana with great interest and we recognize its value. However, we felt that definite improvement in operation would be obtained by the use of single-pole reclosing:

1. The disturbance to the rest of the system attending the dropping of load being carried by the line when a fault occurs will be decreased if the amount of load dropped is decreased.

2. While the amount of load to be carried by the line may not be near the stability limit when the line is constructed, major tie lines are often called upon to carry unforeseen amounts of power during emergencies—that is, loss of generating capacity or loss of other tie-line capacity—and any increase in the stability limit of the line may prove invaluable at such times.

3. It is our belief that single-pole reclosing offers all the advantages of three-pole reclosing, and will prove even better in most cases.

J. E. Hobson and H. N. Muller, Jr.: We are glad to have the comments of Crary, Kennedy, and Woodrow regarding the type of fault to be used as a basis for determining system stability. It has, of course, been the practice to predicate system design on the ability to endure a double line-to-ground fault. It might seem logical to revise this basis somewhat, as additional data regarding line performance become available, and to base system design on the probability of instability for all types of faults. This approach would include considering the likelihood of occurrence of the various types of faults, the probability of faults occurring, anticipated loads on the system as a function of time of the day and time of the year, and so forth. The basis of system design would then be an estimated allowable probability of outage, taking all of these factors into consideration. This philosophy of design can become more and more effective as additional data regarding line performance become available. Under the present system it hardly is reasonable to base the stability performance of a well-protected, high impulse-level line and the stability performance of an improperly shielded, low impulse-level line on double line-to-ground faults. The probability of occurrence of double line-to-ground faults per mile per year on the latter line may be even higher than the probability of occurrence of single line-to-ground faults per mile per year on the well-designed line, having well-co-ordinated line-ground and line-line insulation. The actual performance of the two lines, each carrying a block of power calculated as the permissible limit to "ride through" a double line-to-ground fault, would be far different. Since the proportion of all faults which will be of the double line-to-ground

type is likely to be low on a well-designed line, the probability of any fault occurring is low, and the combined probability of a double line-to-ground fault occurring at the time of peak transmission may be very low, it is perhaps not illogical to base the stability limits of such a line on single line-to-ground faults.

Analysis of the Application of High-Speed Reclosing Breakers to Transmission Systems

Discussion and authors' closure of paper 42-31 by S. B. Crary, L. F. Kennedy, and C. A. Woodrow, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, June section, pages 339–48.

Eric T. B. Gross (College of the City of New York, N. Y.): When comparing high-speed reclosing with ground-fault neutralizers, it seems to me that all advantages of both systems should be considered. In this country, I believe, all earth-fault coils which have been put into service are being designed for a very short period of operation only, whereas hardly any coil in service anywhere abroad has been designed for less than two hours operation, but most of the coils are for continuous operation. In many cases it has been a distinct advantage that the operation could be continued for a few hours until the point of the fault had been located,[1] and the line-section with the fault switched off the system without any "shock" resulting from a ground fault. In such systems there are no automatic outages for any single ground fault so that the protection is extended from the self-clearing ground fault to all single-phase ground faults.

The temporary operation with two-phase wires at full line-to-line voltage above ground does not bring severe additional stress on the insulation of the system; in hardly any case will this occur for a period longer than 12 hours altogether in a year (the sum of the durations of all single-phase ground faults during 12 months). It seems to me that in this country the field of application of ground-fault neutralizers lies within systems of lower voltages, that is up to about 66,000 volts, and in such systems the cost of the neutralizer should be small in comparison with the cost of relays and apparatus for quick reclosing at each end of the line sections.

J. E. Hobson and **H. N. Muller, Jr.** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Power-system and application engineers appreciate the benefits to be obtained in increased transient power limits and reliability of service from the use of ground-fault neutralizers and high-speed reclosing, both gang- and single-pole operated. The scheme to be used in any situation will be determined after a careful evaluation of the engineering and economic factors involved. The curves presented by the authors, resulting from a-c network calculator studies, will be useful in helping to evaluate these engineering factors.

Since the most commonly encountered problem today is that of raising transient power limits and improving reliability of service on existing transmission systems, and since those existing systems 110 kv and above are, almost without exception, operated with a grounded neutral, the ground-fault neutralizer is usually uneconomical compared with other schemes. This is caused by the extensive system changes necessary to convert a grounded-neutral system to utilize a neutralizer.

Several of the generalized statements contained in the various sets of conclusions presented in this paper merit discussion. A few of the more important conclusions, relating particularly to the choice between three-pole or single-pole reclosing, will be considered.

The authors state that 50 per cent longer deionizing time may be required for satisfactory arc extinction on a 100-mile line if single-pole rather than three-pole reclosing is used. It is recognized that charging current from the sound phases will flow in the arc while the faulty phase is isolated, and it is also recognized that this may be an important or even limiting consideration when very long lines are involved. Existing data on time for arc deionization and on critical arc currents are so meager that the discussers question whether it is possible to state any figure such as the 50 per cent presented by the authors. It should also be remembered that charging current is not only a function of line length, but a function of the square of the voltage, so that any limitation imposed by line length has little meaning unless it is qualified to apply to a particular voltage class. It is not believed to be practical, in view of the absence of definite data, to state for what line lengths and voltage classes arc deionization becomes significantly longer when single-pole rather than three-pole reclosing is applied. We believe this factor is not likely to be important for the shorter lines usually encountered.

The authors state that single-pole reclosing appears to offer important advantage, only on single-circuit interconnecting lines, and when the generating capacity of one of the interconnected areas is not much greater than the load on the interconnecting line. We have performed calculations on a system where the receiver was assumed to be infinite, and where the sending end capacity was several times the load to be transmitted over the interconnecting line. Rather large gains in transient power limits for single-pole as compared to three-pole reclosing resulted for reclosing times of both 35 and 20 cycles. For 35-cycle reclosing this gain was 42 per cent, and for 20-cycle reclosing 22 per cent applies.

The authors also state that single-pole reclosing offers no advantage over gang operation for faults involving more than one phase. Our calculations show that for double line-to-ground faults the gain is smaller than for single-phase faults, but in particular cases this gain may still be quite significant.

Transient power limits obtainable with 20- and 35-cycle three-pole reclosing are compared with the limits obtainable with 35- and 60-cycle single-pole reclosing. Conclusions drawn by the authors from such a comparison are somewhat exaggerated in favor of the three-pole operation, even if the 50 per cent longer deionizing time given in the paper is assumed to be necessary for satisfactory single-pole operation, since 35-cycle operation permits over twice the de-energized time that 20-cycle reclosing permits. A similar comparison exists for 60- and 35-cycle reclosing speeds. Even then, a conclusion drawn from this comparison states that a gain is realized by the use of 35-cycle single-pole as compared to 20-cycle gang reclosing.

We suggest that the more rigorous method of symmetrical components could be used to advantage in calculating the arc current in the faulted phase during the de-energized period, rather than the approximate method used by the authors. The quantity V_a' in the equations of appendix III may differ considerably from 0.5 V_b under the unbalanced condition with one conductor isolated.

J. J. Trainor (Public Service Company of Indiana, Inc., Indianapolis, Ind.): These authors seem to prefer the use of ground-fault neutralizers to that of single-pole reclosing.

Probably no one in the country is better aware of the operating advantages and the improvement in line outages and service interruptions to be gained through the use of ground-fault neutralizers than we: In the United States, the fifth installation of ground-fault neutralizers and the sixth neutralizer, was placed in service by Public Service Company of Indiana, at New Castle, Indiana, on December 6, 1936, on a 33-kv delta transmission system having about 160 miles of wood-pole line without static wires. After a few months' observation of the operation of this neutralizer, its value was appreciated, and four additional neutralizers were ordered from the manufacturer. The seventh installation in this country, involving these four units, was completed on August 15, 1937, for the protection of approximately 1,300 miles of 33-kv line without static wires on a delta system. At this time, we had 45 per cent, or 5 of the 11 neutralizers in service in the country, protecting 54 per cent, or 1,460 of the 2,700 miles of line so protected.

It may be of interest to note that we operate some 1,200 miles of 33-kv delta line in parallel with three ground-fault neutralizers on the parallel system. This operation was not at all practical before the installation of the neutralizers, and we were obliged to separate this section of the system into three isolated parts. It may be of further interest that we note no appreciable difference in the ratio of line outages to total system faults on the system having three neutralizers in parallel to the same ratio on the two isolated sections protected by individual units, the ratio being 60 per cent to 65 per cent in either case. Up to December 31, 1941, the neutralizers had successfully cleared 1,687 of a total of 2,634 system faults, or 64 per cent.

However, the present discussion is concerned with the operation of 138-kv transmission systems, most of which are designed and insulated for grounded-neutral operation. The application of ground-fault neutralizers on such a system requires that all line, insulation, and arrester voltages be increased to the value required for delta operation on the entire system, or that these be increased to the required value on that section of the system to be protected by the neutralizer, and an insulating transformer installed between that section and the remainder of the system. In view of the practically complete interconnection of the entire 138-kv systems in the eastern half of the country, involving thousands of miles of line and numerous substations, the isolation of particular systems by means of insulating transformers would be most expensive. This difficulty would be further complicated by the number of points at which interconnections occur. In our own system, we would require five insulating transformers for complete isolation, the locations being Lafayette, Kokomo, New Castle, Cincinnati, and Louisville. Such transformers would limit the useful capacities of the lines to the capacities of the transformer banks.

S. B. Crary, L. F. Kennedy, and C. A. Woodrow: The discussers indicate some differences of opinion as to the interpretation of the network-analyzer stability results, although not in the results themselves. This is not surprising, as the application of these results depends upon all the factors including the economic ones which affect the individual system or situation. Our objective was to show the technical factors which enter into the selection of means for improving reliability and the necessity of basing a selection upon the system characteristics.

Messrs. Hobson and Muller believe that a 50 per cent longer deionization time for satisfactory arc extinction on a 100-mile line, if single-phase rather than three-phase reclosing is used, is overly conservative or pessimistic. This assumption was made to illustrate the use of the curves in obtaining a comparison between single-phase and three-phase reclosing. The curves are such that any assumed de-energization time may be used. However, the general conclusions will be unchanged whether the single-phase reclosing time is or is not appreciably increased over three-phase reclosing. For the line-to-ground fault case, the rate of change in power limit with de-energization time is not very great. Messrs. Hobson and Muller point out that they have calculated rather large gains in power limits for single-phase as compared with three-phase reclosing, in one case 22 per cent gain in limit for 20-cycle reclosing. Although they do not specifically say so, this is undoubtedly for a line-to-ground fault. For the conditions they have outlined of an infinite receiving end and a sending-end capacity several times the transmitted load, it may be questionable whether this additional increase in transient limit for a single-line-to-ground fault is necessary. We have found that for systems of this kind the line-to-ground fault power limit with single-phase reclosing is usually appreciably higher than the load required to be transmitted over the circuit. This, we believe, is an important consideration when determining the advisability of using single-phase reclosing rather than three-phase reclosing. For systems of this type, as pointed out in our paper, three-phase reclosing can adequately provide stability for even the more severe three-phase faults with 20-cycle reclosing for the required line loadings. For short lines, where the thermal limitations of the circuit set the maximum power which can be carried, it may not be economical to use means which increase the stability limit for line-to-ground faults above the thermal load limit.

For double-line-to-ground faults we cannot agree with Messrs. Hobson and Muller that the gain may still be quite significant over three-phase reclosing. In the first place the gain is small even for the same reclosing time. Secondly, on many systems the number of three-phase faults may be as great or greater than the number of double-line-to-ground faults. Thus the advantages of single-phase reclosing for other than line-to-ground faults are very questionable.

In our paper results are shown for wide-range reclosing times. In one section of the paper we interpreted these results in terms of present-day standard breakers. Since the present application of single-phase reclosing breakers has been for longer reclosing times than three-phase reclosing breakers, it was natural for us to compare 20- and 35-cycle three-phase reclosing breakers with 35- and 60-cycle single-phase reclosing breakers, respectively. However, any other sort of desired comparison can readily be made from the data included in our paper. We do not believe that reasonable variations in practical comparisons will give results which are inconsistent with our general conclusions.

Messrs. Hobson and Muller suggest a more rigorous method be used for calculating the arc current in the faulted phase during the de-energization period rather than the approximate method used in appendix III of the paper. In using the network analyzer we represented the system as three separate phases with a neutral return circuit representing the ground and ground-wire return. With this representation we were able to impose on the circuit the simultaneous dissymmetries which occur, due to clearing line-to-ground or double-line-to-ground faults with single-phase switching. On the network analyzer the currents in the arc and the fundamental frequency recovery voltage after the fault is cleared were easily obtained during the angular swing when the faulted conductor is de-energized, while the method of symmetrical components becomes quite involved when the number of simultaneous dissymmetries exceeds two. These results indicated that for the angular displacement at which reclosure must take place in order to maintain stability, the magnitude of the arc current and the steady-state recovery voltage was not reduced very much from that given in appendix III. Because of this confirmation, it was felt that the approximate method gave a reasonably correct quantitative value for the arc current and recovery voltage which should be allowed for during single-phase de-energization. Furthermore, the current and voltage at the arc would conform most nearly to the approximate method under those conditions of light system loading and would be (except for effect of distributed constants) almost entirely correct at no load.

We regret that the limited reference to ground-fault neutralizers has lead Messrs. Hobson, Muller and Trainor to emphasize the limitations of this device under some conditions where high-speed reclosing appears to be the sound solution. We had no intention of attempting to offer the ground-fault neutralizer in place of reclosing. It was felt, however, that it should be mentioned as it provides an easy means of minimizing the effects of single-phase-to-ground faults where applicable.

Mr. Gross's discussion calls attention to differences between foreign and domestic practice in the operation of ground-fault neutralizers. The question of length of time to operate a ground-fault-neutralizer system with a permanent ground fault depends on many factors. In general, operators in this country prefer to switch permanent faults off quickly. This is the case even when neutralizer coils have been provided with a continuous rating. The type of system influences this considerably. If the system is of relatively low voltage 33 to 66 kv, for example, and essentially radial in character covering a large area, it becomes good practice to switch permanent faults off quickly in order to avoid simultaneous faults and an increase in the amount of load interruption. Other advantages also result, such as reduction in telephone interference, patrol time, and number of incorrect relay operations due to simultaneous faults.

Performance of Ground-Relayed Distribution Circuits During Faults to Ground

Discussion and authors' closure of paper 42-8 by C. L. Gilkeson, P. A. Jeanne, and J. C. Davenport, Jr., presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 40–8.

William Shuler (Dayton Power and Light Company, Dayton, Ohio): I wish to give an operating man's impression of the value of instantaneous ground relaying on distribution circuits during faults to ground. We started originally with ground relays connected on two 12-kv rural circuits. These relays operated in from one to two cycles, and, after clearing the fault, the breaker was immediately reclosed. The average time from the initiation of the fault to the reclosing of the breaker was approximately 35 cycles, and an operation for the second opening, should the fault persist, was controlled by time-induction relays which were set to permit main and branch-line sectionalizing fuses to blow. We were so well satisfied with the success of this scheme that ground relays either have been or are being applied to all of our four-wire feeders, including our heavily loaded power circuits in urban territory.

Some tests were made on one feeder supplying a customer who has a large load consisting of squirrel-cage, slip-ring, and synchronous motors, as well as rotary converters. A fault was placed on this circuit which was cleared, and the breaker reclosed

without losing any motor load except two motors whose service depended upon contactors energized from the a-c source. The 250 volt d-c rotary converter, which was loaded only to 25 per cent, went through the interruption without flashing over or dropping out of step.

As I see it, the use of ground relays and instantaneous reclosures on overhead circuits has two advantages:

1. It gives a type of service almost equal to duplicate service.

2. It very materially reduces the damage to overhead conductors because of fault currents.

In applying ground relays to circuits having main or branch-line sectionalizing fuses, it is necessary that maximum short currents available be known, and that a fuse be selected having a time current characteristic which will permit the fuse to go through one operation without damage before the relay and circuit breakers clear the circuit.

In some cases it has been necessary for us to install reactors at the substation to hold the short-circuit current down to a value which will protect the fuses. On those feeders where this has been worked out carefully, no trouble has been experienced, and, although our rural feeders are very heavily fused, we have relatively few main or branch-line sectionalizing operations.

In the paper mention is made of the fact that 40 amperes is about as low a fuse as can be used successfully. It is my opinion that fuses having a lower rating may be used on long circuits since it is only a question of the fuse being able to carry without damage the short-circuit current available for longer than seven cycles.

I also want to mention the fact that we are now occupying poles jointly with The Ohio Bell Telephone Company, in territory near our urban district but removed from our four-kv system where we need only one phase wire and a neutral of a 12-kv feeder and can fuse the branch lead at a value which is satisfactory to the telephone company engineers. An engineering study is made of each case, but as a result of several years' co-operation we now have many poles jointly used.

I want to express my appreciation for the work done by the project committee of the Joint Subcommittee on Development and Research that collected the data which formed the basis for this paper. Our company is of the opinion that this work was of a very considerable value to us.

W. R. Brownlee (The Commonwealth and Southern Corporation, Jackson, Mich.): The widespread use of instantaneous reclosing relays has greatly enhanced the value of any operating scheme which permits substituting additional short-time interruptions in order to reduce the number of sustained interruptions. The comprehensive oscillograph information of the four companies' studies is excellent confirmation of the good performance secured by a large number of operating companies with instantaneous reclosing and ground relaying.

Several years' experience on the system of the former Tennessee Electric Power Company convinced the writer that even more sensitive ground settings than the author's suggested limit of 25 amperes may be used without danger of "tree grounds" causing unnecessary operations. Many three-phase, three-wire, 11-kv grounded neutral circuits on that system were operated with ground relay settings as low as 10 amperes primary.

There is some advantage in following the practice of one of the companies studied, namely, that of permitting the high-speed relays to be in operation for the instantaneous reclosure, as well as for the original disturbance. Objects such as tree limbs which are blown onto the line will sometimes fail to fall away from the line in the brief interval of instantaneous reclosing, and the second operation of the fast ground relay prevents an unnecessary sustained interruption to the affected branch at the expense of a few seconds' interruption to the entire feeder.

Fortunately, the telephone cable or conductor of a joint use installation provides a low enough resistance path to ground so that reliable operation is obtained with ground relays set on the order of full load current. It is much more difficult to insure that a fallen conductor in contact with the ground will be cleared properly, since contact resistance may limit the fault current to a value materially less than the full load current. In the case of three-wire circuits, or even four-wire circuits with neutral grounded at the supply station only, ground relays may be set independent of load current, and standard devices provide as sensitive settings as practicable. However, devices and methods are still lacking for providing sensitive ground relaying on the more common three-phase, four-wire circuits, especially at the lower distribution voltages.

G. Fred Lincks (General Electric Company, Pittsfield, Mass.): Messrs. Gilkeson, Jeanne, and Davenport's presentation of operating data indicates the advantages of a system of relaying that apparently is being adopted by an increasing number of utility companies. Their data support the conclusions as to the improvement in service continuity obtainable with such relaying as presented in my paper, "Relative Values of Different Types of Overcurrent Protection for Distribution Circuits." Table I of this discussion, giving additional data to that in the curves of my paper, shows the relative improvement obtainable with single-element fuse cutouts employed at each of the branches or at a number of the sectionalizing points connected in series, when nonreclosing relays, reclosing relays, or reclosing relays with the instantaneous ground relaying facilities are used. The authors only refer to branch-line fusing. Table I shows that relaying—so the substation breaker opens once ahead of all sectionalizing or branch protective devices and then provides time delay so these devices will clear ahead of the second opening of the breaker—generally provides greater benefits in the improvement in service continuity with line sectionalizing than with branch protection. Such relaying permits securing greater reductions in consumer minutes outage with less costly branch and line-sectionalizing equipment than is required with nonreclosing or reclosing relays and breakers. For example, single-element sectionalizing fuses with the instantaneous ground relaying are more effective than an equal number of three-element reclosing cutouts with just a reclosing relay.

The authors state that "instantaneous ground relays would not be expected to save branch-line fuses below 30- or 40-ampere rating." It is assumed that this limitation applies to the system for which the data are reported. In setting up such a relay and line protective scheme, the minimum fuse rating would be determined by comparing the total clearing time for the relay and breaker with the melting time-current characteristic curves for the fuses. A 25 per cent factor should be applied for variables (see Figure 14, "Trends in Distribution Overcurrent Protection" by G. F. Lincks and P. E. Benner, AIEE Transactions, volume 56, 1937, January section, pages 138–52). The minimum fuse rating which will provide the desired selectivity of operation will depend on the relay setting and breaker opening time and the current available at the point on the system where the line protective device is located. In studies on actual circuits

Table I. Comparison of the Effectiveness of Substation Protective Equipment

With Single-Element Cutouts and 75 Per Cent Temporary Faults

No. of Branches or Sectionalizing Points	Substation Protection: Nonreclosing Breaker	Substation Protection: Automatic Reclosing Breaker	Substation Protection: Reclosing Breaker Set for 1st Opening Ahead of Line Fuses	Maximum Protection Obtainable (Permanent Faults Only Cause Outage)
	Per Cent Consumer Minutes Outage*			
Protecting 5-Mile Branches				
0	115.7	101.0	101.0	100.0
1	85.0	75.0	78.9	72.2
2	65.5	57.8	56.1	54.8
3	51.8	46.0	44.2	42.8
4	42.0	37.2	35.6	34.5
5	34.8	31.0	29.4	28.4
6	29.2	26.1	24.7	23.8
Protecting at Sectionalizing Points				
0	115.7	101.0	101.0	100.0
1	100	92.6	74.3	64.0
2	92	87.0	64.5	53.2
3	87.5	83.4	60.0	48.0
4	84.2	81.3	57.0	44.0
5	81.7	79.5	54.8	42.3
6	80.8	78.5	53.5	40.9

$$\text{* Per cent} = 100 \times \frac{\text{Consumer minutes outage caused by permanent faults plus temporary faults for any specific system setup}}{\text{Consumer minutes outage caused by permanent faults alone with no branch protection or line sectionalizing}}$$

it has been found that with instantaneous ground relaying, proper selectivity of operation is possible with fuse ratings as low as 10 amperes where such fuses are located well out on the line where the available short-circuit currents are low.

The authors' report on the high quality of the performance of fuses is indicative of the improvement that has been made in this product during the past few years. It shows that modern fuse links are meeting the requisites of greater dependability and accuracy demanded by such co-ordination practices.

C. L. Gilkeson, P. A. Jeanne, and **J. C. Davenport, Jr.**: The authors wish to thank Messrs. Shuler, Brownlee, and Lincks for their interesting and instructive discussions of this paper. In reply to the question regarding the statement in the paper that instantaneous ground relays would not be expected to save branch-line fuses below 30- or 40-ampere rating, the authors were referring to relatively high kilovolt-ampere capacity feeders, such as those on which most of the observations were made. Where the fault current is limited to relatively small values, either due to long feeders or neutral impedance, smaller fuses could be protected, as Mr. Shuler stated.

In suggesting minimum ground-relay settings of 25 to 35 amperes, the authors wished to be conservative, particularly with respect to four-wire multigrounded neutral feeders. As Mr. Brownlee states, lower settings may be feasible, and have been used on three-wire unigrounded neutral systems.

The following errors appeared in this paper as published in the AIEE TRANSACTIONS (volume 61, 1942, January section, pages 40–8):

1. Table II. The subheading "Instantaneous" under "Ground Relays" applies only to the column just preceding "Reclosure Practice."

2. Table III. In the footnote ## "cleared" should read "clear."

3. Table B. In the title "Local" should read "Load."

Relative Value of Different Types of Overcurrent Protection for Distribution Circuits

Discussion and author's closure of paper 42-2 by G. F. Lincks, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 19–26.

R. O. Loomis (Georgia Power Company, Atlanta, Ga.): Line-sectionalizing devices provide an economical means of reducing interruptions to electric service, which means improving the quality of the service. As in practically all engineering problems, the cost is the important element. Since investments in distribution lines are an important part of total system investments, opportunities for reducing these investments cannot be overlooked. Mr. Lincks has compared in this paper the relative value of different types of devices, enabling selection of the method providing the greatest improvement at the lowest cost. Mr. Lincks has made a definite contribution by providing a method of comparison. This paper is very pertinent at the present time when restrictions in material will prevent more expensive methods of improving service.

In applying sectionalizing devices, it should be remembered that proper co-ordination is essential. I suppose that one of the assumptions employed was that perfect co-ordination was obtained, and that no fuses broke mechanically or blew because of poor mechanical condition of cutouts. Some forms of cutouts tend to overstress the links mechanically upon closing. Cutouts in poor condition may overheat. Mechanical failure of reclosing fuses to reclose occurs. It will be necessary to use only one make and type of link on a given line. This usually means the use of only one make and type of link by the entire company, or at least by one operating district. Attention to such details is necessary to approach perfect operation. I would like to know what the effect on the results would be if an assumption had been made that, say one fuse link out of ten blew incorrectly, or unnecessarily.

Assumption 6 states that a trouble crew is available to start instantly. In rural areas where much of the sectionalizing is employed, this is seldom true. The additional time required apparently increases the benefits of sectionalizing.

In assumption 7, permanent faults are repaired very rapidly. Sometimes such faults require a crew larger than the trouble crew, and sometimes they are difficult to find, so I am inclined to think 30 minutes on the average is low. Increasing this time apparently increases the benefits of sectionalizing. Sectionalizing helps in locating the faults difficult to find, which is an added advantage.

Assumption 10 is often not true in rural areas. On the other hand, in urban areas where short-circuit currents are larger, and relay current and time settings are higher, because of larger loads, and to co-ordinate with larger transformer fuses, branch fusing may prevent burning down lines, since the branch fuse may blow in a time short enough to prevent damaging the conductors, where the substation breaker will not open quickly enough to prevent burning of conductors. This advantage is also obtained by using pole-mounted oil circuit reclosers, but they are not so adaptable to urban distribution as sectionalizing fuses. Although mechanical breakdown of conductors by automobiles, trees, and so forth, occur, I have not found a case where conductors burned down when protected by oil circuit reclosers.

The curves presented deserve careful study. They show the effects of a high percentage of temporary faults, particularly on line sectionalizing. I am surprised that the percentage of temporary faults does not have more effect in branch fusing as shown in Figure 5 of the paper. The conclusion that "Single-element fusing of branches provides approximately 85 to 95 per cent of the total improvement obtainable" is rather startling to me. I would like to know what effect the percentage of temporary faults has on branch fusing when all the customers are on the branches: for example, when all branches at the end of a trunk feeder are fused. Other conclusions appear reasonable and justified.

C. R. Craig (General Electric Company, Pittsfield, Mass.): Because of the fact that conclusions drawn from a mathematical study of operating conditions must necessarily be tempered by experience and inherent characteristics of individual systems, it should be borne in mind that the benefits of the different types of protection presented in Mr. Lincks' paper for a system as a whole may just as well be applied to only a portion of a particular system. If this portion of the system were subject to an especially high percentage of temporary faults, as compared to the system as a whole, an efficient combination of protection on the troublesome branches or small section of feeder would materially reduce the percentage of temporary faults on the entire system, thereby lowering the over-all outage time.

In paragraph 5, under the heading "Of What Value Is Branch Protection," the author calls to attention one of the most important conclusions. This shows that single-element cutouts furnish the major percentage of the total improvement attainable by branch protection. From the standpoint of initial cost, this means that the single-element cutouts give the most protection for the money invested. For example, let us assume some comparative costs of protective equipment, and then determine the comparative benefits of the combinations of protective equipment.

While actual costs may vary a great deal, for the sake of illustration, the following somewhat arbitrary values are assumed for initial installed costs:

One-element cutout	$ 20 each
Two-element cutout	30 each
Three-element cutout	70 each
Line automatic recloser	120 each
Nonreclosing substation Breaker and relays	1,000 each
Automatic reclosing substation Breaker and relays	1,350 each

The division of the total cost of branch protective equipment by the cost of substation protective equipment alone will give the per cent increase in initial cost of combined substation and branch protection over that for no branch protection. This result can be compared with the per cent improvement in system protection as shown in the paper for the corresponding system setup (see Figures 5 and 8 of the paper). A summary such as Table I of this discussion, constructed from the above assumptions and data calculated for the paper, serves to illustrate the comparison between attainable improvement in protection and the cost of the protective equipment.

Even though the above assumed comparative costs may not be exact for cutouts or breakers, it is evident from Table I, for example, that with a nonreclosing substation breaker, single-element cutouts on branches furnish 52.7 per cent improvement in protection with only 6 per cent increase in total installed costs over no branch protection. An increase in cost of 15 per cent (21–6 per cent) for three-element cutouts over the cost of single-element cutouts is necessary to obtain only 1.3 per cent (54–52.7 per cent) increase in protection furnished by the three-element in place of single-element cutouts. Similar comparisons may be made with the

Table I

Substation Protection	Three 5-Mile Branches† Branch Protection	Consumer-Minutes Outage in Per Cent of "Yardstick"	Initial Cost	Per Cent* Improvement in Protection	Per Cent Increase in Cost
		For 75 Per Cent Temporary Faults			
Nonreclosing breaker ($1,000)	None	110	$1,000		**
	3 One-element cutout ($20 each)	52	1,060	52.7	6
	3 Two-element cutout ($30 each)	51	1,090	53.6	9
	3 Three-element cutout ($70 each)	50.6	1,210	54.0	21
	3 Automatic recloser ($120 each)	50	1,360	54.5	36
Automatic reclosing breaker ($1,350)	None	100	1,350		♯
	3 One-element cutout ($20 each)	46	1,410	54	4.5
	3 Two-element cutout ($30 each)	45	1,440	55	6.7
	3 Three-element cutout ($70 each)	44.7	1,560	55.3	15.5
	3 Automatic recloser ($120 each)	44	1,710	56	27
Permanent faults only		43		♯♯67	

* Per cent improvement in protection = attainable decrease in outages, expressed as a per cent of the per cent consumer-minutes outages attainable with no branch protection. Example—$\frac{110-52}{110}\times 100=52.7$ per cent.

**100 per cent base cost = $1,000 for nonreclosing breaker, relays, etc. (Substation protection only.)

♯100 per cent base cost = $1,350 for automatic reclosing breaker, relays, etc. (Substation protection only.)

♯♯67 per cent in this case represents the maximum per cent of decrease in outages attainable (all temperature faults cleared immediately).

†Assume 7,500-volt single-phase, line-to-ground neutral, requiring only one protective unit per branch.

other types of equipment and with the automatic reclosing breaker at the substation as shown in the table. This example illustrates how actual costs may be applied in the author's mathematical study to be used as an aid in actual system planning.

To the loss of revenue and initial costs, there must be added the cost of maintaining the protective equipment on a system. It would be possible and advantageous to determine comparative maintenance costs for various combinations of protective equipment from a similar mathematical study with assumptions and conditions parallel to those in the paper under discussion. Calculations of actual outage time alone would serve as a basis for figuring labor costs for restoring service after outages with the different combinations of protective equipment. Auto and truck mileage would form a portion of the maintenance cost, but from the assumptions in this paper they would be uniform and proportional to the number of miles of line, because the number of outages and consumers per mile were assumed uniform. While it might be difficult to introduce actual costs into a maintenance study, because of the diversity of setups of distribution systems, comparative percentages would show the relations between the values of different types of overcurrent protection and the labor time necessary to maintain the protection.

Bruce O. Watkins (nonmember; Rural Electrification Administration, St. Louis, Mo.): Mr. Lincks is to be congratulated for this contribution to the solution of distribution-line-sectionalizing problems.

The so called "area-electrification" program such as practiced by the Rural Electrification Administration opens up an entirely new field in distribution engineering. So far distribution engineers have only scratched the surface on this subject.

Rural distribution systems financed by the Rural Electrification Administration vary widely in characteristics, but for purposes of discussion, a "representative" system as such usually involves between 300 and 400 miles of line, served by a single substation. Most systems are sectionalized by means of fuses. The substation protection consists of a three-shot reclosing fuse cutout, with the line sectionalized by two or three-shot cutouts. Branch laterals are usually controlled by a single-shot cutout. Operating practices on each system vary to suit local conditions, but for the purpose of this discussion the following practices are considered:

1. Substation is unattended.
2. Very little or no communication facilities are available.
3. Roads are usually poor, particularly during wet weather.
4. Line-crew personnel live a great distance apart or are usually out connecting new consumers or maintaining the lines.
5. Ends of lines may be 60 miles or more from the central office.

It can be seen that the above conditions are vastly different from those encountered in city or urban distribution.

Systems fused in the above manner have not given the results that have come to be expected for good service, particularly in lightning areas. Due to inadequate communication facilities, outages are not always reported promptly, and when they are reported, the problem of assembling a crew delays the restoration of service. The actual patrol of the lines to locate the trouble, and the travel over poor roads further increase the outage time.

To solve the communication problems, REA has been experimenting with two devices:

(*a*). A carrier-current outage recorder which immediately notifies the office of the location of an open sectionalizing device.

(*b*). A carrier communication system with portable transmitter-receiver and coupling capacitor in the trucks and with fixed equipment in the office.

Single-pole automatic reclosing circuit breakers, described by Mr. Lincks as "resetting reclosers," were installed on some of the earlier Rural Electrification Administration systems in conjunction with gap-protected transformers. Though many of these reclosers failed (failures largely due to improper insulation co-ordination), the results on the whole were so encouraging that in 1939 a program for installing an unprecedented number of such reclosers on systems located along the eastern seaboard was begun.

Table I indicates the results of a survey in one of the midwestern states where this type of recloser is being used. Gap-type transformers are in use on most of these systems. Since the recloser design was changed during this period, the two types of reclosers in use are differentiated by the terms 1 and 2, number 2 being the later design. All reclosers are of the same make.

On the eastern seaboard projects the reclosers are installed both on feeders and branches so that each one controls about 20 miles of line. No fused cutouts are installed on the load side of the recloser. In some cases reclosing fused cutouts are used for feeder sectionalizing and branch protection near the substation. Most of these systems have conventional arrester-protected transformers.

So far there has not been sufficient data accumulated to draw any final conclusions on the performance of these reclosing circuit breakers installed along the eastern seaboard, but the available information indicates much better operating results, both in shortening the length of interruption and decreasing maintenance costs, than with the previously fused systems. Quantitative results are being accumulated, but have not yet been tabulated; indications are that the per cent of lockouts to total operations is less than 10 per cent, and in some cases less than 5 per cent, during the lightning season. Only one complete recloser failure has occurred to our knowledge out of about 1,500 installed. Unfortunately, quantitative results for the previous fused cutout operation were not obtained, and hence no numerical comparison can be made. However, operating reports are not complete, but they do indicate that service has been improved considerably with the reclosing breakers and would seem to bear out the conclusion reached by Mr. Lincks that a very substantial improvement over fused cutouts is possible by using the recloser for sectionalizing, where there is a high percentage of temporary faults.

I agree with Mr. Lincks that continuity of service is always an operating engineer's major object, but there is also another angle to economical system operation. How much can we spend to eliminate fuse replacements? Estimates from Rural Electrification Administration system managers indicate that a few trips to refuse a distant cutout will cost much more than investment and maintenance costs on the recloser.

Since most faults are temporary, the recloser eliminates the majority of the previously necessary refusing trips.

There are still disadvantages to the presently available reclosing single-pole breaker:

1. As Mr. Lincks points out, it is not always practicable to provide automatic selectivity between the smaller size reclosers and the transformer fuse. This is particularly true for internally fused transformers.

2. There is an insufficient number of recloser sizes which will co-ordinate for proper sectionalizing on lengthy lines.

Both of these difficulties can be overcome, to some extent, by the introduction of inverse time delay in the recloser opening. New design reclosers have appeared on the

Table II. Report of Single-Pole-Reclosing Circuit-Breaker Operation on 20 Rural Systems in a Midwestern State to November 1, 1940

Most Systems Are Equipped With Gap-Protected Transformers

Total number of circuit reclosers reported	417
Total reported circuit recloser months of operation	5,098
Total number of operations reported	20,973
Total number lockouts reported	271
Per cent of lockouts to operations	1.29
Total operations where operations and number of reclosers were both reported	20,973*
Total number of reclosers as of above	301*
Average number of operations per breaker where both were reported	69.6
Average number of operations reported per recloser per month	4.11
Total reported number of recloser failures due to:	
Lightning	24
Worn parts	2
Oil	
Other	21
Total reported recloser failures, including those not segregated	59
Percentage of total recloser failures to number installed where both were reported	16.1
Percentage of total recloser failures per 12 months, where number of failures and months of operation were both reported (Excluding system 18 where installation date was not given)	13.5
Total reported failures:	
Design 1 reclosers	56†
Design 2 reclosers	3
Percentage of total design 1 recloser failure per 12 months, where number of failures and months of operation were both reported	21.8
Percentage of total design 2 recloser failures per 12 months, where number of failures and months of operation were both reported	2.04

*Number of reclosers and operations not always simultaneously reported.

†Systems 10 and 14 indicate failures but do not give the number. Other information on hand for system 10 indicates not more than two failures occurred, both due to recloser misapplication in interrupting rating.

market with such inverse time delay, but the experience with them is insufficient as yet to form any conclusion. Rural Electrification Administration is instituting further development of this inverse-time-delay feature in the recloser opening.

Mr. Lincks states that overlapping the substation reclosing protection with single-element fusing at the branches or sectionalizing points approaches very closely to providing the minimum consumer minutes outage attainable.

Such a scheme is used on Rural Electrification Administration systems in the Tennessee Valley Authority area and works very satisfactorily. However, I do not feel that it is advisable on an extensive system.

1. Outages, even if momentary, are objectionable if over a large system.

2. It is difficult to reach all the way out on the system with the substation breaker.

3. The cost of the reclosing substation breaker would cover a great many single-pole reclosers.

In my opinion, definite advances can be made in rural distribution sectionalizing by the development of a small reclosing breaker similar to the present recloser, but with practically instantaneous first opening and inverse time delay on succeeding openings. The first reclosure should be as rapid as possible. Such a device should be inexpensive and should reset automatically. In order to reduce outage time on temporary line faults, the use of this breaker is advisable on most rural distribution feeders and long branch lines. By means of the instantaneous first opening and inverse-time-delay second opening, all short branch lines then could be protected with single-shot fuses, thus achieving the best over-all results. This idea seems to agree fairly well with the conclusions reached by Mr. Lincks concerning a reclosing breaker-fused branch combination, although Mr. Lincks discusses a different type of breaker. Also, I believe that to reduce outage time, the device should be single-pole, and, in order to prevent three-phase motor burnout with this device, effective and economical three-phase motor protection should be simultaneously developed.

Perhaps some new type of apparatus can be developed which will accomplish these results. At any rate continued research on the problem should advance the rural circuit sectionalizing art.

L. G. Smith (Consolidated Gas, Electric Light and Power Company, Baltimore, Md.): The author has prepared an excellent paper. In the field of distribution engineering there is a need for more papers of this type. In such studies the analytical approach based upon operating data should lead to conclusions that indicate:

1. Where to spend capital and maintenance dollars to obtain the best operating results by directly comparing operating benefits with the cost.

2. Where capital and maintenance dollars should not be spent.

3. What can be done to obtain the maximum improvement in continuity to service.

This paper should inspire further engineering studies of this type. However, additional operating data are necessary on which to build premises for further analytical studies.

The author refers to temporary faults varying from 15 to 85 per cent of the total. It is believed that in the usual distribution system the percentage is certainly above 50 and probably more of the order of 70.

With the help of summary tables in a preliminary copy obtained from the author, Table III was prepared. If I have correctly interpreted the data, and if the data on one curve are comparable with those of another,

Table III. Per Cent Consumer-Minutes Outage. Relative Effect of Various Methods of Branch Fusing

Three 10-Mile Branches

Station Protection	Fusing of Branches	75 Per Cent Temporary Faults (Per Cent)	85 Per Cent Temporary Faults (Per Cent)
Nonreclosing breakers	none	107	113
	1 element	33	40
	2 element	32	38
	3 element	31	37
Reclosing breakers	none	101	103
	1 element	30	35
	2 element	29	33
	3 element	28	31
Reclosing breakers set for instantaneous trip on first opening. Branch protective device delayed beyond first opening of breaker	none	101	105
	1 element	28	31
	2 element	27	30
	3 element	27	29

I question the validity of two apparent conclusions derived from the author's data:

1. The data indicate less than a 10 per cent reduction in customer minutes outage by changing from a nonreclosing to a reclosing station oil circuit breaker as compared with about a 60 per cent improvement for branch fusing. The operating data of the company with which I have been associated show that 70 per cent of feeder troubles are restored without a lockout by reclosures of the station breakers.

2. In view of experience with reclosing station breakers, it is believed that actual operating experience would show a greater advantage in two or three element branch fuses.

G. F. Lincks: The author greatly appreciates the contributions made by those discussing the paper. There have been a number of points brought out in these discussions which should enhance the paper's value for those interested in the improvement of service continuity on distribution systems.

As Mr. R. O. Loomis points out, the study presented in the paper is based on securing perfect co-ordination. It has been experienced by a number of utility companies which, in addition to standardizing on only one type and make of fuse link for a given line, eliminated the possible causes of mechanical breakage of the fuse links, and poor mechanical and thermal conditions in the cutouts as well. Without doubt, Mr. Loomis had in mind reviewing the possible benefits to be derived from such elimination of defective devices, in raising the question as to the effect on the results "if, say, one fuse link out of ten blew incorrectly or unnecessarily." "Incorrectly" might imply improper sequence of operation without any increase in the actual number of outages, whereas "unnecessarily" would tend to indicate an increase in the number of outages. In either case, the effect on the results would vary with the location of the cutout which was causing the improper operation. In analyzing this point, it was assumed that the causes of such difficulty would be localized to one or two specific cutouts and would not be spread evenly over the whole line.

In case one out of ten devices operate "incorrectly," it was assumed that the cir-

cuit was opened at the next point closer to the substation than at the point where incorrect operation occurred. With line sectionalizing, this would tend to decrease by about one-tenth the improvement provided by the defective single-element or reclosing sectionalizing device. With single-element or reclosing branch protection, the station breaker would open, taking out the whole line instead of isolating the fault to the individual branch. Thus, the improvement over the "Yardstick" as provided by the branch protection employed under the specific system setup would be reduced by one tenth. The effect of defective equipment which causes incorrect operation is considerably greater at branches than at sectionalizing points.

In the case of devices operating "unnecessarily," and thus causing an additional number of outages to the one per mile used in the calculation, in the ratio of 1 to 10, it would be necessary to add from two to six units to the percentages shown on the curves for line sectionalizing with protective devices connected in series. The two should be added if the troublesome sectionalizing device is located close to the substation, and the six added if the troublesome device is located at the last sectionalizing point on the line. It varies about proportionately in between. With branch protection the effect is negligible, amounting to the addition of one unit to the percentages shown on the curves. With either branch fusing or line sectionalizing, the improvement provided by a defective reclosing device would be reduced by one tenth of the difference between the percentage shown on the curves for the actual device and for a device having one less reclosure.

Mr. Loomis is interested in the effect of the percentage of temporary faults on branch fusing, when all the consumers are on the branches, rather than evenly distributed over both the branches and the main feeder, as in the paper. A further study indicates that under such conditions, branch protection provides two or three units greater improvement for single-element cutouts, but no greater relative improvement for different devices or different percentages of temporary faults.

Apparently there was a misunderstanding of some of the values given in the paper on the part of Mr. L. G. Smith, which led to his questioning of the validity of two of the conclusions. Mr. Smith indicates that the operating data of the company with which he has been associated shows that 70 per cent of the feeder troubles are restored without a lockout. This operating experience lines up quite well with the values given in Table IV in the appendix of the paper. The values used in the calculations for determining the consumer minutes outage from which the curves were plotted are shown, in Table IV, to line up with this operating practice. This shows that while the reduction of the number of outages by reclosing equipment may be a very high percentage of the total, it does not necessarily indicate the same reduction in consumer minutes outage when related to the whole system. Consumer minutes outage takes into consideration the time it takes to go out and locate the fault, make repairs, and so forth. A large proportion of this time is required for permanent faults even with a high percentage of temporary faults. Single-element line sectionalizing and branch fusing reduce this time as well as decreasing the number of consumers affected. With branch fusing the consumer minutes outage caused by fuse blowing on temporary faults is a very small percentage of the total for the whole line, since only those on the one branch are affected. Therefore, even though reclosing devices on branches do restore service on 70 per cent of the faults without lockouts, the improvement in consumer minutes outage is very small when related to the system as a whole. However, as pointed out by Mr. Craig, the treatment of an individual branch as a unit would show a much greater improvement for reclosing equipment, and this might be sufficient to warrant special attention where some peculiar condition exists on that branch. It might even improve the consumer minutes outage on the whole system, if the percentage of temporary faults on the branch were particularly high as compared to the percentage of temporary faults on the system as a whole.

Mr. B. O. Watkins brings out some of the problems involved in rural electrification. He draws the conclusion that the automatic resetting recloser provides the real answer to the rural problems. As partial substantiation of these conclusions, he cites some data based on circuits employing gaps for lightning protection of the individual transformers. It should be recognized that such a setup has a fictitiously high percentage of temporary faults, since the automatic reclosing devices are called upon to give not only overcurrent protection, but also a part of the function that proper lightning protection should give. A tabulation of the number of successful reclosing operations without lockout should show up well, because the arc across the gaps is very likely to go out, as quickly as the recloser opens the circuit the first time, and is not likely to be re-established. The data presented in the paper are based on a normal system with the better conventional lightning protection, where the reclosing protective devices are not called upon to do double duty in interrupting the accidental plus gap-created short circuits. Therefore, the improvement indicated for reclosing devices in the paper will fall short of the improvement shown by data which include numerous additional operations to clear on the first reclosure arcovers on gaps employed for lightning protection.

Mr. Watkins stresses again the limitation in the number of reclosers that can be connected in series and the difficulty of coordination with the fuses at the transformer, which is brought out in the paper. He gives his idea of an ideal design which would have instantaneous operation on the first opening and then inverse time-current characteristics on subsequent operation. Such a device would have some advantages over the present design, although it would not provide for any increase in the number of devices that could be connected in series. The instantaneous operation on the first opening would retain the advantages of the present design in the preventing of burning down of lines, which is mentioned by Mr. R. O. Loomis when he states, "I have not found a case where conductors burn down when protected by oil circuit reclosers." It would probably have a similar advantage as regards the burning back of gaps employed for lightning protection, which might become excessive more quickly with reclosers having a longer time of operation on the initial opening. Actual operating experience is available only with the rapid opening.

All of these factors should be considered when employing the curves of the paper for the study of the relative value of different types of protective devices, when the characteristics of the devices or the type of the application vary from the assumptions of the paper.

Mr. Craig has presented some additional information and suggestions for applying the data presented in the paper, which should extend its value.

Relays and Breakers for High-Speed Single-Pole Tripping and Reclosing

Discussion of paper 42-35 by S. L. Goldsborough and A. W. Hill, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 77–81.

Eric T. B. Gross (College of the City of New York, New York, N. Y.): In connection with the application of relays acting upon the phase-angle shift between two sets of phase-sequence quantities, it might be of interest to mention that a similar problem arises in the problem to secure correct operation of distance relays in delta-wye connected systems. One of the solutions to this problem makes use of wattmeter-type phase-sequence relays.[1]

Evening Courses at Graduate Levels—a Challenge to Colleges of Engineering

Discussion and author's closure of paper 42-34 by Robin Beach, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 88–94.

P. L. Alger (General Electric Company, Schenectady, N. Y.): This paper is very welcome for its record and advocacy of advanced education for engineers in industry. It is obvious that any four-year or even six-year course in college is only the beginning of an engineer's education. All who aspire to professional standing, therefore, must continue their studies for many years after leaving the halls of the university. Heretofore, most graduates have found it sufficient to learn from the hard knocks of experience and the advice of their associates, supplemented by occasional periods of individual study. It must be expected, however, that very many men in the future will wish to accelerate this process of continued learning, and will welcome the help of experts in so doing.

There are several reasons why the colleges should seize this opportunity for expansion, besides the mere filling of a growing educational need. For one thing these older students, engaged in practical engineering work, will bring to the university definite ideas on the utility of various sorts of knowledge, and numerous problems whose solutions are needed. Thus, the college professors will be jarred out of any academic ruts and stimulated to extend their own knowledge. In this atmosphere research programs will naturally grow up, industry support for them will develop, opportunities for student employment will arise, and undergraduate education will become more realistic.

Also teaching practicing engineers how better to perform their daily work is a public service of immediate economic value. The tuition fees received in consequence are likely to be multiplied many times in the college income, merely because of the community of interest and co-operative spirit thus created between the university and the town.

Any step that lessens the time between spending money for education and reaping its rewards reduces over-all costs and strengthens the financial position of the college. To advocate as some do that the government finance large numbers of students for a fifth or sixth year of college residence is, therefore, economically unsound, and, by the same token, evening courses for graduates are economically sound. They open the way for many young men to learn things they could not otherwise afford to study.

I believe that the future trend of these evening courses will be to include many more civic and cultural subjects that will make the engineer a better citizen, a man of affairs rather than a technician. It is only after an engineer has begun to carry business and family responsibilities that he can put to use a knowledge of law and accounting, or of history and government, or indulge his tastes for art. He should study these things after college, therefore, rather than postpone his technical courses on their account. The largest field of future service for the colleges may be the civic and cultural education of mature and busy men. If the colleges undertake this work, the professors will gain a far better understanding of business economics, and the business men will lose some of their commercialism, to the great benefit of us all.

F. R. Stansel (Bell Telephone Laboratories, Inc., New York, N. Y.): As a recipient of the doctor of electrical engineering degree from Professor Beach's institution, I wish to express my gratitude for the opportunities afforded to me by the Polytechnic Institute of Brooklyn and to add a few observations from the student's point of view.

A year or two after graduation many young engineers find themselves faced with a dilemma. They realize that in any of the fast-growing fields of engineering, the basic training acquired in their four years of undergraduate study is insufficient, but they often feel that it is impractical for them to now leave their jobs and go back to school for advanced training. Besides the obvious reasons of money and family relations, there are many other considerations including the realization that industry itself is a vast school. The engineer while realizing the need of more training in the basic principles for his future advancement, wonders if the training in engineering practice offered by industry is not of more immediate importance. Evening graduate courses of the type outlined by Professor Beach offer a solution to this dilemma, allowing the student to broaden his knowledge of the fundamentals and, at the same time, retain his position in industry.

From the financial angle, evening graduate study is peculiarly advantageous to the young engineer. The cost is automatically spread over several years without the necessity of seeking loans or scholarships, and the engineer is able to retain a job much more remunerative than part-time employment which he could obtain as a full-time student.

Professor Beach referred to evening graduate students as differing "from the conventional graduate student of the day session in a number of essential characteristics." One of the characteristics he refrained from mentioning, however, is the student's fatigue from having already accomplished a full day's work. Due to this fatigue, problems of classroom ventilation and illumination assume major proportions. Another great help in this matter of fatigue would be the more wide-spread use of mimeographed notes covering the more complicated mathematical formulas, and particularly drawings, thus relieving the student from acting as a transcribing machine, and allowing him to concentrate on understanding the material placed before him.

Finally, the picture of evening graduate study would be incomplete without a mention of one other group of persons—the wives and girl friends of the students. Many a graduate schedule has been completed only because of the unselfish willingness on the part of the student's wife to give up the companionship of her husband for one and frequently more evenings each week.

Robin Beach: The unusually large attendance at this meeting, as well as the active participation in discussion, both by members of industry and of the teaching profession, have clearly demonstrated the wide-spread interest in this field of graduate education through evening courses.

The general approbation of the progress already made by a number of engineering colleges in graduate study through evening programs of courses was indeed encouraging, and it should serve as a stimulus to those who contemplate entering this challenging field in the near future.

The author takes this opportunity to express his appreciation of the thought which has been directed to his paper by all of those who contributed so interestingly and so richly to this educational session.

Utilization Voltages

Discussion and author's closure of paper 42-69 by H. P. Seelye, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, March section, pages 147–51.

W. J. Russell (Westinghouse Electric and Manufacturing Company, Mansfield, Ohio): Mr. Seelye has made a very interesting presentation of voltage-variation data, which should be of considerable value to the industry. As manufacturers of domestic appliances, we would like to introduce a short discussion of the effects of voltage variation on small appliances (small portable devices).

The effect of voltage variation within reasonable limits on small appliances is, as a rule, of little practical concern. According to Mr. Seelye's investigation, the voltage range for appliance use is approximately 110–125 volts. Since most small appliances are now designed for 115 volts, the cases of underwattage will be less than those of overwattage. It is the former that is the basis for most customer complaints.

The trend toward automatic or thermostatically controlled devices has minimized the effect of voltage fluctuation. With automatic temperature control, sufficient wattage may be used to provide for proper operation under any normal voltage condition without danger of overheating on the higher voltages.

Nonautomatic devices are usually of lower wattage, and voltage variations are of more concern. However, we have found from long experience that cooking operations may be slowed or accelerated without harmful results within the range of known voltage variations.

The allowable wattage for standard wall receptacles is limited to 1,650, and, on some of the larger portable appliances, such as roasters, broilers, and double hotplates, this has caused trouble with slow operation when low voltages are encountered. However, improvements in efficiency have been made in the past few years which have largely overcome this trouble within the normal voltage range.

In the design of all appliances, sufficient factor of safety is included to take care of

voltage variations so that they will have little effect on the life of the device. Life tests on our devices are conducted on an average voltage of 125.

We believe that with the existing voltage range, as shown by Mr. Seelye's study, we should continue to use 115 volts as the design voltage for small appliances, inasmuch as with this voltage the slowing effects of underwattage are not serious, and the overwattage can be taken care of by proper design. An increase in the design voltage to $117\frac{1}{2}$ or 120 volts at the present time would increase the field complaints, particularly on nonautomatic devices, due to slow heating in cases where the service voltage is on the low side of the range.

C. A. Powel (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Seelye's paper is quite timely in view of the work being done by the joint EEI-NEMA committee on preferred voltage ratings on the revision of the 1930 report. His plea for a general conception of utilization voltages as a band rather than a fixed value should command attention. In the past we have spoken of "nominal system voltages" and "rated circuit voltages"; it would seem desirable to revise this idea and speak only of a "nominal system voltage," which would be expressed as a band or would be understood to constitute a band, leaving the term "rated voltage" to be applied only to the equipment used on a system of the corresponding nominal voltage. There appears to be no good reason for having a single voltage value assigned to a system, particularly since it is admitted that of necessity we cannot select any such value which will be correct for all parts of the system of a given voltage class.

Utilization appliances must, of necessity, be given a single voltage rating at which their performance is specified, but, to a large extent, they are self-compensating and will give quite satisfactory performance over a fairly wide range of voltage variation. The life of the appliances is also not noticeably affected by reasonable voltage variations.

In regard to the lamps, it is desirable to keep down the number of special lamps which have a relatively small market. Orders for small quantities of these special lamps are quite burdensome to the manufacturers in that the stoppage and adjustment of equipment required for their manufacture interrupts and delays the production of higher-demand units. Moreover, they constitute a problem in that stocks have to be maintained in most cities and towns.

A. H. Kidder (Philadelphia Electric Company, Philadelphia, Pa.): Those who are interested in utilization voltage problems are especially indebted to Mr. Seelye for his progressive contributions and for his preparing so fine a review of the work. There are only two points which I think may deserve more consideration than has been given in the paper. The first is the effect of emergency operations upon supply voltage, and the second is the problem of the odd ratio.

Emergency Voltage

Provision for motors to start at 90 volts was made a part of both the maximum utilization voltage spread and the preferred voltage spread for residential customers. The need for the provision is not self-evident, and I do not recall mention of it in the paper, for the summary shows the maximum voltage drops in normal operations alone, as reported by the 14 companies. With the increasing dependence of customers upon continuous electricity supply, the time has come when emergency operations generally satisfy the need for at least partial service restoration, long before it is possible to complete the repairs necessary to restore normal conditions. When the supply to a distribution circuit has been interrupted, therefore, it is usual practice to transfer the load to adjacent circuits, if possible, and to supply it in the meantime, despite a possibility of low voltage.

To illustrate, assume that the normal voltage drops are the minimum values given in the author's table; that is, $2\frac{1}{2}$ per cent in the transformer, 2 per cent in the secondary, and 7.5 per cent total. If it is then assumed that the last transformer has failed on the circuit illustrated in Figure 3 of the paper, and its load has been transferred temporarily to the adjacent transformer, it will be seen that the load on the adjacent transformer will have doubled while both the circuit length and the load will have become three times normal in the secondary branch that is used to pick up the load which had been lost. Under this emergency condition, the voltage drop in the transformer would increase to 5 per cent and that in the secondary would increase to 18 per cent (2 per cent $\times 3 \times 3$), or an overall increase of $18\frac{1}{2}$ per cent above the $7\frac{1}{2}$ per cent normal voltage drop. In a system designed for 125 volts maximum, the refrigerator or oil-burner motor whose thermostat calls upon it to start under such conditions would have not much more than 90 volts. There are, of course, many possible examples, but this one is thought to be sufficient to show that secondary design for greater voltage drop probably requires provisions for dividing the load of the circuit in trouble between more than one adjacent circuit, if the load at the time is sufficient to require the additional emergency load transfers. Because urban distribution designs more often observe the limitations imposed by emergency rather than normal operations, it is quite natural that the normal voltage spread in urban distribution, and particularly in networks, may be somewhat less than in suburban distribution.

Odd-Ratio Utilization Voltages

Figure 4 of the paper illustrates very well the nature of voltage spread for even-ratio equipment under normal operating conditions at even-ratio voltage. It does not, however, represent the much wider range of voltages which is faced by even-ratio equipment on circuits which supply either even or odd-ratio voltage—a situation the paper mentioned very briefly in the comments on 240-volt equipment. Motors are now almost the only utilization equipment which has not been made altogether adaptable to odd-ratio supply. Since the odd-ratio circuit is not yet used extensively outside of urban areas, it may be well to consider the problem in terms of the urban voltage spread of Figure 4, which needs only to be extended, in the accompanying chart, to illustrate the place in which even-ratio equipment finds itself on the odd-ratio urban circuit. For this purpose the reference point is taken to be the average voltage for the even-ratio connection on the odd-ratio circuit, and all deviations from that average are expressed as percentages.

From the above illustration it will be seen that the even-ratio motor, which is required to operate interchangeably on either even-ratio or odd-ratio voltage, must be prepared to meet satisfactorily a voltage range of +5 per cent to −18 per cent or a range of voltages up to 1.28 times the minimum odd-ratio voltage in urban distribution of the characteristics represented by Figure 4. This range is about midway between the 1.24 range, from 197 to 245 volts *preferred*, and the 1.30 range, from 193 to 250 volts maximum which the author mentions as being considered for such motors. All of these ranges are greater than that of 1.22 between the 90 per cent and 110 per cent limits established in the American Standards for Rotating Electrical Machinery, as being the allowable variation from rated voltage for motors. The American Standards must be revised, therefore, to permit use of any range greater than 1.22, no matter how carefully the rated voltage may be selected. Provision in the American Standards, for a greater voltage range (and retention of the standard "208-volt" single-phase motor line for difficult odd-ratio situations) seems to be the only practical solution to the odd-ratio problem in single-phase motors for which some such compromise solution seems to be inevitable.

On the other hand, discussion of the odd-ratio problem in three-phase motors has led to the suggestion of a possibility that the speed-torque-excitation characteristics of such a motor can be made to be exactly reproducible when it is supplied from any three-phase circuit connection that happens to be at hand, be it even or odd-ratio volt-

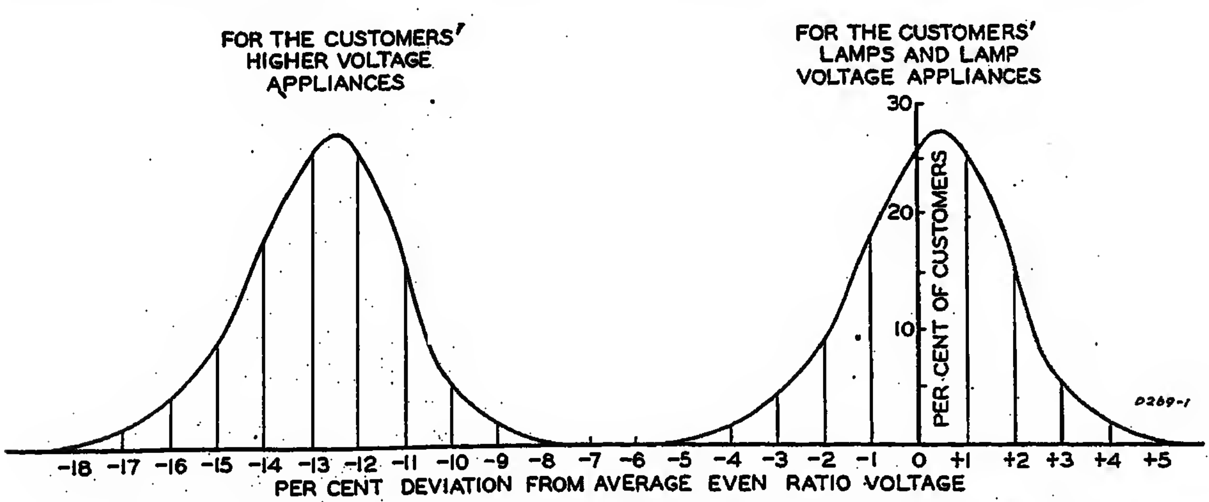

Figure 1. Illustrative distribution of voltages supplied by the odd-ratio urban circuit

age. It may, therefore, be possible that the odd-ratio problem in three-phase motors is susceptible of an exact, rather than the compromise solution necessary for the single-phase motor. If an exact solution should be found to be practical, there would appear to be no justification for adding any special, approximate, or halfway measures to the present American Standards for three-phase motors.

The proponents of an exact solution for the three-phase motor argue quite convincingly that the differences between even-ratio and odd-ratio voltages in three-phase circuits are due entirely to differences in the coil connections, which could be adjusted almost as easily in a suitable motor as in its supply transformer. They point out that the exact solution can be attained by building the present so-called "208-volt" line of motors with the same number of coils and only two more taps than are standard in the present line of 220-volt three-phase motors. With such connections the motor could be connected so as to have exactly the same performance characteristics on each one of the three possible three-phase secondary distribution voltages: lamp-socket voltage, twice lamp-socket voltage, or odd-ratio (1.73 times lamp-socket voltage), as the case may be.

Such a motor, if practicable, would be seen to include one connection which is so nearly 110 volts as to make it quite probable that the now separate standard 110-volt line of three-phase motors could be discontinued altogether. It would also have the advantage that the American Standards for Allowable Variation from Rated Voltage for Motors would not need to be revised, except possibly for the special case of the single-phase motor. I believe the suggestion may be worthy of more serious consideration than it seems to have received.

Hamilton Treadway (Rural Electrification Administration, Washington, D. C.): The problem of standardization of utilization voltages presented by the author becomes critical in the development of large rural systems spread over several hundred miles. In such systems the spread in voltage must necessarily be wider than in the urban and suburban communities or even in the near-by high-density rural area. As the rural area becomes thinner, the economic gains to be realized by closer voltage control are much smaller. The difficulties in standardization of utilization voltages consequently are increased.

This suggests another approach to the problem; namely, voltage co-ordination. By voltage co-ordination is meant co-ordination of the appliance rating voltage with the voltage prevailing at the consumer's outlets. Approaching the problem from this angle would suggest perhaps three or four utilization voltage spreads to be used by the manufacturer, for example 105 to 115; 110 to 120; 115 to 125; and 120 to 130. This may require a change in our fundamental thinking and may place a greater burden on the supplier of electric service to advise the consumer of the proper appliance voltage rating to be used on his premises. Whatever change may be required in this direction, it is probable that voltage co-ordination lends itself more readily to supplying adequate and efficient service than does the establishment of a single utilization voltage spread.

In light of the author's figures on over-all voltage spread, it appears that the trend toward the purchase of 120-volt lamps might well be reversed if economic light production is to be obtained by the consumer. Undoubtedly the real reason for the past and present trend is not so much due to a difference in the schools of thought on the proper voltage at which to operate incandescent lamps as to a lack of information in the hands of the user on the most economical voltage at which the incandescent lamp should be operated. There is likewise a similar lack of knowledge on the part of the consumer on the most economical voltage at which to operate other appliances. A program of system voltage co-ordination is again the suggested solution.

Approaching the problem of utilization voltages from the voltage co-ordination view should permit the manufacturers to design more efficient appliances for consumer use. It should also reduce investment in lower consumer density areas without impairing the quality of service rendered. Of course the need for a narrowing of the utilization voltage spread throughout an operating system and particularly between systems cannot be overemphasized.

Howard P. Seelye: The fact that the discussions of this paper which have been presented contain very little criticism would seem to indicate quite general agreement on the main ideas offered, namely, the need for standardization of utilization voltages, the desirability of considering the voltage standard as a band of voltages rather than a single voltage, and the specific values suggested for that band. Only one, Mr. Treadway's, proposes the very different approach of setting up a multiplicity of bands. As a general practice, however, this would seem to be a step backward, adding confusion and hence cost in manufacturing and distributing appliances. The survey of operating systems and the fact that service conditions are, in general, quite satisfactory does not indicate that any such step would be justified.

Mr. Kidder's analysis of the operation of even-ratio equipment on odd-ratio systems is logical but does not take sufficient account of the fact that odd-ratio systems, being essentially three-phase, four-wire, are almost entirely confined to areas of high load density where the voltage is well regulated. The minimum voltage is likely to be 115 volts or more, giving at least 200 volts for the three-phase motors. Past practice has shown that 220-volt motors have, in most cases, had little difficulty in operating as such voltages. There is at present no evidence of any tendency toward the spread of the use of odd-ratio systems to more lightly loaded areas, although, of couse, it cannot be guaranteed that this will not occur eventually.

Mr. Powel brings out a point which was mentioned in the paper but which should be emphasized. It is necessary, of course, that any appliance have a voltage rating, designated as a single voltage, to which its other ratings and characteristics are referred. Such ratings may be different for different appliances. On the other hand, it is highly desirable for general use that a single name be given to the whole class of appliances which will correspond with that of the system on which they are used—in other words a *nominal* voltage, which could well be 120 volts in view of the preponderance of the 120-volt lamps. This nominal voltage would merely designate the standard band or spread of voltages and should not be considered as a mid-point, which would be actually $117^1/_2$, if the proposed spread is adopted. If voltage *ratings* for appliances can be made to coincide with the nominal voltage, possibly by giving a different tolerance for plus voltage than for minus, confusion would be avoided, but if this is not practicable, the nominal voltage should be emphasized for general use, the rating being relegated to an auxiliary position for technical purposes.

Overhead Distribution Systems in Wartime (42-45)

Discussion and authors' closures of paper 42-60 by Philip Sporn, paper 42-62 by L. R. Gaty, paper 42-42 by H. P. St. Clair, paper 42-61 by F. C. Poage and M. W. Reid, and paper 42-45 by Harold Cole; presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, March section, pages 105–07; 107–12; 112–17; 117–22; 123–6.

B. M. Jones (Duquesne Light Company, Pittsburgh, Pa.): I can assure you that Mr. Sporn's paper covers many ideas that are really worth-while and that will help the utility people with their problems in these trying wartimes. We in our company have been using many of the methods he calls attention to. Appreciable reduction in material requirements has been obtained by the methods I will mention.

Sacrifice in Voltage Rendered to Customer

We have been maintaining a very good voltage range which was a rather narrow band in most cases, on a peacetime basis, but we found that we could let the voltage drift in many cases and still render *usable* voltage to the consumers. Actually, in

many cases we changed the transformer taps at the industrial consumer's plant to raise the voltage to compensate for the increased load on *his* distribution system. This is not necessary normally and, in some cases, does raise the light-load voltage somewhat, thus providing a wider band of voltage. Entirely satisfactory performance has resulted from these changes, and system changes have not been required, nor have any materials been required.

On the distribution feeders with feeder regulators at the supplying substation, we have in the past been increasing their voltage range from five to 10 per cent to stay within a narrow band rendered the consumers, but now, in some cases, we are not changing the regulators for voltage reasons and are letting the voltage drift a little during heavy load periods.

In our state (Pennsylvania) we have certain voltage limits prescribed by the Pennsylvania Public Utility Commission. We are well within these limits and in peacetime have spent money and performed construction and used materials to keep the very narrow band of voltage even above such requirements. Now we are permitting the voltage to approach the commission requirements before we use materials to improve service.

Relative to loading of equipment we have been crowding our equipment for the last few years and have been doing considerable research work to discover means of crowding it still further. We have determined individual ratings for power transformer banks in transmission substations and in distribution substations, and also for induction feeder regulators, both indoor and outdoor, and we find that a considerable increase in capacity can be obtained by operating these pieces of equipment on the thermal basis governed by the particular load cycle. We discovered that this would relieve our material requirements appreciably, as well as save the man-hours required to design and construct new installations. Ventilation is a field well worth exploring, and our experience has been that this is well worth any research work that you do. It is surprising how little *air movement* is required to get an appreciable increase in capacity. We also find that you will probably have to do a considerable amount of local research, due to the particular conditions surrounding your equipment, such as age, conditions of equipment, natural ventilation, indoor, outdoor, load cycle, and so forth.

Similar investigations have been going on on overhead lines and underground cables, and appreciable increases have been developed.

Emergency Conditions

Naturally, the same amount of reserve and emergency cannot be provided in wartimes as in peacetimes, because of the scarcity of materials and man power, as well as the lack of time to provide said reserve. Normally, of course, all of us try to render good service under the most extreme adverse conditions, but the ability to do so has gone "since Pearl Harbor."

To build two lines and provide two transformer banks to industrial customers, in most cases does not appear to be justified, and I suspect you would have a hard time getting an approved priority application to provide for this reserve. However, this does not mean that we should sacrifice on the quality of design or the strength built into the installation. Because of the fact that there is some reduction in reserve, the design should be at least equal to the good old peacetime quality if possible.

I seriously question the advisability of providing reserve, in many cases, for breakdowns which can be repaired in a relatively short time, such as a transmission-line burndown, which can be repaired in a matter of 8, 24, or 36 hours. Of course, such cases must be tempered by the business of the customer, for an interruption to a plant which merely curtails production, where production can be resumed practically immediately upon restoration of power is one thing, whereas an interruption to a plant where curtailment means considerable loss of material and requires a large amount of time to restore production, or endangers the lives of a large number of employees (such as coal mines) might require some degree of reserve over and above others.

Materials

The utilization of different materials from what you would normally use is necessary, of course. We must use wood structures if we cannot get steel; we must use different size and type transformers if we cannot get what we want to have. We must use the different type and styles of circuit breakers with necessary control interlocking and sequential relaying schemes to keep the duties within the capacity of the breakers; we must use fuses instead of breakers if we don't have the breakers. By and large, we must use materials that we have or can get, and must not make our material requirements a burden on the already overburdened material situation. Some suggestions have been made that the excess materials (if any) among utility companies and others be pooled and used where most urgently needed. This, of course, is merely good sound horse sense necessary to help win the war, which we must do.

Planning

All planners, particularly in utility companies, must plan the system in an entirely different manner, generally along the lines outlined above, and our company has been doing this for quite a while, and we find that it is satisfactory. Of course, we are going to get complaints here and there due to outages, low voltage, flickers, and so forth. Such complaints will just have to be tolerated where their correction cannot be justified under present conditions. Of course, too many complaints or too serious a complaint must be taken care of.

We may have to tolerate voltage flickers to a greater degree, even to the point where they are slightly objectionable to lighting consumers, but if too many objections are made, the voltage flickers will have to be corrected.

Load Shifting

Load shifting to ease the burden of demands on equipment is a possibility, and individual systems will have to investigate and see what can be done. Obviously spreading the same loading over twice the time reduces it in half, but this is merely academic and not practical. You can really shift the peak load on an electric utility system by staggering working hours in different manufacturing plants, or by shifting some of the day work to night work. Curtailment of nonessential loads is also a fertile field which, I believe, will be cultivated before the war is won.

While these comments are directed to Mr. Sporn's paper, some of them apply to companion papers presented at this meeting, particularly those of Messrs. St. Clair and Cole.

Conserving Equipment Necessary

I was particularly interested in many points brought out in Mr. St. Clair's paper relative to loading the equipment to the absolute safe thermal limit, and even beyond, to some extent. In these wartimes we have to sacrifice some life of the equipment rather than to replace it with larger equipment, or to consume materials needed elsewhere in order to manufacture this larger equipment.

Our company has been doing many of the things Mr. St. Clair mentioned, and we have had particularly good success with them. We are just purchasing a 3,000-kva portable substation, 22/4 kv, for use in emergency and for maintenance and repairs. The secondary of this transformer has various voltage combinations which will permit using it on many installations. Actually, as a result of this portable substation being available soon, we have curtailed the amount of transformer capacity installed in some of our newer semirural districts—all at an appreciable savings in capital investment and in savings in materials.

Switching Equipment

I can assure you that considerable economies in investment and materials will result from the selective relaying, wherein a group breaker is tripped instead of the replacing of individual feeder breakers with larger ones. We made a very careful analysis of this some years ago, and the evidence disclosed that there were very rare instances wherein the failures occurred at locations which would produce short circuits in excess of the small feeder breaker capacity, and, therefore, such group breaker tripping would not affect service adversely except in very, very rare instances. We have, therefore, been employing this practice with marked success for a number of years, and just last year we finally completed this selective relaying scheme in our four-kilovolt distribution substations. In fact, I am very glad we did, for I doubt if we could obtain larger breakers.

We have also adopted sectionalizing tripping for larger transmission substations, which means that the bus tie breaker or breakers are tripped first and practically instantaneously, and then the individual line breakers are well within their capacity. This latter feature has been in force on our system for 10 or 12 years.

Relative to tapping transmission lines with distribution substations, we believe that this is an excellent plan for curtailing expense and material requirements. We have just recently installed a 4,000-kva, 66/4-kv distribution substation and con-

nected it onto our 66-kv transmission ring, because we had no 22-kv line anywhere near the proper location for the new substation. This has worked out quite satisfactorily, even though we did encounter considerable opposition in our own company to connecting such loads onto the so-called "sacred" transmission ring. However, economies justified it, and we had to proceed with it.

Certain benefits, of course, have resulted from the revising of our operating practices, particularly with reference to taking equipment out of service. We just do not take it out of service now until we absolutely have to do some work on it.

One comment on Figure 3 might be of interest. A modification of this would be for the step-down bank and the four-kilovolt bus to be in the same location rather than 0.7 mile apart. We have several of these substations, one at 66 kv, as referred to earlier, and several relatively similar to this at 22 kv. We have installed on the high-voltage bus a single-phase grounding disconnecting switch, which is actuated by the differential relays and upon their operation, actually places a ground on the high-voltage system. This is done, because a fault on the low side of the bank, but not within the area of the differential protection, might be of such low magnitude, particularly where the bank is small, that the high-voltage transmission-line relays at the nearby substation would not get sufficient current to operate. We developed this switching method in our own laboratory and made several trial installations and put it through its paces. We found it quite satisfactory and have been using it for some time.

Harold Cole (The Detroit Edison Company, Detroit Mich.): I want to describe a method of reinforcing a subtransmission system to enable it to supply increasing loads, a method which The Detroit Edison Company has recently applied to good advantage, and which may have application to other systems. We are just completing the changeover of the transmission network serving nearly half of our total service area from 24-kv to 40-kv operation. This changeover is being made at a very low cost, considering the increased capacity obtained.

The conditions were, of course, very favorable to the adoption of this scheme. The area involved, the so-called "Thumb" district of Michigan, has a low-load density, and the load growth will probably be slow. The distance from power sources to the extreme limits of the area are over one hundred miles, and voltage regulation had been a serious problem for several years. All substation transformers in the area were connected delta-delta, and about the only expense involved in changing to a wye-delta hookup was the cost of changing bushings. Circuit breakers at switching stations in the area had to have new bushings and be modified to obtain higher interrupting capacity and better clearances. Very little line reinsulation was found necessary for operating at the higher potential. Autotransformers were purchased to step up the voltage at the points of connection between the 24-kv and 40-kv system. These have a low impedance, so that the total over-all regulation of transformer and line will be improved as much as possible over the regulation of the lower voltage line alone.

As a result of this change, the lines in this area can carry more than twice the load they formerly carried before reaching limits of voltage regulation. The cost of making the change is much less than any other of the possible expedients studied, although some of the other expedients would have made possible a greater increase in load. If it becomes necessary later to reinforce the supply to this area, however, the higher subtransmission voltage will be very helpful in keeping line costs to a minimum.

We are now planning to use this same method of increasing line capacity to take care of new defense loads coming on in several suburban areas where distances from supply sources are too great for economical supply at the 24-kv level. The savings in the use of vital materials are obviously large, and if, as in our case, ways can be seen to fit the autotransformers required into the future changeover of a large portion of the suburban system to higher voltage levels, the scheme has great possibilities in contributing to the war effort without any great sacrifice in ultimate economy.

G. H. Fiedler (Rochester Gas and Electric Corporation, Rochester, N. Y.): I have reviewed Mr. Cole's paper on "Overhead Distribution Systems in Wartime" which I think is very timely.

We have found that a considerable amount of conductor could be saved by running two-wire services rather than three-wire, unless the customer has equipment which actually requires 240 volts. It has been our policy for many years to install three-wire circuits if a residence had four or more lighting circuits. We are still encouraging the installation of a three-wire riser and distribution panel for these customers but are extending only two service wires at present and installing two-wire meters. In some instances, the extension of the third secondary wire is saved, and to date we know that several thousand feet of conductor have been conserved on services alone. Very few voltage complaints have resulted and we intend to continue this practice until critical conditions are relieved.

G. S. Van Antwerp (Philadelphia Electric Company, Philadelphia, Pa.): Mr. Cole is to be congratulated for having stated clearly and concisely the principles that must be observed in extending and maintaining overhead distribution systems with smaller amounts of critical materials. It is difficult to believe that anyone can object to using any or all of these methods where at all applicable to his individual problems. With a reduced and limited amount of material available, either new or reclaimed, there is set up a real challenge to line departments.

Should we leave customers "out of service," because there are no bright and shiny arm braces, guy clamps, secondary racks, splicing connectors, guy rods available? Or shall we straighten the bent and dirty braces, hand-serve the stranded guy wire, use a wood bracket or arm in place of the rack, make up a wrapped joint for the connector, forget the guy rod and run the guy wire to a buried dead man?

It is a fine feeling to get a supervisory group together, enlist their enthusiasm, patriotism, loyalty, and co-operation to carry out a program such as this. But what a different reaction one gets "near the belt line," after finding that the fine words and elaborate procedures still build scrap piles of reusable materials—mounds of good intentions gone wrong.

Sell the supervisory group, yes, but that is not enough. Before positive results can be achieved, the man on the job, the layout man, the estimator, the storekeeper, the foreman, the lineman, and the lowly helper must be with you and Uncle Sam. That's where they want to be—helping; so give them a chance. Not only will they show you more ways of saving materials, but I suspect they will fight for reclaimed materials to—

Keep those kilowatts rolling!

Floyd M. Fuller (Pennsylvania Power and Light Company, Allentown, Pa.): To a distribution engineer of an operating public utility, the papers presented are very interesting reading, as describing current good practice which, no doubt, is being followed by many engineers.

All distribution engineers know, either from experience or from rules promulgated by governmental bodies, the limitations in regulation, and from their executives, the continuity of service required. In most cases limits of construction are imposed either by regulatory bodies or "codes" which, in many cases, are now used as the standard of construction. These restrictions have been imposed upon the distribution engineer in his practices, and we all know how difficult it is to change such codes and regulations.

As an organization why cannot we take some action and take it promptly to obtain a relaxation of present requirements. For example, in the Commonwealth of Pennsylvania voltage regulation must not exceed plus or minus five per cent of the standard voltage. If this is exceeded, and all of us in the industry know it may be exceeded to a certain extent, why not have the regulations waived for the duration, as long as the customer can live with the regulations Another example is guying over railroad and telephone facilities where electric lines, except for the lower voltages, are able to be installed with guys having a factory of safety of three, which in our estimation is excessive.

For improving the voltage, Mr. Cole, in his paper, very wisely stresses the need of saving material in new construction and the use of regulators, boosters, and capacitors. He might also to good advantage have brought out in his paper the benefits accruing from increasing the voltage. In the case of changing from a three-wire 2,300-volt to a four-wire 4,000-volt system using a common neutral (in many cases the existing secondary neutral), very little material will be required, in fact a lightning arrester and fuse cutout will be salvaged from each single-phase transformer installation and this increase in capacity may eliminate the need of replacing existing conductors with larger ones to provide additional capacity.

Similarly increased capacities may be obtained by changing from 6,900, three wire, three phase to 12,000 volt four wire, three phase without replacing transformers. It may also be advisable in certain cases to

obtain the additional capacity by converting a system from 2,300 or 4,000 to 12,000 volts.

Another way to conserve in material is in street lighting: where the work is necessary and justifiable. By the installation of modern luminaires, having double the efficiency of the old equipment and using higher mounting heights, one-half the number of lights now existing on the boulevard standards can be installed, and the old obsolete equipment salvaged for defense.

The distribution engineer can and will change his practices in the interest of the conservation of material, but he could go much further in such conservation, if the walls of regulatory bodies and the requirements of reliability of service are lowered for the duration of war. An earnest request is made at this time that suitable action be taken by our officers with this in view.

H. E. McDowell (nonmember; Ebasco Services, Inc., New York, N. Y.): In the several papers, pages have been devoted to stating the problem and the conditions that are responsible. Simply stated: Many of our systems are short of capacity in certain respects or locations. There is a shortage of materials. Hence, the utilities will have to get themselves out of their predicament as best they can.

Bench Marks

Occasionally, one hears about the bold and courageous steps that must be taken to meet the present emergency. Without any desire to disparage the thought, it might be considered that many, if not most, of the measures that have been suggested will closely parallel practices that are characteristic of companies whose finances never have permitted gold-plate or chromium trim. Bold practices in the eyes of some are but customary in the eyes of others.

Select Plans That Have Multiple Advantages

It should be obvious that the times call for extreme simplification. Further, it is not too late to work toward a higher degree of standardization. This refers to practices, basic designs, flexibility of application, rather than to detailed specifications.

Whereas this discussion represents no attempt to boost the fortunes of the manufacturers of capacitors, it is worthy of consideration that the capacitor presently is the most useful article for increasing system capacity, improving voltage, or providing load relief that can be obtained on short delivery. It carries the advantages of *multiple uses*, referred to above, as well as the benefits of mobility or salvageability, means of reducing system losses—all being things that you are familiar with but which you may not have added up. It is well nigh axiomatic that a company cannot make a mistake in buying somewhat too many capacitors so long as its load is growing. They unquestionably have a great variety of uses.

A recent example that will illustrate the point is that of a company short of generating capacity, this being due in part to lack of reactive kilovolt-ampere capacity in its generators to supply lagging components of loads, together with the necessary reactive required to import available power from neighboring systems. In order to release this "captive" kilowatt capacity, amounting to some 15,000 to 20,000 kw, plans were made to install 35,000 kva of capacitors. At the same time, load growth generally had been such as to require load relief on approximately twenty four-kilovolt feeders. This would involve under usual practices a considerable construction program, including new feeders and allied improvements. The installation of capacitors, which were fully justified by virtue of salvaged generating capacity, so altered the program for distribution-system construction that but one new feeder became necessary, the remaining program consisting of shifting feeder regulators, installation of automatic switching on certain groups of capacitors, and other minor improvements. Cash required for the distribution-system program, exclusive of the capacitors which were justified by reason of generating capacity salvaged, was a fraction of that which otherwise would have been required. The saving in use of critical materials was in like proportion.

Another case in point involved the installation of condensers, capacitors, or both, to strengthen transmission channels to a large section of the company's territory. Choice lay between 15,000 kva of condenser capacity, 15,000 kva of capacitors, or some combination of the two. The selection made was one 5,000-kva condenser and 10,000 kva of capacitors, most of the capacitors being installed on distribution circuits (voltage regulation being largely controlled by existing synchronous condensers). The net result so far as the distribution systems were concerned was to obviate any general improvements to take care of the substantial load increases experienced.

Make Due Allowance for Flexibility in Planning

Planning with an eye to future changes or growth always has been smart—how much more so when conditions are changing with such rapidity now! This refers not to overbuilding but to:

1. Provision of ample ground space (usually a proportionately small item of cost).
2. Flexibility of arrangement of structures, circuits, and so forth, for easy rearrangement.
3. Mobility of equipment. The accomplishment of these objectives is a matter of skill rather than of free use of money.

Maximum Use of Transformers

The writer questions whether due emphasis has been placed upon the possible benefits to be derived from paralleling distribution transformers as to capacity saving, voltage improvement, or both. The majority of utility companies in this country has been reluctant to adopt this method of operation, but the writer calls to mind a company that has for more than 20 years judiciously, but quite thoroughly, pursued this practice with entire success. This company operates in a metropolitan area and is in the class that at least enjoys a modest amount of "chromium trim."

Considerable discussion has been given to more thorough utilization of substation transformers. The writer calls to mind one company that averaged between 300 and 500 individual transformer shifts each year during a period of several years when load growth was rapid. Perhaps that might be charged to poor judgment or planning, but that particular system always enjoyed an exceedingly high degree of utilization of all of its components.

Elimination of Nonessentials

It is perhaps trite to say that the way to save materials is to exclude nonessentials, but there can be little question that an astounding saving could be made by eliminating from the conventional systems those gadgets that the simplest systems do not have. This reference in the main is to certain classes of apparatus that have for their justification service improvement. It is suggested that a good start on such a policy might be a visit to some of the poorer country cousins.

Salvaging Operations

But few companies have indulged in a comprehensive way in salvaging used materials. Such companies as have done so justify the expense in part as an offset to pensions and by the greater satisfaction and happiness to old employees in being usefully occupied rather than idle. It would seem that all companies in the present circumstances are duty-bound to embark on a thoroughgoing salvage program, and they might well do so with an eye to its available "pension" features.

R. G. Hooke (Public Service Electric and Gas Company, Newark, N. J.): About three weeks ago, at the request of the power group of the New York section of the Institute, I gave a paper on "Wartime Electric-System Planning in a Major War-Industries Area,"[1] and the remarks which I wish to make by way of comment on the papers presented this afternoon are supplementary thereto.

First, as to methods of limiting the short-circuit duties on oil circuit breakers, there are two suggestions. We have for many years resorted to sequential tripping of breakers on substation transformers in cases where the breaker on one side was likely to be overstressed, while the switch on the other side was adequate. More recently, in a particular situation, we have effected a major postponement of investment by adoption of a plan to operate with a tie circuit between two substations, open at one end under normal conditions. This involved two substations each supplied by four or five 13-kv cables and with a tie line between, which under normal conditions is only lightly loaded. The addition of several thousand kilovolt-amperes in war demands to one substation necessitated installation of a new transmission line, which in turn increased the short-circuit duties on the breakers beyond the values considered safe. Since the tie line between the two substations delivered heavy short-circuit currents in either direction, due to the many feeds to each substation from the source, and since it is an important part of the transmission network only when a circuit to one group or the other is unavailable, it was decided that under normal operation it might be left open at one end; in case of a fault, this end would immediately be closed. After the fault, with one line in the network

from the source out of service and the tie circuit in, duties on the breakers were just within rating.

There are three schemes for avoiding investment in the circuit breakers which would ordinarily be considered necessary with increasing loads. All of these involve using available breakers with paired connections to them. Substation transformers may be paired on one breaker on each side with disconnecting switches, the arrangement being such that in case of a transformer fault, a defective unit can be disconnected, and the other quickly restored to service. Meanwhile short-time emergency ratings on other available transformer banks would be recognized.

While we feel we have overcome the likelihood of simultaneous outages of open wire circuits on one pole line, due to lightning, we have not found any means of controlling the auto driver who occasionally takes down our poles. It has, therefore, been our policy to provide in any transmission network for complete loss of any pole line. From this it follows that, if new transmission is needed in a network containing two circuits on a pole line as the maximum outage to be provided for, we may save the installation of switches for the new line by pairing the two open wire circuits on one switch at each end. By doing this we have lost nothing in firm capacity to the area, and if disconnecting switches are installed at the terminals of the paired lines, the loss of flexibility in the transmission system is almost negligible.

In other cases we have found it economical to pair on one breaker at each end small-capacity transmission cables, when a new circuit to the substation is required, and when the capacity of the new circuit is approximately equal to the sum of the capacities of the two lines to be paired. This same policy has been followed in situations where added load in future is expected to be handled by an increase in transmission voltage, thus making it desirable to prevent installation of more breakers than will be needed when the voltage change comes about.

In the matter of investment in transformers, our experience like that of most other companies, has been that failures almost never occur, and that, consequently, every means should be employed to secure higher average use of the units without jeopardizing service, in case one should be unavailable for a brief time. About two years ago we accepted emergency ratings based on 115 degrees centigrade maximum hot-spot temperature. We have also investigated each substation to determine the frequency of high loads and established a "probability allowance factor" for transformer ratings, based on the relative infrequency of occurrence of high peak loads. For example, in a residential area that peak load may occur only on Christmas or New Year's Eve. In such a situation, the probability of concurrence of peak load and transformer outage is very remote. We, therefore, consider that an increased emergency rating is justifiable, recognizing that if a fault should occur at the peak time, we would abnormally impair the life expectancy of the transformer.

We are very much interested in this matter of equipment life and have recently carried out some studies for transmission, similar to those discussed by Mr. St. Clair for transformers. The problem, of course, is to balance the annual cost of new investment against the increased maintenance costs and retirement charges which will result from emergency operation at higher temperatures. It will be found that, in a great many cases, the investment required, if operating temperatures are to be held down to present accepted values, is far more costly than is the higher maintenance and retirement cost which results from higher temperatures and shorter life.

In the transmission system, many of our circuits are limited in capacity by short sections of cable at the ends. Where the lines are short so that voltage drop is not a problem, we have found it highly economical to increase the capacity by either replacing cable sections with cables of larger size, or by putting in additional cables and pairing them at the ends with the present ones, so that one open wire circuit may have two cables in parallel wherever underground construction is required.

By following these expedients and many of the others mentioned in the papers here this afternoon, we have since 1938 expanded our system to meet a 37 per cent increase in peak demand at a total over-all cost from coal pile to customer's meter approximately equal to what, 15 years ago, was considered a reasonable charge per kilowatt for a new turbogenerator.

REFERENCE

1. WARTIME ELECTRIC-SYSTEM PLANNING, R. G. Hooke, E. C. Plant. ELECTRICAL ENGINEERING, volume 61, April 1942, pages 192-6.

E. V. Sayles (The Commonwealth and Southern Corporation, Jackson, Mich.): The five papers dealing with the effect of wartime construction and operation on electric distribution systems should prove to be of much value, if reviewed and studied by engineers charged with the design and operation of electric systems. While much of the material presented constitutes a review of practices, some of which have long been in common use by some companies, it is doubtful if all companies have employed all of these suggestions to the fullest extent. Detailed study of these papers in the light of the present wartime status of the country should unquestionably be helpful.

It would appear that the greatest effect of war on construction programs for transmission and distribution systems is to change us from our normal basis of "economic design" to a new basis of "material conservation." Efforts to conserve materials can be carried to great lengths, and there is little question but that all construction should be carefully reviewed to insure the minimum use of critical materials. In the case of transmission and distribution circuits, this may result in the use of smaller conductors and greater energy losses than would be permitted from an economic standpoint. However, reduction in conductor sizes cannot be carried too far, because voltage drop immediately assumes control, although in many instances voltages may be permitted to be just a little bit lower "for the duration" than might otherwise be considered proper.

With the industry now confronted with carrying greater loads on electric distribution systems, one factor of principle importance—perhaps of greatest importance—is the inherent capacity built into distribution systems for the purpose of providing duplicate service to principal load centers, or for carrying these loads when certain normal facilities fail. For example, there are occasional primary distribution circuits supplied from one substation, which during emergencies can be served from another primary circuit supplied from another substation. In some cases there has been a tendency to keep these circuits lightly loaded in order that they could be used as tie circuits between these substations, in the event of failure of power supply to the distribution substations. While this is a frequent practice, it would seem that transmission-and-distribution-substation design should be such as to permit greater confidence in it, thereby releasing primary-circuit capacity for the supplying of greater loads. It will be recognized that this general philosophy can readily be applied all along the line, starting from the low-voltage secondaries up through the transmission systems. Perhaps a relatively small expenditure to improve the reliability of a single transmission circuit may obviate the necessity for construction of a duplicate circuit.

Each of these papers emphasizes the conservation of materials. This is particularly evident in the case of transformers and transformer loading—something which cannot be stressed too greatly. Mr. Cole has discussed this rather completely for line transformers and has referred to the ratio of demand on a circuit to the total installed transformer capacity. While it is true that this ratio is not a proper measure of loading of individual transformers, nevertheless, it is a figure which is readily available and, if used with discretion and judgment, may reveal a general condition of excess or possibly lack of line-transformer capacity. Obviously, if this ratio is 40 or 50 per cent on one primary circuit and 100 per cent or more on a similar circuit, an investigation is warranted, although such differences may be expected and justified on circuits serving loads of dissimilar characteristics.

Many companies have thoroughly studied the overload abilities of substation transformers in the light of load curves and have already taken advantage of increased loading of these power transformers, actually finding that loads in excess of name-plate ratings were not overloads at all. Excellent data are available regarding permissible loadings of power transformers, and a study of particular transformers may indicate that substantial overloads for short periods may result in no sacrifice in useful life or perhaps a small sacrifice which may be justified in the light of present conditions. In such analyses, proper allowances should be made for ambient temperatures at time of peak, possible low temperature rise of the transformer at full load as determined from original test data, possibilities of different types of forced cooling for short periods, and other factors brought out in these papers.

Mr. Cole has stressed the matter of secondary banking, and Mr. Gaty has called attention to the possibilities of secondary networks. Underground secondary networks have received much attention in the past few years, and their possibilities must be now generally appreciated. Much can

be accomplished with overhead secondary networks by occasionally banking transformer secondaries in the less populated urban areas to take care of spotty poor voltage conditions. There should be many opportunities where extending three-wire secondaries "around the corner" or installing a "couple of spans" to connect two small transformer areas may obviate the necessity of changing transformer sizes, establishing new secondary districts, or changing secondary conductor sizes. The results of such practice may be surprising. It would seem that much greater consideration should be given to a limited use of such "baby networks," particularly in view of the excellent service record of low-voltage secondaries, which, when properly installed, cause little or no trouble.

None of the papers has referred to the increased capacity of a distribution system which results by changing from delta to wye operation. The entire history of overhead distribution is intimately associated with the changing of distribution systems from 2,400 volts, three-wire delta, to 4,160 volts, four-wire wye, with a common primary and secondary neutral. Similarly, in recent years some 4,800-volt delta systems have been changed to 8,320 volts wye, and it has been common practice to change 6,900- and 7,200-volt systems for wye operation. In the case of transmission lines, additional capacity has been secured by changing 24,000-volt transmission to 41,600 volts, and so forth. In many cases, studies have been made to determine whether some of these changes could be justified economically, and, if adverse decisions regarding such changes have been made, perhaps they should be reviewed in the light of material conservation. Certainly the capacity of a distribution system can be increased substantially by such a practice without the addition of copper. In some cases, generating equipment, synchronous condensers, or large motors now in operation may make such a change more costly, but the possible reconnection of this equipment or the use of autotransformers may be feasible.

It would seem that in this series of papers there should be some reference to the service voltage furnished to residential customers. While two-thirds of the lamps sold in the country are rated 120 volts (indicating voltage levels based on 120 volts), many systems are still operated on a 115-volt base. Since many of the complaints about low voltage result from unsatisfactory operation of appliances, would it not be opportune in the case of so-called 115-volt systems to consider raising voltage levels to 120 volts? By so doing, an improvement of from three to five volts can be secured for all types of utilization equipment without appreciably increasing complaints of high voltage except possibly for lamps. The 115-volt lamps would, of course, burn out more rapidly, but lamps sold in the area would be changed to 120 volts rating, and the voltage levels could be raised gradually over a period of several months until the 120-volt level is reached. Therefore, it is believed that consideration should be given to this suggestion, especially in view of the recent utilization voltage recommendations by committees of the Edison Electric Institute.

Messrs. Poage and Reid have pointed out the desirability of power-customer co-operation to help reduce system peak loads. Power-customer co-operation should also be encouraged to the greatest degree in connection with the power supply to new plants and the facilities which a large power user should require in order to guarantee dependable service. Surely the transmission, distribution, and substation design engineers should be able to give these customers the benefit of much valuable advice in planning their substation facilities, to the end that much material and equipment can be conserved by simplified layouts, with due consideration being given to continuity of service. This co-operation might extend to helping the customer determine his own distribution voltage, type of switching equipment, and outdoor substation facilities with special consideration given to the kind of transformers used, their proper taps, the necessity for spare units, duplicate busses, duplicate metering, and so forth.

The use of automatically operated air-break switches to take the place of high-voltage oil circuit breakers as pointed out by Mr. St. Clair is worthy of much study by many companies. It is surprising how much can be done by properly planned installations of this type at enormous savings in materials used, cost of equipment, and time required for construction.

M. M. Samuels (Rural Electrification Administration, St. Louis, Mo.): The worst feature of this symposium is the fact that it did not take place three years ago or even five years ago, but I suppose that if it were presented then, the authors would have been called warmongers or even worse names, and possibly would have lost their jobs.

The symposium is certainly timely. The industry is struggling to keep up with production of additional generating capacity, even though some ostriches still claim that there is no shortage. There was no shortage of steel or copper either. Everything was lovely.

But very little has been said about a shortage of distribution capacity. These papers, indeed, present a very pessimistic picture, but in the last few months we have become accustomed and acclimated to pessimistic pictures. We got so that we can take it, and let us hope that we can take this one too.

The seriousness of the situation cannot be overemphasized. Reports from cities in which there is an enormous war activity indicate that distribution systems find it difficult to carry the existing loads, to say nothing of carrying additional loads, in existing industrial war plants and for war plants yet to be built.

Stretching will not solve the great problem of distribution capacity, particularly when the peak periods are no longer just 30 minutes or one hour but become four or five hours. We are in for a long war. Stretching may solve the problem for a very short time but not for a long time. When we get the additional generating capacity, the new powerhouses may be all dressed up with no place to go, because there will be very inadequate distribution. The problem must be considered as a part of our great war problem in general. No individual can decide or should take it upon himself to decide how important his activity is in the great problem of the war. This can only be decided by those who are responsible for running the war. If additional capacity is required to follow through with the government program of production, those in charge of running the war will have to see to it that this capacity is made available, and they will see to it.

Two years ago, before the Engineers Club at Raleigh, North Carolina (November 13, 1939) and again before the Florida Engineering Society (April 12, 1940), I spoke of "Power for National Defense" and had to be careful not to use the word "war."

I called attention to the need of preparing for this emergency. At that time many things could have been done by every utility that would have made the present problem easier. But there is no use of even talking about spilt milk. They just were not done, and it is never too late to start.

Mention is made in some of the papers of mobile substations as high as 15,000 kva. As an indication of how far behind we are in this respect from the viewpoint of a world war, I merely want to mention that in the London magazine, *The Engineer*, October 14, 1938, there is a photograph of a German portable substation of 100,000 kva, 220,000-volt to 10,000-volt, with all kinds of taps, and it was reported that the Germans had quite a few such substations. This is big-time power for war purposes, and we have to begin to think in terms of big-time power for war purposes.

Another item, a very important item, which is overlooked in all these discussions, and to which I called attention in North Carolina as well as in Florida, is the fact that in time of war, we must plan what we are going to do in case part of a power system is destroyed, either by enemies or by crackpots from within.

Nothing is mentioned in the papers about how the power that is left will be scheduled to the most important places, and whether or not the circuits are so arranged that they can be so scheduled. How will it be possible to bring whatever power is left to such places as hospitals, cold-storage plants, police radio, traffic lights, water supply, and so forth?

In case of a network, separate sources of supply to unusually important loads are very difficult to provide. I suggested on many occasions that every city, particularly those that have network systems, should provide themselves with a number of small mobile powerhouses that can run through the streets like fire engines and then bring power immediately to hospitals, first-aid stations, bomb shelters, and other such places. Very little has been done along this line, and it is never too late to start. One of the reasons, probably, why utilities did not take up the idea is psychological. Most of the small units are Diesel-driven, and the Diesel to a utility man has always been like a red flag to a bull.

To show what these little mobiles can do, I will recite an incident that happened only about a week ago. The army was about to start construction on a $26,000,000 camp and could not get a power supply brought it on time. One of the rural electrical co-operatives, quite a distance away, had 2,100-kw mobiles in temporary operation, pending completion of an incoming power circuit. The army asked for the mobiles to be able to

start construction. Everybody worked that night to compete the circuit. In addition, some complicated legal papers had to be made out. In spite of that, the mobiles were on their way next day and got to the army site ahead of time. I have been told that they were pulled on the highway at 50 miles an hour. You all know, of course, that the Germans and the English have hundreds of small mobiles. We, too, should have had hundreds of them by this time.

Mention is made in one of the papers of load-curve control. This, too, is a very important item that has received insufficient attention. According to the paper, the particular company has been able to secure voluntary co-operation of the customers to reduce the peak. It should be possible everywhere to secure such co-operation and reduce peaks, thus adding considerably to the capacity of the power system.

We hear so much lately about a kilowatt-hour shortage as against a kilowatt shortage. When you speak of water power, a kilowatt-hour shortage can only mean a shortage of water. We had that. If you speak of steam, a kilowatt-hour shortage may mean either a shortage of fuel or a low plant factor brought about by a high peak. By load-curve control, whether voluntary or by force, it should be possible to reduce peaks considerably, and when peaks are reduced, both generating capacity and distribution capacity can take care of more energy.

In conclusion, I may say that, based on the papers presented here today, immediate action should be taken by all utilities to correlate distribution to generation and transmission, correlate the whole system to the government war purposes, and co-operate fully with those who are responsible for running and for winning the war.

In time of war: "Our country, right or wrong." Always, why not: "Country before company"?

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): One of the main thoughts throughout the papers is to increase the loading on existing equipment in order to reduce sharply the amount of critical materials required for new installations. As indicated in my 1939 AIEE paper, "Load Ratings of Cable,"[1] we have been establishing since 1930 new and higher temperatures for emergency operation of various kinds of cable, in order to postpone installations of new lines. I have been actively interested in the matter of operation at high temperatures since about 18 years ago when I had something to do with the research on paper insulation at the Massachusetts Institute of Technology.

Nevertheless, I should like to call for caution and perspective on this whole matter of temperatures for transformers, contacts in circuit-interrupting equipment, cable, and so forth. Our planning from the standpoint of the war emergency has to be on a basis of several years, because our government is planning the national efforts on the basis of the war's lasting several years. A recent Gallup poll showed that half of our citizens thought the war would last more than two years.

Tests and operating experience indicate that if one wishes to have a life of say 50 years for a given piece of equipment, then the operating temperatures may be anything up to a certain value, depending on the equipment. I have indicated this point at A in Figure 1. The limit may be determined by physical and chemical deterioration of the insulation as in a transformer, or by ionization as in an impregnated-paper-insulated cable, or by sheath cracking in the manhole as for a lead-covered underground cable, or by mechanical troubles as in a large alternator.

With further increases in temperature, the life of the equipment decreases uniformly, perhaps on a logarithmic basis down to a point, B, as indicated in the figure. In specifications and standards for cables and transformers in this country during the past few years or so, the industry has established temperatures for emergency operation which correspond to temperatures approaching point B. These temperatures are usually 10 or 20 degrees centigrade above our previous limits for normal day-in-and-day-out operation. Research at

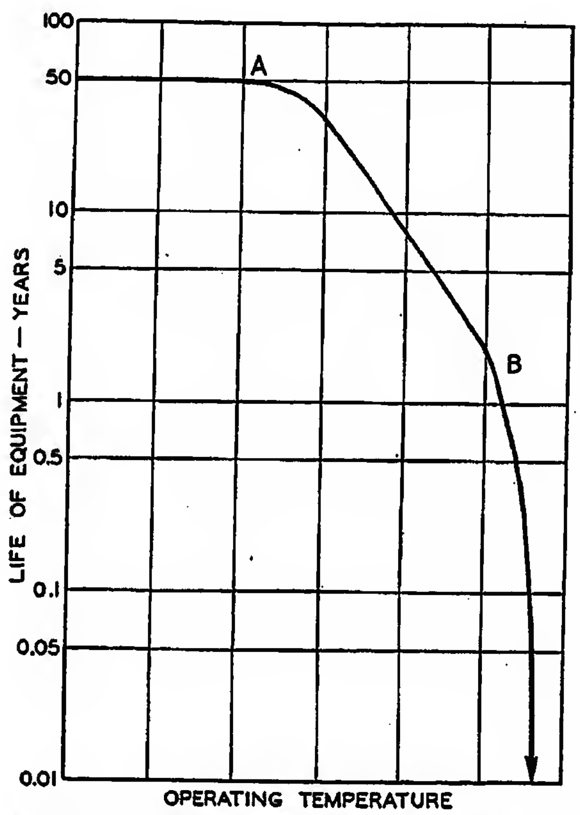

Figure 1. Temperature scale and shape of curve varies with equipment

the Massachusetts Institute of Technology for The Engineering Foundation–AIEE project on insulating oils and cable saturants has shown that with continuous exposure of oil-impregnated insulation to oxygen, charring of the insulation occurs in a matter of a couple of weeks at 105 or 115 degrees centigrade, which is the range of the upper emergency temperatures recently established for transformers. Other researches, including a current one by the Commonwealth Edison Company, have shown that with no oxygen present, the rapid loss of the mechanical integrity of the insulation begins to occur at 120 or 130 degrees centigrade.

If, during the war, equipment is normally operated at temperatures up to A and a little higher and equipment is operated at toward B during emergencies, in line with recently established limits, then we will increase our loading of existing equipment over past practice and cause some shortening of the life. However, the equipment will generally last without any particular trouble for the duration of the war. On the other hand, operation normally with temperatures toward B with occasional operation at temperatures above B during emergencies will greatly increase the likelihood of failures during the next few years. The new established temperatures for emergency operation are, incidentally, much above the limits in European specifications and standards.

Our operation in general should not be such that within a couple of years, and before the war is over, reliability of service would become very poor, and much equipment would be ruined and would need to be replaced when the country is short of critical materials and labor. Instead, installations should be made judiciously and consideration should be given to measures to avoid very excessive temperatures by methods such as indicated in today's papers and discussions.

I have a few special comments to make about Mr. Gaty's paper, "Underground Distribution Systems in Wartime":

Method of Supply, beginning of first paragraph: Regarding the relative advantages of a network system over a radial distribution system, our experience with the radial distribution four-kilovolt system has been, in general, quite satisfactory from the standpoint of service and economy of materials. Emergency temperature limits have been established for the underground cable and overhead wire and distribution transformers. Also, arrangements are made for emergency relief through emergency connections to take care of a load of a given feeder that has failed by having the load transferred to adjacent feeders.

Reliability of Supply, fourth paragraph: We have installed 66- and 132-kv transmission lines in the same conduit as lower-voltage cables without any bad consequences. The cables are each fireproofed in the manholes, and the relaying is fairly fast and has operated almost always as expected.

Reliability of Supply, fifth paragraph: The comments that the stock of cable and spare materials should be higher than normal are interesting, but the requirements of the War Production Board preference order may not permit putting this idea into effect in many cases.

Reliability of Supply, seventh paragraph: In connection with making quick repairs, one scheme that has been successful for many years in Chicago has been to connect the conductors of a joint and apply tape over the individual conductors, and omit soldering the joint sleeve to the cable, and omit filling the joint with compound. These open-air joints have been left to operate for several hours, until nighttime usually, when the joint construction has been completed with the line made dead again. Such operation has resulted in no troubles. Of course, where the water level tends to be high in the manhole, steps have to be taken to keep the manhole pumped dry for the several hours of the emergency. This general scheme has been used on joints rated at 12 kv and less.

The general ideas in the paper on the need and value of further work on limitations of insulations, conduit, and sheath are, to my mind, very much in order. It has been such work that has enabled industry in the past several years to establish emergency cable ratings that are 5, 10, or even 25 per cent above normal ratings.

Also, I want to emphasize point 4 in the author's summary on the need to "maintain an adequate inspection and maintenance program." With higher loading of equipment, the chances of trouble are greatly increased, but we may be able to give fairly reliable service if steps are taken to make relatively small expenditures for inspection and maintenance. This point, like many other points in this interesting paper, is one that many people agree on but do not always put into effect.

REFERENCE

1. LOAD RATINGS OF CABLE, Herman Halperin. AIEE TRANSACTIONS, volume 58, 1939, October section, pages 535–53.

M. S. Oldacre (Commonwealth Edison Company, Chicago, Ill.): Frequent reference is made in this group of papers to "defense industries" and "emergency conditions" or similar phrases. We should say "war industries, and so forth," so that it will be impressed on the minds of all of us at all times that we are faced with immediate problems and not with something we can do next week.

The authors have covered a wide field and necessarily have been able to devote only small space to each item. I should particularly like to comment on some of the transformer problems that we should face.

As pointed out in several places in the papers, most operating men try to avoid loading equipment so that any of the life will be consumed, and, in general, the nameplate rating is the limit. Under peacetime conditions this was justified as it has given some of the elasticity or slack in an electric distribution system that makes possible greater load capacity for war conditions.

The authors have made very little reference to how long the increased load is to be carried.

Shall equipment be loaded to the utmost, without regard to effect on the life of the apparatus, thus shooting all our ammunition in one shot, or shall the best available data be used as a guide to load the transformer to the limit that will still leave the transformer available for service as long as needed?

Most likely the latter method is the only one considered by most of us, and it is suggested that the recommendations in the American Standards Association standards for transformers be consulted as a guide for the average transformer. These data are based on the research of the larger transformer manufacturers and present, in more usable form, data partially covered in the references in the papers. The ASA recommendations are of necessity rather conservative, as they are intended to be applicable to almost any transformer, but I would not be surprised if many operating men voice loud objections.

For larger transformers and special conditions, study of the individual transformers is justified, and it will generally be found that more actual capacity is available than indicated by the name plate. In several instances such studies have delayed for two or three years additional installations costing a quarter to a half million dollars each. In still another instance a large transformer bank's capacity was increased one third to take care of a temporary condition that has now continued for 12 years.

Such studies develop along several paths, some of which are:

1. More extensive use of the transformers in their existing condition:

(*a*). This requires that the transformer will be loaded to the safe temperature limit for continuous operation, taking into account load cycle, ambient, and actual characteristics of the transformer.

(*b*). It requires further that for emergencies due to equipment failures, and so forth, the transformer will be loaded to at least the emergency limits of the ASA standards.

2. Providing additional cooling facilities of some of the types mentioned in the papers. In this case all additional facilities reasonably feasible should be added as one operation. Then loading for regular and emergency operation along the lines mentioned above should be employed.

New installations offer an additional problem that is well worth study and adoption where possible to save materials needed for war purposes.

In the larger installations load and load cycle is generally fairly well-known, and the transformers should be specified to provide conservative operation under normal conditions, but for emergency conditions the maximum temperature conditions that will still give a reasonable life should be specified.

This is best illustrated by an example: It is proposed for a specified load and load cycle that three transformers be installed, each capable in an emergency of carrying one half of the total maximum load. Normally all three will operate in parallel. An emergency may be of two days' duration to repair the underground cables that feed the transformers, or it may last for a month or two, if a transformer repair is necessary. It is proposed that for the emergency rating with forced air cooling, the temperature rise of the copper may be 75 degrees centigrade above the usual ambient of an average of 30, and a maximum of 40 degrees centigrade in 24 hours. This emergency rating would be about 60 per cent above the usual self-cooled rating that would be applied to the core and coils.

There is an indicated saving of materials of 35 to 40 per cent over a straight self-cooled transformer, and 15 to 20 per cent over the usual self- and forced air-cooled transformer. With other types of cooling, such as forced oil, circulation or spraying of water on the transformer might make further savings possible.

A good share of the saving will be in steel and copper—two strategic materials.

Philip Sporn: The striking fact brought out by all the discussions is not only that all utilities have been doing thinking on the problem, and that all have found particular ways and means of making existing distribution systems more effective, or ways and means of extending the capacity of distribution systems more economically than was felt desirable or even possible in peacetime, but that substantially they have been doing so for some time. One of the aims of the symposium was to bring all these ideas together and to place them as a complete unit before the distribution engineers of the power-supply systems. I believe the discussions show that it has accomplished that preliminary purpose. Once this has been done the final objective, that is, making existing distribution systems perform more work or making new systems perform necessary tasks more efficiently can, I am confident, be left to the skill, industry, and patriotism of those carrying on the detail task of designing, constructing, and operating the distribution systems of the country.

H. P. St. Clair: As we had hoped, the authors of the papers in this symposium have not been disappointed in the many valuable comments and suggestions which have been contributed by the discussers of these papers. To mention a very few, I should first like to endorse Mr. Halperin's timely warnings as to the possible dangers of going too far with the overloading of transformers to the extent that temperatures exceed or even closely approach the point B on the curve in Figure 1 of his discussion. While a considerable margin of safe overload capacity is undoubtedly available in many transformers, particularly on a short-time emergency basis, it is quite true that loss of life goes up rapidly, on a logarithmic scale with temperature, and also that temperature itself increases more rapidly as greater overloads are applied. It would indeed be false economy in the use of materials to allow failure of distribution or of transformer equipment to occur in the midst of our war effort. This only emphasizes the importance of a careful analysis of the overload capabilities of equipment so that the increased loading will be applied on a sane and sound basis.

Referring to the arrangement described by B. M. Jones, whereby a single-phase ground is intentionally applied by closing a disconnecting switch actuated by the differential relays of a transformer bank where high-voltage circuit breakers are not provided, I should like to say that the description of our typical "medium-capacity" transmission substation shown in Figure 4 failed to mention the fact that this station is, likewise, arranged for closing a disconnecting-switch ground when the differential relays operate. As a matter of fact, this scheme is employed on this and on one other 132-kv stepdown station on our system for the same reason as that described by Mr. Jones, namely, to insure clearing the high-voltage line in case of a transformer fault which would in itself not provide sufficient fault current to relay the high-voltage line.

The practice described by Mr. R. J. Hooke, whereby, in certain suitable instances, pairs of lines or cables can be paralleled on a single breaker and operated as a single circuit, is quite sound, and a proper addition to the various schemes mentioned in the paper. While it was not brought out as such, the arrangement shown in Figure 9 of the paper represents one such case where conditions were entirely favorable for this expedient. The practice has been followed in one other case, on the system with which the author is associated, and we are in full agreement that opportunities for such economies should not be overlooked.

Harold Cole: The discussion has brought out a number of valuable suggestions for conserving the use of material in overhead distribution systems which were not mentioned in my paper. Mr. Fuller and Mr. Sayles have pointed out the possibilities of converting 2,300-volt, three-wire delta sys-

tems to 4,000-volt, four-wire wye, and similar changes at higher-voltage levels, as a means of securing increased capacity with a minimum use of material. Certainly, expedience of this kind should be carefully studied, where the existing system connections are such as to make the change possible.

Mr. Sayles and Mr. McDowell have also advocated the "banking" of distribution transformers on the secondary side, as a means of conserving material. It has seemed to me that, in most cases where the practice has not been followed in the past, a considerable amount of new conductor material would have to be installed to do a proper job of "banking." It is, therefore, questionable whether a net saving of critical material would result. One of the principal advantages of "banking" is the reduction of voltage dips, and it has been pointed out that such minor inconveniences may have to be tolerated for the "duration." I hasten to add that I do not want to be taken as deprecating the practice of "secondary banking" as poor engineering in peacetimes. For many years the practice has been followed by The Detroit Edison Company, wherever the conditions were at all favorable, and its use justified from the point of view of economy as well as improvement to service.

Mr. Van Antwerp's comments on the need for encouraging ingenuity, organization, and enthusiasm, to carry out a program of getting the most use out of the material available, is certainly very much to the point. The practice cited by Mr. Fiedler of the use of two-wire services, which could later be readily converted to three-wire, is a good example of the type of ingenuity which accomplishes very worthwhile results. In this same connection, I understand that it is now possible to purchase meters which may be readily changed from three-wire to two-wire in place, at a very small increase in cost over the standard three-wire meter. This makes it possible to avoid the purchase of two-wire meters, which would later be difficult to use, because of the increasing requirement for three-wire services.

F. C. Poage and **M. W. Reid:** Mr. Samuels in attempting to cover the over-all situation, refers to shortages of facilities in almost universal terms. This is not a strictly accurate picture. There are also surpluses in certain locations, and there will be others in the future as many peacetime activities are curtailed. To the extent that facilities can be rearranged and reused, the apparent shortages will be relieved.

We have pointed out a few of the means for conserving essential materials and man power by the electric-power industry for "the duration" to the end that "the duration" may be shortened.

The discussion by Herman Halperin is particularly appropriate in this symposium, because of its clear exposition of the basic relation between operating temperature and useful life of organic insulating materials. It is the application of the principles which he has cited to the loading of equipment that we have urged in our paper.

It seems rather irrelevant, however, to speak of normal life of transformers and other equipment, when the life of the nation itself may be in jeopardy. If by loading equipment on a short-life basis, we can make more war materials and man power available now—not sometime in the future—to put into planes, ships, tanks, and guns, and thereby shorten the war by ever so little, the failures that may later ensue and the replacements to follow will be well worth their cost. The country needs the materials and the men *now*, and we must be guided at present more by the point of view of what we have to do now rather than by the strictly technical concept of what might otherwise be altogether prudent. The electric-power industry must and will, we are certain, make the necessary sacrifices to win the war and to win it quickly.

The Electric Strength of Nitrogen and Freon Under Pressure

Discussion and authors' closure of paper 42-33 by H. H. Skilling and W. C. Brenner, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April section, pages 191–5.

G. C. Nonken (General Electric Company, Pittsfield, Mass.): The authors have expressed the breakdown voltage of the gases as tested between spheres in form of linear equations involving pressure and gap spacing. Their equations are of the form

$$V = KPS + C$$

when

V is the breakdown voltage
P is the absolute pressure (atmospheres)
S is the gap spacing in inches
K and C are constants for a particular gas

This equation is an expression of the well-known Paschen's law. Many research workers have found that their data deviate widely from Paschen's law at high pressures or at large gap spacings. Figures 1, 2, and 3 give the breakdown data of Freon, nitrogen, and air taken from the authors' and five other papers.[1–5] These tests are all made between spheres or uniform field gaps. The pressures range from atmospheric to 600 pounds gage pressure, and the spacings vary from 0.05 inch to 1 inch.

With few exceptions, these data lie on straight lines when the voltage gradient is plotted against the absolute pressure in logarithmic co-ordinates.

The general equation for these data is

$$\frac{V}{S} = CP^b$$

when

V is the breakdown voltage
S is the gap spacing in inches
P is the absolute pressure in pounds per square inch
C and b are constants. b represents the slope of the line and C determines its position vertically

The equation for the voltage breakdown of Freon is

$$\frac{V}{S} = 24.4P^{0.805}$$

and is plotted in Figure 1. For these data, the constant C varies from 21.7 to 28 or over 20 per cent, while the constant b changes only from 0.79 to 0.805 or slightly less than two per cent. The variation in C indicates the differences due to the different investigators' test setups, electrodes, and so forth, while the constant b is affected very slightly by variations in test procedure but is a constant typical of the particular gas.

The authors' equation

$$V = 183PS + 4$$

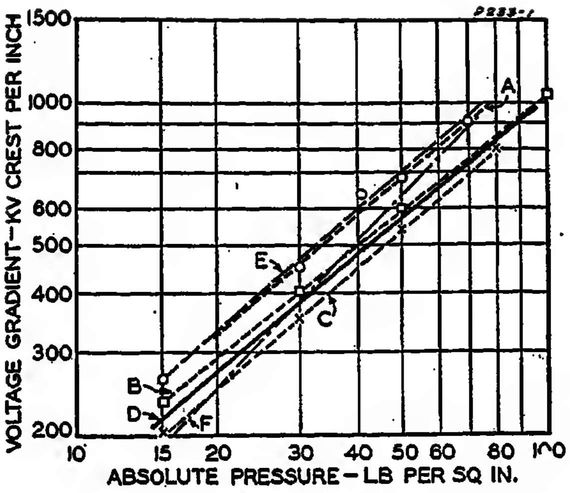

Figure 1. Breakdown voltage gradient of Freon

A—Skilling and Brenner—0.05-inch spacing
B—Trump, Safford, and Cloud—0.2-inch spacing
C—Nonken—0.39-inch spacing
D—Proposed equation $\frac{V}{S} = 2.44P^{0.805}$
E—Skilling and Brenner equation $V = 183PS + 4$ ($S = 0.05$ inch)
F—Skilling and Brenner equation $V = 183PS + 4$ ($S = 1$ inch)

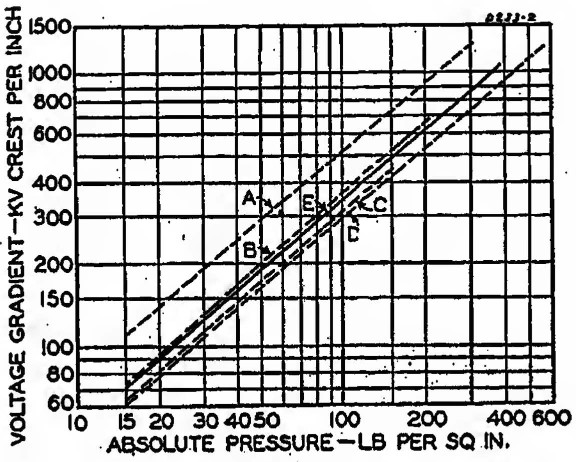

Figure 2. Breakdown voltage gradient of nitrogen

A—Skilling and Brenner	$S = 0.05$ inch
B—Nonken	$S = 0.39$ inch
C—Finkelmann	$S = 0.76$ inch
D—Goldman and Wul	$S = 0.079$ inch
E—Proposed equation	$\frac{V}{S} = 7.6P^{0.835}$

for the breakdown of Freon is also plotted in Figure 1. This equation has different values of V/S for each spacing. The authors have chosen the correct constant for a 0.05 inch spacing, which is represented by curve E. The curve for a one-inch spacing according to the equation is shown by F. It is necessary to choose different constants for each gap spacing to make this equation fit the curve.

Figure 2 shows similar data for the breakdown of nitrogen. The equation suggested for this data is

$$\frac{V}{S} = 7.6P^{0.835}$$

For this data, the constant C varies between 12.5 and 6.4, while the constant b varies from 0.8 to 0.835.

Figure 3 gives similar data for the break-

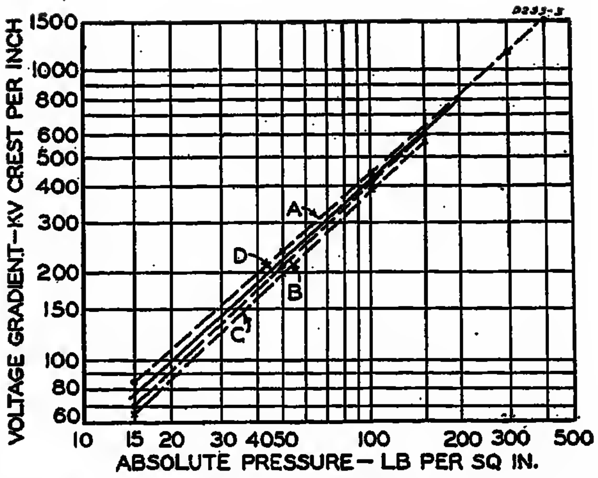

Figure 3. Breakdown voltage gradient of air

A—Howell	$S = 0.25$ inch
B—Trump, Safford, and Cloud	$S = 1$ inch
C—Finkelmann	$S = 0.76$ inch
D—Proposed equation	$\frac{V}{S} = 6.15\ P^{0.925}$

down of air. The equation suggested for this data is

$$\frac{V}{S} = 6.15P^{0.925}$$

For this data the constant C varies between 5.6 and 6.9, while the constant b varies between 0.875 and 0.935. Paschen's law is expressed by the above equation when $b = 1$. Freon deviates the most from Paschen's law with an average value of $b = 0.805$, while the values of b for nitrogen and air are 0.835 and 0.925 respectively. The breakdown characteristics of gaps which have corona previous to breakdown do not follow such a simple law as the one above. As the authors suggest, caution must be exercised in drawing any general conclusions or extrapolating any data in connection with the breakdown of sharp-edged gaps in high-pressure gas.

G. W. Dunlap (General Electric Company, Schenectady, N. Y.): In these days of shortages and priorities much thought and effort are being expended toward the utilization of substitute materials, but in the field of insulations the search for new materials has been going on for many years. More particularly and more recently much consideration has been given to the use of compressed gases in place of oil. This involves the comparison of the two mediums on the basis of not only dielectric strength but of weight, heat transfer, fire hazard, mechanical construction, mainte-

nance, availability, and cost. These cannot be discussed at length here but must obviously be considered in detail for any given application. Since the paper under discussion concerns the dielectric characteristics of gases, these remarks will also be confined to those characteristics.

Gaseous insulation has been used satisfactorily in a number of special cases including cables, capacitors, electrostatic generators, potential transformers, and probably with the most spectacular results in the new million-volt portable industrial X-ray unit described in AIEE TRANSACTIONS for December 1941. In addition, the increasing use of the air-blast principle in circuit breakers, while not ordinarily thought of in the same category with closed system insulations, is truly a great application of gaseous insulation. These uses amply justify the work which has been done and should encourage further investigation in this field where even now not too much is known. The following remarks, therefore, wherein they disagree with the authors should be taken as cautionary rather than discouraging in the application of gaseous insulation.

To take up the authors' conclusions in order, the relative strengths of nitrogen and air between smooth electrodes do not remain the same, even over the pressure range shown in Figure 1 if the length of gap is increased to the order of one centimeter. This is shown by Finkelmann[1] who found differences up to 20 per cent for one-centimeter gaps between flat plates 13.5 centimeters in diameter at 16 atmospheres, and up to 15 per cent at 10 atmospheres for gaps between 18 and 20 centimeters diameter concentric cylinders. Conclusion 2 is, of course, consistent with this.

Conclusion 3 regarding the relative strengths of Freon and nitrogen checks with the results of Charlton and Cooper (authors' reference 3) and Nonken,[2] and also with the experience of the writer which indicates that the 2.5 ratio holds out to spacings of at least four centimeters between 6.25-centimeter spheres. However, the formula $V = 183PS + 4.0$ does not necessarily hold for this same range as may be seen from Table I where some of the writer's data which are comparable with Nonken's are compared with values calculated from the formula.

Regarding mixtures of Freon and nitrogen (conclusion 4), the question might be raised as to the practicality of providing a fan for mixing the gases as the authors found necessary.

For the case of Freon between pointed or other corona-forming electrodes, irregularities of such magnitude exist that the data presented by the authors—data which do not include some of these irregularities—may give too optimistic a picture of the general situation. It is true that the strength of Freon may be four times that of nitrogen as stated by the authors, and, in fact, the ratio may be even greater under some conditions. For example, Nonken shows about six times for a six-centimeter standard rod gap at atmospheric pressure. However, under conditions of greater spacing and voltage than the range covered by the authors, Freon gives a "hump" in the pressure-voltage curve similar to that shown for air in Figure 7, except that the maximum occurs at a much lower pressure in the Freon. For this reason the strength of Freon may actually be less than that of nitrogen at some pressures, and the writer has taken data in which this was the case.

In addition, and even more important in many applications, the high strength in the "hump" portion of the curve results in situations where the 60-cycle strength may be twice the impulse strength, and an impulse ratio comparable to that of transformer oil is rarely obtainable. This phenomenon has been verified by both Nonken and the writer. As the authors point out, this high 60-cycle strength is found with corona-forming gaps, but it would seem to be a case of more corona shielding in Freon due to decreased mobility of the space charge rather than an impeding of corona formation as indicated. A number of investigators[2,3] have measured the corona starting voltage in Freon and other gases and have found no discontinuities corresponding to the "hump" in the breakdown voltage curve.

As pointed out above, there have been several applications of gaseous insulation in which very satisfactory performance has been obtained. Experience shows, however, that it is necessary to study each application in detail with careful consideration of its particular requirements. If these requirements are such that conditions for optimum gas performance can be maintained, the use of gas may prove very advantageous. For such a case marked reductions in size and weight of equipment may be effected as was done with the million volt X-ray outfit.

Table I. Breakdown of 6.25-Centimeter Sphere Gap in Freon

PS	Test Kv	Formula Kv	Per Cent Deviation From Formula Kv
	1 cm spacing		
0.39	90	76	+18
0.78	155	147	+ 5
1.58	225	291	−23
2.36	300	436	−31
	2 cm spacing		
0.78	130	147	−11
1.58	255	291	−12
3.15	350	580	−40
4.72	460	868	−47

Henry M. Hobart (Consulting Engineer, Schenectady, N. Y.): Conclusion 6 of the authors' paper states that, for dielectric purposes, compressed Freon would be inferior to compressed nitrogen at compressions greater than 150 pounds per square inch (10.5 metric atmospheres). At that pressure and for a 50-mil spacing between one-inch-diameter spherical electrodes, the 60-cycle electric strength of Freon, estimated by the authors' formula, is 2,000 crest volts per mil. For that gap and spacing it is the writer's opinion that the 60-cycle electric strength of nitrogen will not exceed 1,600 crest volts per mil, no matter how great a compression is employed.

Corresponding to a compression of 10.5 metric atmospheres, the condensation temperature of Freon is 44 degrees centigrade. The writer would value an expression of opinion by the authors as to any difficulties foreseen by them in employing Freon in cases where (for the attainment of a particular purpose) a temperature considerably greater than 44 degrees centigrade is required. For example, at a temperature of 100 degrees centigrade a compression of 25 metric atmospheres would not condense Freon gas, and its 60-cycle electric strength for a 50-mil spacing between one-inch-diameter spherical electrodes almost certainly would be considerably more than 2,400 crest volts per mil (that is, more than 50 per cent greater than nitrogen's limiting strength of not over 1,600 crest volts per mil for that spacing).

The application which the writer has in mind, relates to a compressed-gas transformer in which the gas shall partly or completely condense after each passage through the active material (core and windings) of the transformer, each time returning to its starting point cooled by having transferred its heat by the vaporization of a liquid of appropriately low vaporization temperature. It is evident that for such a cycle the conditions are improved, and the size and cost of the transformer and heat exchanger are decreased, the higher the permitted temperature. If, in such a vaporization-cooled transformer, there can be employed a temperature very much above 100 degrees centigrade, the liquid to which the gas transfers its heat, can be water, and we have the advantage of its wide availability, its usually almost negligible cost, and its very great latent heat.

The writer would value the authors' opinion (based on their considerable familiarity with Freon), as to how high a temperature could be employed for the Freon gas without encountering any prohibitive chemical difficulties. Owing chiefly to their higher condensing temperatures for given compressions, and on account of their price and of their dielectric characteristics at high pressures, the writer considers SO_2 and CCl_4 to be attractive alternatives. Consequently he would also much appreciate the authors' comments anent these materials for the purposes here described. Such a design obviously involves various compromises. It is believed that we now have available a considerable variety of adequate heat-resisting materials for the turn and layer insulations and for their impregnating constituents.

Amongst other features which will be embodied in such transformers is the decreasing of the core loss by employing the "Maclaren effect." Since this feature requires a core temperature much in excess of desirable winding temperatures, the core will be separated from the windings by a "thermal screen" of asbestos or fiber glass or Mycalex or other suitable material. High-voltage compressed-gas power transformers embodying these various features will not require any high-voltage entrance bushing but will be supplied through a surge-attenuating underground transmission line comprising compressed-gas-insulated conductors enclosed in a welded-steel pipe line.

Thus we arrive at a system providing 60-cycle underground conductors for the long-distance high-voltage transmission of great amounts of power and for power pools. No time should be lost for seeking economical alternatives for our present outmoded overhead, high-voltage, power-transmission system with its aboveground, outdoor installations of oil-type power transformers and switchgear. If the project here briefly sketched could be promptly developed and employed, then the impending annual expenditure of many hundreds of millions of dollars for the urgently required increase in the nation's electricity supply need not perpetuate the decades old constructions with their serious susceptibility to interruptions from lightning, from storms of ice and sleet and wind, from enemy depredations in wartime, and from interference with aircraft traffic and with communications systems. The high-voltage transformers no longer will require expensive and none too dependable inlet bushings of awkwardly great height, nor internal shielding for surge protection, nor will they contain inflammable and sludging oil which imposes a very low temperature limit. Their compressed-gas successors will be lighter, cheaper, and in all respects more dependable. The consequent conservation of the nation's oil supply is also a factor not to be overlooked.

Our present overhead tower systems and our oil transformers are carryovers from the historic Frankfurt-Lauffen long-distance transmission installation built just 50 years ago. To meet the vastly more severe modern requirements the fundamentals of this pioneer line have been retained to a great extent but revamped to provide for more power and higher voltages. For their present tolerable adequacy thanks are due to the skill and ingenuity of many able engineers. The result, however, has been attained at a cost which seriously handicaps the desired far wider use of electricity and with a disappointing degree of dependability.

The writer recalls the interesting article by one of the authors of the present paper which was published in *Electrical World* a few years ago. The article was devoted to the description and advocacy of a compressed-gas underground system in which the high-voltage transmission conductors were pipe-enclosed. It would be of much interest to learn from Professor Skilling to what further extent he has gone with the development of that project.

The authors have done well in especially emphasizing the extremely important characteristic of Freon in virtue of which its electric strength is not so greatly impaired by increasing nonuniformity of the field as is the electric strength of nitrogen. Thus in analyzing the results published in Mr. Nonken's recent AIEE paper entitled "High-Pressure Gas as a Dielectric," the writer finds that with a pressure of nine metric atmospheres and a spacing of 800 mils, Freon's electric strength in the rod-gap test decreased to 40 per cent of its strength in the sphere-gap test, whereas the electric strength of nitrogen under these same conditions decreased down to only 30 per cent of its sphere-gap strength. The authors' tests with pointed electrodes as shown in their Figure 7, disclose the same trend, but much intensified, as they apply to a greater extreme of nonuniformity of field than corresponds to the rod gap.

This paper is certain to be of much value to those working on application problems involving the use of compressed gas as a dielectric. Already it has proved very useful indeed to the present writer.

Wm. C. Brenner and H. H. Skilling: The principal purpose of this paper is to present experimental results on the electric strength of Freon gas and of mixtures of Freon and nitrogen, giving information covering a region of pressure and electrode spacing for which adequate data have not been published. As a convenience in estimating the sparking voltage under the conditions of the experimental work, an equation for sparking voltage is given.

Much of the discussion is related to the applicability of this equation to other ranges of pressure and spacing. Mr. Gordon Nonken proposes an alternative equation in his discussion, of the form $V=CP^bS$. He suggests the application of this form to sparking in air and nitrogen as well as in Freon. He says very truly that many investigators have found that their data deviate widely from Paschen's law at high pressure and large spacing. This was emphasized in a previous paper by the authors on "The Electric Strength of Air at High Pressures—II" (reference 2 of the present paper). In that earlier paper a modification of the familiar form of Paschen's law was given to apply to the authors' results in air. Paschen's law, applicable at pressures up to atmospheric, and substantiated by physicists for over half a century, is of the form

$$V=75.4PS+1.7 \text{ kilovolts} \tag{1}$$

P is in atmospheres, S in inches. The modification to fit the authors' data at pressures up to twenty atmospheres was

$$V=\frac{76.0PS}{1+cP}+1.7 \text{ kilovolts} \tag{2}$$

This equation 2 has the advantage of reducing to the accepted form of Paschen's law at low pressure (c is a constant much smaller than unity). Mr. Nonken's formula does not share this advantage; in particular, the constant term is absent from his exponential form which approaches zero sparking voltage at low pressure. Paschen's law, to be sure, fails to apply if the pressure-spacing product is below 0.05 inch-atmospheres, but an exponential formula will deviate from observed data considerably sooner.

Equation 2 has the further advantage of taking into account the length of spark gap. It will be seen from Figure 3 of Mr. Nonken's discussion that the voltage gradient is *not* independent of the gap length; the authors' equation 2, above, takes this into account, and results computed from this equation may be plotted in Nonken's Figure 3 as a family of lines, one for each spacing. This appears somewhat more satisfactory for representing the family of experimental curves than does a formula giving a single line. Equation 2 gives excellent agreement with Howell's results, and good agreement with Trump's, if compared with the curves published by those authors. The equation also agrees with the present authors' measurements in air (reference 2) which could be plotted in Mr. Nonken's Figure 3 as a curve lying above all those shown but approaching them at very high pressure.

In devising a formula to apply to experimental results in Freon, the authors naturally sought a form similar to Paschen's law. It seemed desirable not only for its simplicity and familiarity, but also because it is a form so well-established in air and other gases. Thus the equation suggested is:

$$V=183PS+4.0 \text{ kilovolts} \tag{3}$$

It must again be emphasized that this equation does not apply near the pressure at which Freon condenses to a liquid and therefore should not be used above about four atmospheres.

Whether this form or another is used is a matter of choice at present. There is not yet enough data to permit a decision, although it seems likely that an equation, to take into account all the peculiarities of Freon, would necessarily be a fairly complicated one. The authors' equation 3 gives reasonable agreement with their own results. It gives even better agreement with the results published by Trump, Safford, and Cloud in their Figure 4 (of reference 9) at pressures below 60 pounds per square inch absolute. No attempt was made to derive a formula for a wide range of pressure and spacing, for it is our opinion that more information is needed before that can profitably be done.

Dr. Dunlap presents new and interesting data that substantiate this opinion; yet it is remarkable that the authors' equation 3 turns out to be as good as it is under conditions of board extrapolation. With extrapolation of the pressure-spacing product to five times that for which the formula was designed, the deviation between the experimental results and the formula is given by Dunlap as only about ten per cent.

Dr. Dunlap shows that in other cases the deviation is as much as 30 or 40 per cent, but since his data were obtained at pressures practically as great as the vapor pressure of Freon at room temperature, and quite beyond the range of equation 3, this is not surprising. It seems best that experimental sparking values in this pressure range be used directly, for generalization in any kind of formula would probably be unsafe.

Regarding the mixing of Freon and nitrogen, the authors suggest that in commercial applications of gaseous insulation it would be more convenient to mix the gases before injecting them into the equipment to be protected. When once mixed they will, of course, stay mixed, and there is no need for a fan within the vital parts of a cable or a million-volt X-ray outfit.

Mr. Hobart's interesting discussion brings to attention several points that might be clarified.

1. The conclusion 6 to which Mr. Hobart refers should have been qualified for the sake of clarity, for it was intended to show that Freon at room temperature was inferior to nitrogen at 300 pounds per square inch for the various stated reasons, and it was meant to convey the idea that where structural or mechanical limitations would not allow pressures above 150 pounds per square inch, Freon (at room temperature) should be carefully considered.

2. The equation $V=183PS+4$ for the breakdown kilovolts (V) for sphere gaps (where S is in inches and P in atmospheres) was determined at temperatures ranging from 55 to 73 degrees Fahrenheit (considered to be constant at the time of measurement) and for pressures all below the vapor pressure of Freon at room temperature.

To extrapolate the curve for higher pressure regions, one should take into account the temperature effect realizing that the density of the Freon is the important factor. For constant temperature the density was adequately represented by pressure, but to be more complete the form of the breakdown equation should be of the type

$$V=\alpha\frac{P}{T}s+\beta$$

Again it should be mentioned that the original equation was not checked at the vapor pressure, and unless it is intended to use Freon at elevated temperatures where the gas has some degree of superheat, it would be well to check the equation for several points at the vapor pressure, lest unhappily saturation of the gas may be accompanied by some sort of discontinuity.

As to the stability of Freon and the other mentioned gases in Mr. Hobart's discussion, it is well to consult the manufacturer as to the thermal decomposition of the various gases. As to the effects of electrical disintegration, none need be considered unless there is an electrical discharge taking place, and the degree and seriousness of this should be determined by the particular application. For smooth surfaces with no or only occasional arcing, decomposition may be disregarded, but for applications where corona may possibly exist, the seriousness of the decomposition is to be determined by the effects of corrosion and the requirements of adding or changing the particular gas in question being used for its high insulating properties.

Referring to the proposed Freon-cooled transformer feeding into a Freon-filled cable, one thing must be remembered, and that is, that if high pressures are to be utilized, the entire interconnected system must be maintained at a temperature sufficiently high to prevent the Freon's liquefying, thereby reducing its high insulating strength.

It seems that Freon would best serve at ordinary temperatures and pressures below the vapor pressure where the entire system could be maintained at a constant pressure; otherwise, there would arise the above mentioned problem of maintaining elevated temperatures for the entire system, or the need for gas tight bushings between the various elements of the system. However, for special cases the use of high-pressure Freon may prove quite valuable and should bear further investigation.

Saturated Synchronous Machines Under Transient Conditions in the Pole Axis

Discussion and author's closure of paper 42-43 by Reinhold Rüdenberg, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, June section, pages 297–306.

S. B. Crary (General Electric Company, Schenectady, N. Y.): This paper presents an interesting graphical analysis of the effect of saturation on synchronous-machine performance. Any analysis of the influence of saturation must necessarily be approximate. When such approximations are necessary, the value of the analysis is increased when it is used with a full knowledge of the assumptions made. Dr. Rudenberg's analysis is necessarily limited to the effect of saturation in the main flux paths rather than in the leakage paths and is more nearly correct when the major part of the saturation is in the pole body. The analysis, therefore, can be used for transient disturbances, which are for periods of time in which the relatively slow field transient is important, such as in the calculation of alternator swing curves.

The method described in the paper is similar to that given by Mr. F. R. Longley in "Calculation of Alternator Swing Curves —Step-by-Step Method" (AIEE TRANSACTIONS, volume 49, 1930, page 1129), except that Rüdenberg suggests taking into account the additional effect of saturation by the addition of an equivalent field magnetomotive force acting along the direct axis. This method of taking saturation into account has been used in the calculation of swing curves with the network analyzer, except that the pole saturation was corrected, not only as a function of the direct-axis pole flux, but also as a function of the air-gap flux, in order more properly to take into account the effect of stator saturation. In terms of per-unit quantities and the nomenclature which has been established in this country, Rüdenberg's equation for calculation of the effect of saturation when a machine is connected to an external reactance would take the form of

$$T_{do}pe_\psi=e_I-\frac{x_d+x_e}{d'x+x_e}e_\psi-e_s$$

where

T_{do} = open-circuit field time constant
e_ψ = voltage behind transient reactance
e_I = voltage corresponding to exciter voltage
e_s = voltage corresponding to saturation magnetomotive force

For swing-curve calculations the vector diagram is of the form shown in Figure 1. e_s can be determined as a function of the voltage back of Potier reactance, which may be less than the transient reactance, as well as of the direct-axis pole flux. Although this method, as well as Rüdenberg's method, is approximate, it does give an answer which more accurately describes the machine performance than if saturation were neglected entirely. The point of interest is that by using the main-field winding flux or voltage behind transient reactance, the calculations can be carried out, using the open-circuit time constant in the equation for the rate of change of field-flux linkages without concern as to the impedance of the external circuit. This was previously pointed out by Longley for the case of no saturation.

The method described by Rüdenberg is approximate in that:

1. It neglects the effect of voltage produced by the rate of change of stator-flux linkages which, as he mentions, produces a d-c current or natural frequency oscillation.

2. It assumes rotor flux as only a function of the open-circuit saturation curve and therefore neglects

(*a*) Effect of saturation of the leakage paths due to stator currents.

(*b*) Effect of field-current load saturation. Actual rotor saturation is a function of both field excitation and direct-axis rotor air-gap flux, as shown in reference 13.

(*c*) Effect of change in leakage-path saturation due to redistribution of field-leakage flux.

The errors due to these assumptions are particularly appreciable under short-circuit conditions, and it becomes necessary, in any analytical method which attempts to approach actual conditions, to include properly these effects. It has been previously shown that saturation of the leakage paths is the principal cause for low equivalent short-circuit reactance. It is not sufficient to assume, as Rudenberg has done, that the subtransient current can be determined at the first instant by including only the stator leakage reactance and neglecting the effect of amortisseur or rotor leakage reactance. Actually the stator leakage reactance is reduced, particularly in the case of turbine generators. Then the problem becomes one of determining the amount by which both the stator and rotor leakage reactances are reduced.

As will be readily recognized, Rüdenberg's method assumes that the transient reactance and Potier reactance are equal to the sum of the stator- and rotor-field leakage reactances. This is not the case. It is well known that Potier reactance varies, depending upon the amount of load saturation, and even at normal operating voltages is usually less than transient reactance ("Armature Leakage Reactance of Synchronous Machines" by L. A. March and S. B. Crary, AIEE TRANSACTIONS, volume 54, 1935, April section, pages 378–381).

R. Rüdenberg: The discussion by Mr. Crary indicates that he is still wholeheartedly on the ground of the classical linear theory, which has had its great merits in clarifying the principles. Significantly, he begins with the assertion that "any analysis of the influence of saturation must necessarily be approximate" and with similar statements of axiomatic character.

Fortunately, though, this is not the fact. The saturation in synchronous machines can be taken into account by methods having the same rigor as the classical methods have for the linear case. It is only necessary to develop a transient analysis which can be applied graphically rather than analytically,

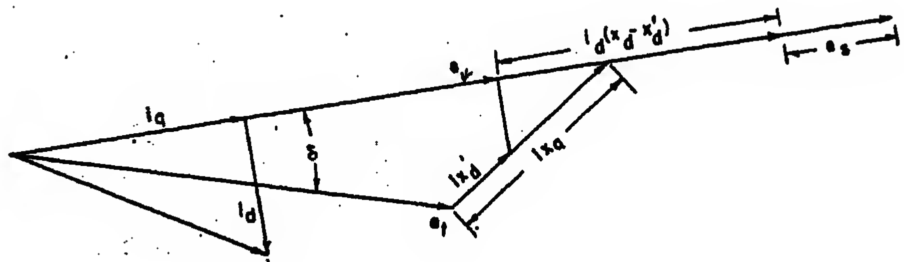

Figure 1

since for the most part the saturation functions of machines are given graphically.

If Mr. Crary will go over the paper again, free from the bias of a nomenclature of parameters developed solely for nonsaturated machines and not applicable therefore to the present case, I think he will be surprised to see how simply the rigorous consideration of the saturation under transient conditions actually works out.

It is by no means necessary to develop first a nonsaturated transient theory as most authors, including those referred to by Mr. Crary, have done for fear of a too complicated saturated analysis, and then try to correct such a linear theory by "additional effects" of saturation. It is the object of my paper to consider saturation from the very beginning as a fundamental element and to show that a rigorous and yet a highly practicable nonlinear analysis can be developed without the crutch of subsequent corrections.

Mr. Crary deduces as an analogue to my main relation (equation 14) a similar but not identical equation expressed in terms of his preferred nomenclature. However, his is not a relation of equivalent value, since it contains parameters which are defined for nonsaturated conditions only and actually are not constant for saturated machines. Thus, although the analysis sketched by Mr. Crary may be, according to his own words, an approximate one, due to his introducing saturation a posteriori, the method of my paper is definitely a rigorous one in considering saturation a priori. All the many omissions, assumptions, and approximations which Mr. Crary ascribes to the new method are by no means actually contained in it but are merely imaginary, caused by his viewing the present problem from an unsuitable angle.

This may be verified by two examples among many others. Mr. Crary asserts in his second and third paragraphs from the end that I have neglected saturation of the leakage paths due to stator currents. However, he seems to have overlooked paragraph 9 of section 4 of my paper, with equation 29 and Figure 16, where I show analytically and graphically the manner in which saturation of stator and rotor leakage paths enters this analysis and can be considered rigorously from the very beginning. Also, the last sentence of my paper, before the summary, generally treating nonlinearity with current, seems to have been overlooked by Mr. Crary in writing his discussion.

In his last paragraph, Mr. Crary asserts that my method would assume the "transient reactance" and "Potier reactance" as equal to the sum of the stator and rotor leakage reactances. This is contrary to my statements. Actually, I have proved in paragraph 7 of section 5, by means of Figure 19, that "transient reactance," a classical notation which I do not use elsewhere in my paper, with saturated machines always appears materially greater than the sum of stator and rotor leakage reactances. "Potier reactance," on the other hand, is, for good reasons, not used nor mentioned in my paper.

And so it is with all the other objections of Mr. Crary. It seems to me that by the simplicity of the new method, which considers saturation as a primary effect, Mr. Crary is misled in believing that this method would not cover the many secondary effects which apparently he has in mind. Simplicity, however, is not of itself a preventive of accuracy.

Formulas for the Magnetic-Field Strength Near a Cylindrical Coil

Discussion and author's closure of paper 42-27 by H. B. Dwight, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, June section, pages 327–33.

A. U. Welch (General Electric Company, Pittsfield, Mass.): The formulas in this paper form a very complete solution of the problem of computing magnetic fields within and near a cylindrical coil. Where great accuracy is not required, the desired information could be given much more conveniently by curves. The writer had plotted such curves a number of years ago and has found them very convenient. They are, therefore offered here in the hope that they may prove helpful to others.

These curves are plotted from formulas derived by the writer by integrating and differentiating well-known formulas for mutual inductance and magnetic potential. The formulas used were not so complete as those in the paper, and it was necessary to resort to numerical integration methods with formulas for circles similar to equations 12 and 13 in the paper to bridge the gaps between the limits of convergence of the different formulas. The curves used are as follows:

Radial Flux. It will be seen by differentiating and integrating that the radial

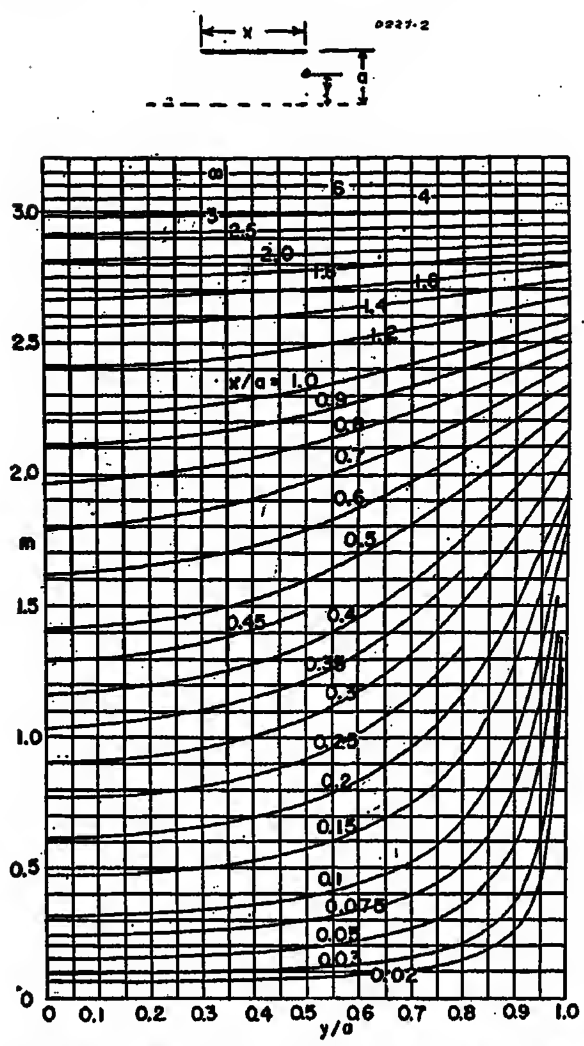

Figure 2. Axial flux density at a point in the end plane of a cylindrical current sheet, point having smaller radius than the current sheet

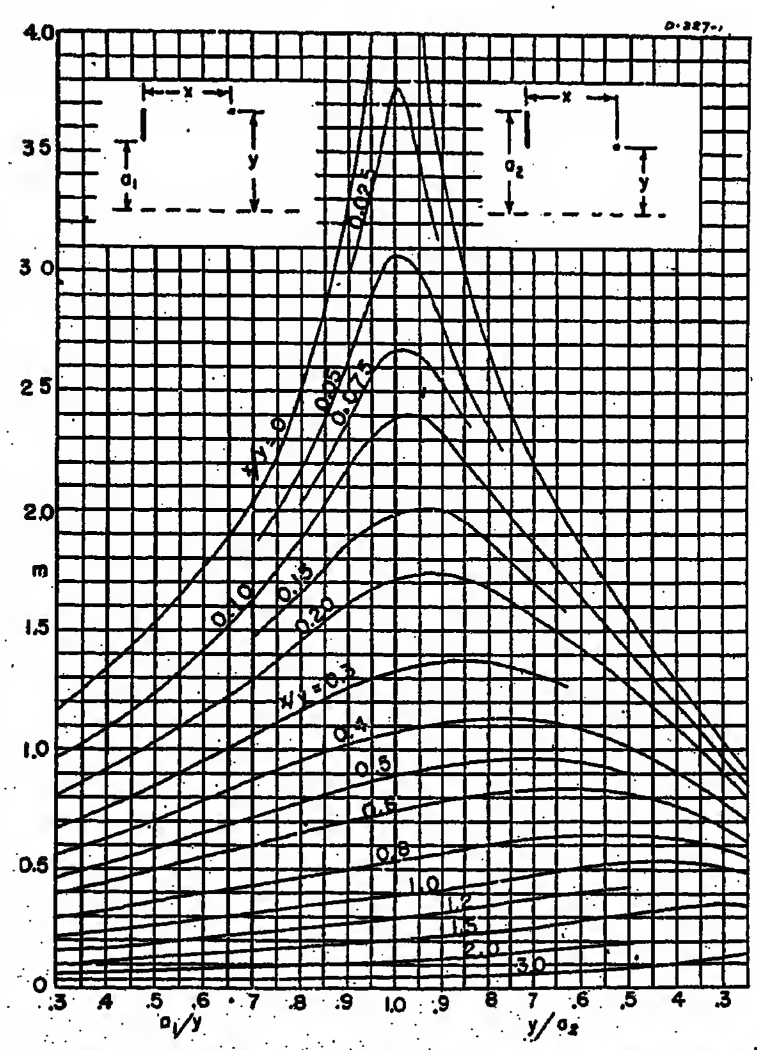

Figure 1. Curves of mutual inductance between coaxial circle and ring

Used for computing radial flux density

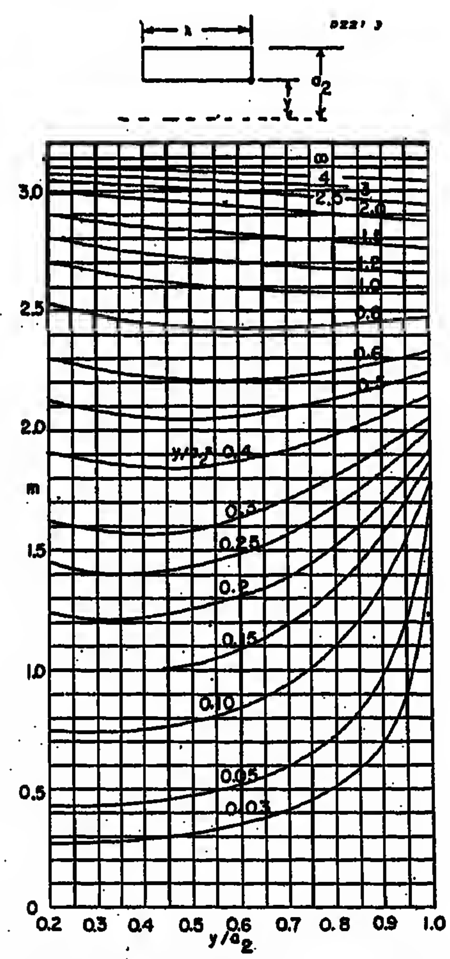

Figure 3. Axial flux density at the inside corner of a coil

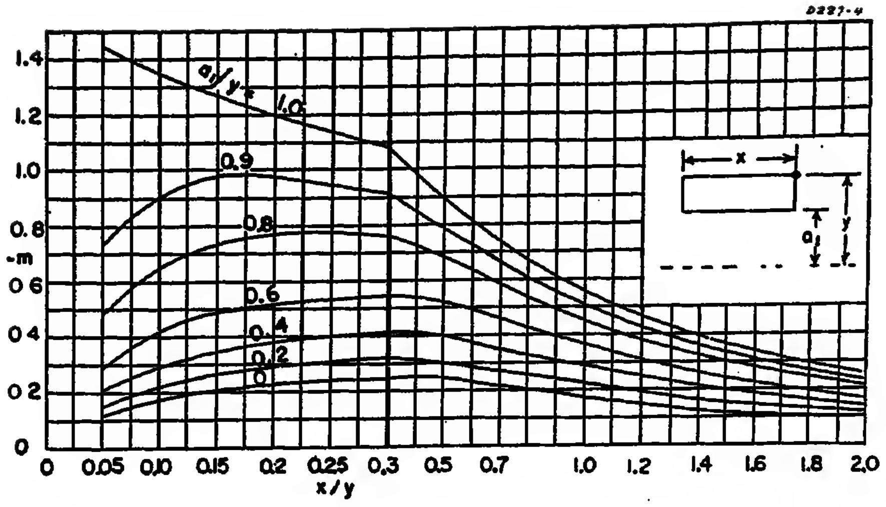

Figure 4. Axial flux density at the outside corner of a coil

flux density at any point is a function of the difference of the mutual inductance between the ring which is the boundary of one end of the coil and a circle through the point, subtracted from the mutual inductance of the other end of the coil and the same circle. If the quantity m be so defined that the mutual inductance is equal to $4\pi ym$, then

$$H_r = 0.2nI(m_1 - m_2)$$

where the definition of terms is the same as in the paper.

Figure 1 and the above formula permit computation of radial flux density at any point having the same radius as the inside or outside of the coil. (Note that in the sketches on the curves the dotted lines are the center lines of the coils, and only one side of the coils is shown.) By subdividing a coil into parts or by adding fictitious parts, if the point is beyond the inner or outer radius of the coil, and weighting the contribution of each part according to its radial thickness (number of turns), the field can be computed at any point within or near the coil.

The radial flux caused by a cylindrical current sheet of zero thickness becomes a function of the difference of mutual inductance of circles. Since complete tables of mutual inductance of circles are available,[1] no curve is necessary for this case.

Axial Flux. Figures 2, 3, and 4 give axial flux density at points in the end plane of cylindrical current sheet and at the inside or outside corner of a thick coil. Axial flux density

$$H_x = 0.2nIm$$

It should be noted that the direction of axial flux is opposite on the inside and outside corners of coils.

By superposition of parts of coils the flux density at any point within or near a coil can be calculated as outlined above.

The curves are unsuitable for computing fields at a large distance from the coil, since the result will be the difference between two nearly equal quantities. Formulas are available which converge rapidly for this case.[2]

2. Reference 2 of the paper.

H. B. Dwight: The curves presented by Mr. A. U. Welch are a welcome addition to my paper. They can save computation by the formulas, which is a rather long piece of work in some cases. His discussion indicates that this general problem has practical applications in engineering. For instance, the mechanical force on a corner conductor of a current-limiting reactor can be computed as the product of the current in that conductor and the magnetic field strength at the corner of the coil.

Example II of the paper is checked very quickly by Figure 2 of the discussion. At $y/a = 0.6$ and $x/a = 0.4$, m as read from the curves is 1.45. Then

$$H_x = \frac{2nI}{10} \times 1.45 = 2.90\,\frac{nI}{10}$$

Impulse and 60-Cycle Characteristics of Driven Grounds—II

Discussion and authors' closure of paper 42-22 by P. L. Bellaschi, R. E. Armington, and A. E. Snowden, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, pages 349–63.

Edward Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In a discussion of a contemporary paper by Messrs. Robertson, Lewis, and Foust, "Lightning Investigation at High Altitudes in Colorado," the writer referred to effects of earth resistivity and geology. This relates also to the paper by Messrs. Bellaschi, Armington, and Snowden. The conductivity of the soil depends principally on the presence of moisture and salts. The ancient rocks are low in porosity, moreover during their long lifetime, soluble salts have been washed out. Where they lie near the earth's surface, resistivity is high. Where the ground resistance is low, there are moisture and soluble salts making electrolyte. In the writer's opinion, the reductions in ground resistance observed at high currents in soil of relatively low resistivity are caused largely by the change in resistivity of electrolyte produced at high currents, whereas in soils of high resistivity the reduction in apparent resistance is produced largely by sparking in the earth as discussed by the authors. In fact, during similar tests made at Trafford in 1929, sparking was actually observed visually on high-resistance grounds when surged with high currents. Those tests were not as exhaustive as the more recent ones described in the Bellaschi, Armington, and Snowden paper, but the results were of similar character. The publication of the early Trafford tests,[1] contained a caution which may bear repetition. The reduction in resistance of what is termed a high-resistance ground achieved at high-surge currents does not necessarily make it a good ground, since the discharge is accompanied by high voltage. The resistance as determined with low-voltage measurements is a good guide to the efficiency of grounds.

In regions of great geological age, the behavior of grounds is of particular interest, since they are inherently high in resistance. Data on this would be of value.

C. Francis Harding* (Purdue University, Lafayette, Ind.): This discussion emphasizes the importance of the use of laboratory tests and models in predicting probable characteristics of grounds in practice. All will recognize the desirability of having the tests made upon actual line installations in so far as possible. However, this is particularly difficult, expensive, and slow of solution in the case of surge potentials. Even in the case of the additional protection against lightning of 4,000-volt distribution lines by means of the interconnection of secondary neutral to lightning-arrester grounds, several years ago, before this Institute, Mr. Roper stated the fact that the laboratory investigation had solved the problem in many years less time and at much less expense than would have been possible by awaiting actual lightning strokes.

Professor J. H. Karr of Purdue University, among others, established a satisfactory close correlation between 60-cycle ground impedances in small volumes of various soils in the laboratory and in actual installations. With the apparently wide variations of such impedances with the shape and depth of grounding electrodes, and with the temperature, moisture content, density, and chemical analysis of various soils, it is obvious that laboratory tests should provide an early solution to such a problem. The authors of this paper have been fortunate in having several types of soil within reach of a surge generator. It is not evident from the paper, however, that ground electrode shapes other than rods of limited diameter were used.

Mr. J. R. Eaton, of the staff of the new high-voltage laboratory of Purdue University, in co-operation with Messrs. Lewis and Foust, is engaged in an attempt to secure further data involving the previously mentioned variables in volumes of various soils in the laboratory using the wide variety of grounding electrodes, sometimes adopted in wooden-pole transmission-line construction. It is hoped that such tests will determine the conditions which contribute most to low impedance offered to surges. Later, by means of a portable surge generator, it is hoped to secure correlations between such laboratory findings and actual installations. Such a procedure should be more rapid and much less expensive than a statistical analysis of actual lightning con-

*Deceased April 13, 1942.

ditions. Both may be necessary for a complete solution of this important problem.

Hamilton Treadway (United States Department of Agriculture, Washington, D. C.): This paper is a valuable extension of the author's previous work on this subject.

There is one point which may give rise to some controversy. The author proposes that the decrease in the resistance of driven grounds with increasing impulse current is due to an increase in effective radius and length due to the increase in voltage gradient. It cannot be doubted that the voltage gradient on the rod results in an increase in both the effective length and radius of the rod. However, it is doubtful whether this is the sole reason for the decrease in resistance.

1. This conclusion assumes that the shell of earth around the ground rod, after the breakdown occurs at the critical gradient, has the same conductivity as the rod, and that the contact resistance of this shell of earth to the surrounding soil is the same as that of the ground rod to the soil. This assumption is obviously incorrect but for all practical purposes may be justified. This point might be clarified by conducting tests on various size rods using values of crest current to give equal voltage gradients on each rod.

2. This conclusion ignores the relation between the leakage resistance of the soil, the contact resistance between the rod and soil, and the capacitance of the rod. The ground rod and lead circuit is essentially an imperfect capacitance in series with a resistance and inductance. The contact resistance is in parallel with the capacitance of the rod. Under transient conditions as the circuit approacnes series resonance, the contact resistance is effectively shunted out, and the resistance indicated is essentially the leakage resistance of the earth itself.

The relation between the constants of the ground circuit is an important one. As pointed out by Mr. Hagenguth in his discussion of the author's first paper on this subject, the impulse impedance will rise rapidly during the first few tenths of a microsecond and in all probability will greatly exceed the 60-cycle value. The impulse impedance-time curve for the parallel combination of grounds F, G, H, and I in Figure 13 of the author's paper substantiates the existence of an initial impulse impedance exceeding the 60-cycle value. This initial rise in the impulse impedance may result in voltage stresses which will exceed the single-shot breakdown voltage of the insulation of low-voltage equipment. This may explain many cases of meter failure which have occurred in rural areas of high lightning intensity. Furthermore, with or without interconnection of lightning arrester and secondary grounds, great danger to life can result from this characteristic of the impulse impedance.

The relation between the inductance, capacitance, contact resistance, and leakage resistance of the ground circuit explains the V characteristic of the impulse resistance-time curves in Figures 11 to 15 of the author's paper. As the point of series resonance is passed, the impulse impedance of the circuit increases, and the impedance again approaches the 60-cycle value.

This V characteristic would be experienced, irrespective of the effect of voltage gradient. With much lower values of impulse currents, where the effect of voltage gradient would be minimized, Towne in his earlier work obtained similar results.

A need is apparent for further research in this field. Work on the evaluation of the ground-circuit constants for the various type soils and ground conductors is desirable. This information will be of great value in the future study of the protection of apparatus from lightning. It is hoped that the author's further investigation of the impulse characteristics of driven grounds will shed some light on the relationship between the circuit constants.

W. E. Berkey (Westinghouse Research Laboratories, East Pittsburgh, Pa.): The authors explain the lowering of the effective resistance of an electrical ground under impulse test in terms of an increase in effective area of the grounding electrodes caused by an electrical breakdown of the ground due to high-voltage gradients. With this assumption they are able to calculate the ground resistance of single or parallel grounds under impulse test conditions with a knowledge of the soil resistivity, the impulse current, and the dimensions of the rod.

It seems probable that the mechanism of conduction through the soil is mainly electrolytic. It is well-known that in electrolytes the conductivity increases (or the resistivity decreases) when the voltage stress is increased. Dilute solutions show a larger increase in conductivity than more concentrated solutions. The increase of conductance depends upon the mobilities, valences, and concentration. This is known as the Wien[1] effect and is not due to temperature or heating effects. For example, in Table I is shown the Wien effect for a barium ferrocyanide solution with conductance $k = 0.000125$ ohm^{-1} centimeter^{-1} or resistivity $= 8{,}000$ ohm-centimeters. The electrode spacing was 0.44 centimeter, and the time constant of the spark discharge was 10 microseconds.

This effect, of course, varies with different electrolytes but may account for the observed lowering of ground resistance in a qualitative way, when it is remembered that probably the conduction through the earth is through electrolytic film-coated particles, in which the voltage gradients may be much higher at the particle contacts than over the particle itself. Debye and Falkenhagen[2] discovered an increased conductance due to an increase in frequency in electrolytic conduction. The conductivity of soil was found by Banerjee and Joshi[3] to increase with frequency of radio waves.

Thus, it would seem possible to account for the lowering of the impulse resistance by assuming that the effective resistivity of the soil is a function of the voltage gradient. Have the authors considered this approach? In the case of ground M shown in the oscillogram of Figure 6 of the paper a real breakdown occurs, in which some of the particles actually flashed over, due to excessively high gradients caused by the abnormally high soil resistivity.

P. L. Bellaschi, R. E. Armington, and A. E. Snowden: The authors want to thank all who have discussed the paper for their contribution to the subject.

Mr. Berkey cites interesting data on the lowering of the conductivity of a barium ferrocyanide solution with increasing voltage gradient. It is suggested that the resistance of grounds in soils may be affected to the same extent by purely electrolytic action. The results of impulse tests we have made on tap water having a resistivity (2,200 ohm-centimeters) which is representative of the ground water at the site of the grounds show that the resistance of the water is practically constant, independent of the voltage gradient. Impulse currents of a 15x30 microsecond wave were applied to electrodes immersed in the water and both current and voltage oscillograms recorded. The measurements cover gradients up to 28 kv per centimeter. The water broke down at 50 kv per centimeter. Within the range of experimental accuracy, all these data show that the resistance of the water remains constant.

The influence of the electrolytic effect in lowering the impulse resistance of natural grounds commonly encountered, similar to those investigated, does not appear to be of more than secondary importance. Exception to this would probably be the case of low-resistance grounds, such as grounds in fills and artificial grounds treated with salts for the specific purpose of lowering the resistance. That is, the exception would be the low-resistance grounds—a point Mr. Beck also brings out in his discussion.

The importance of geology, soil structure, and similar factors in determining the resistance of grounds in a given location, to which Mr. Beck refers, will require a good deal more attention and study. For the problem is of such wide scope that a clearer and more complete understanding of the underlying factors hardly can be reached without a combined approach of field experience, analysis, and actual tests.

As further progress is made, some of the factors Mr. Treadway suggests may be segregated and their respective influence and part in determining the characteristics of grounds better established. However, a good deal more experimental data will be required. In the opinion of the authors, contact resistance and capacitance are factors of secondary importance. There are some exceptions to this statement. For instance, grounds do have a capacitance effect which in very high-resistance soils such as rocks, has a certain contributing effect on the characteristic of the grounds.

Again, the capacitance is a factor of some importance when an abrupt front is considered, particularly in the initial stage of the front discharge.

We agree with Professor Harding that many a complex technical problem has been tackled effectively and economically in the laboratory. The complex nature of ground presents problems which are conducive to fundamental approach in the laboratory. Gradually, the investigation should be extended to the complex forms which the practical problem of grounds in the field present. We always favor correlating field and laboratory results. To accelerate progress and because of favorable conditions, the method and approach presented in the paper were followed. That is, grounds such as employed in service were driven in various soils adjacent to the laboratory and tested at current discharges corresponding to actual lightning.

Shielding of Substations

Discussion and authors' closure of paper 42-14 by C. F. Wagner, G. D. McCann, and C. M. Lear, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 96–100.

G. D. Floyd (Hydro Electric Power Commission of Ontario, Toronto, Ont., Canada.): The degree of protection given to a substation by masts or wires or by a combination of these has hitherto been largely conjecture. This paper should remove some of the unknown factors and permit design of shielding on a somewhat more sound basis. I do not think it is the authors' intention that the data presented should be taken too literally. For example, are not the curves for 0.1 per cent exposure so close to the vanishing point that for all practical purposes all points lying on or below them constitute perfect shielding? Some details of the method by which the authors arrived at a curve where only one stroke per thousand contacted the protected object would give the reader a better idea of the use which might be made of these data in design of shielding.

As a general rule the low-voltage low-capacity substation is not shielded deliberately; the data in this paper offer an explanation. This type of substation covers only a small area and is generally designed to have relatively low elevation. Both factors contribute to the relative immunity enjoyed by such a station. It is rather a nice point to decide whether shielding is justified in the first place, and having decided that it is, to determine the degree in which it should be applied. Whether one per cent exposure is the maximum to be permitted is questionable. I doubt if any substations have such excellent shielding, unless it has been acquired indirectly.

A very common form of shielding is by means of overhead grounded wires, supported either on extensions of the main station structures, or on separate masts. It will usually be found that this combination is cheaper than masts alone for the same degree of protection and can, in addition, be combined with the overhead ground wires of incoming and outgoing lines, to protect these lines as well as the live parts in the station proper. While the data of this paper would appear to cover this combination, I think the advantages of this arrangement might have been shown a little more in detail.

For a given coverage masts and wires are more economical than masts alone and, in certain cases, are also cheaper than structure extensions. A standard height and design of mast is also economical, regardless of the configuration of substation. The required shielding is provided in this case by adjustment in location and number of masts.

It is not quite clear that the cross-hatched areas of Figures 11c and 11d of the paper represent the protected areas for 0.1 per cent exposure. If the locus shown in Figure 11a represents the approximate limit for two masts, should not the corresponding total area for three and four masts be the superposition of the areas between each mast and every other mast? If this be correct appreciable areas shown protected in Figure 11c and 11d would actually be unprotected on the basis of 0.1 per cent exposure.

C. F. Wagner, G. D. McCann, and C. M. Lear: Mr. Floyd's first point is concerned with the choice of 0.1 per cent exposure as a basis for application. Because of the vagaries of lightning the phenomenon involved is statistical in nature. While it is possible to install a network of parallel overhead ground wires, so that perfect shielding is attained, the more conventional construction that usually consists of one or two ground wires leaves large gaps through which a stroke might "infiltrate." It is difficult to assign limiting configurations to such construction that just provide perfect shielding. This may be seen from Figures 3 through 7 in the paper which show considerable displacement between the 1.0 per cent and 0.1 per cent curves. Had sufficient data been taken so that 0.01 per cent curves could have been plotted, some displacement between these curves would still exist. The laboratory difficulties encountered in obtaining such data are evident, inasmuch as to provide data on one point for 0.01 per cent exposure would require something of the order of 100,000 shots. Thus it becomes impractical to obtain data on perfect shielding. The authors have, therefore, chosen the value of 0.01 per cent exposure, as it represents a low enough value upon which data could be obtained and, at the same time, a reasonable value for design purposes. Even these data involved some extrapolation.

The authors agree with Mr. Floyd in the opinion that supporting masts with overhead ground wires are, in general, more economical for the shielding of large areas than masts alone. Some station design engineers, however, fear the danger incident to the breakage of such overhead conductors. It would seem that this difficulty could be alleviated by sufficiently heavy construction.

The question has also been raised regarding the extent to which all points within the shaded areas of Figures 11c and 11d of the paper are protected. These areas were derived from general considerations provided by the test data. Since presentation of the paper, additional tests have been made which definitely establish that all points within the shaded areas have an exposure not over 0.1 per cent for the range of variables given in Figure 10c.

The Influence of Towers and Conductor Sag on Transmission-Line Shielding

Discussion and author's closure of paper 42-37 by R. W. Sorensen and R. C. McMaster, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, March section, pages 159–65.

C. F. Wagner and G. D. McCann (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): A paper presented before the Institute in 1940 by Wagner, McCann, and MacLane discussed the factors that must be correctly simulated in the laboratory so that tests on scale models can be used to obtain data regarding shielding. This paper also described test results concerning the shielding of transmission conductors by ground wires. This work has been extended by two papers presented at this session—one by Sorensen and McMaster which considers the shielding afforded by the presence of the towers and by the sag of the ground wires and conductors, and the other by Wagner, McCann, and Lear which considers the shielding of substations.

The data presented by Sorensen and McMaster is interesting in that it shows, for the particular configuration assumed, the extent to which the tower structure shields the conductors. For distances approximately two times greater than the tower height, little shielding is provided. This effect is epitomized in the curve of Figure 24 of the paper which presumes to indicate the variation of the integrated shielding effect for different span lengths. The ordinate of this curve is labeled "Per Cent Added Protection," which, expressed more clearly but not so concisely, might be called "The Per Cent Decrease of Strokes to the Conductor Because of the Presence of the Tower." The curve in Figure 24 is based upon the assumption that the relative shielding of the tower, as given in Figure 22 of the paper, is independent of the span length. Actually, however, this is not the case. As shown by Figure 7 of the paper entitled "Shielding of Substations," substantially perfect shielding should be obtained for span lengths less than twice the conductor height. The full

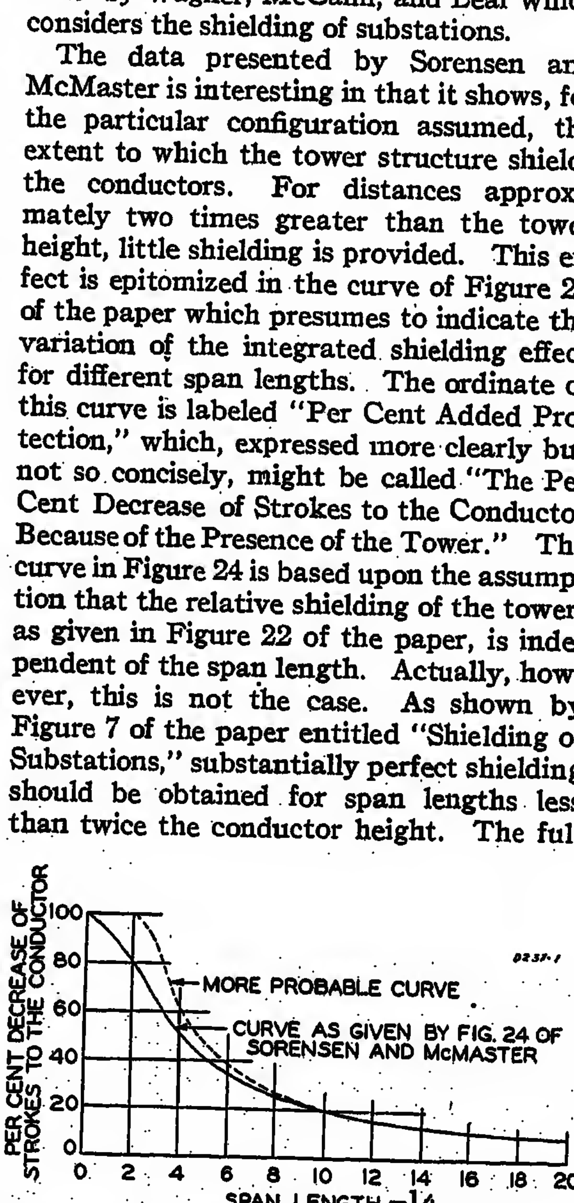

Figure 1. Added protection resulting from presence of towers for various lengths of span

line of the accompanying Figure 1 is reproduced from Figure 24 of the Sorensen and McMaster paper, and the dotted line indicates the more probable curve resulting when an estimate of the change in distribution with span length is taken into consideration. The normal range of span length to tower height lies between 6 and 12, between which values the presence of the tower reduces the strokes to the conductor between 15 and 40 per cent. Thus the previous work on the shielding of conductors by ground wires is conservative to this extent. This represents about the same order of accuracy as one would expect upon extrapolating laboratory results to actual systems. It is assuring, however, that the error by neglecting tower effects is on the side of conservatism. Correction for this effect involves an increase of but a few degrees in shielding angle, which is hardly worthy of consideration.

The curve and the data presented by Sorensen and McMaster apply only to the particular configuration tested which represents a shielding angle of 64 degrees. While this particular configuration was chosen to magnify the effects involved, it would have been interesting to have determined the tower effects for a smaller shielding angle, an angle between 35 and 45 degrees which is more representative of good practice.

Robert C. McMaster (California Institute of Technology, Pasadena, Cal.): Since the writing of this paper, a further investigation of the shielding effect of towers on short transmission-line spans has been completed. Results of model tests conducted under conditions identical to those reported in the paper, for a span of length equal to twice the tower height, are shown in the accompanying curves. Two identical model towers (see Figure 6 of paper for detailed dimensions), each 10 inches in height, were placed 20 inches apart and supported taut conductor and ground wire at a protective angle of 64 degrees as shown in Figure 7 of the paper. Cloud height was five times tower height, as before.

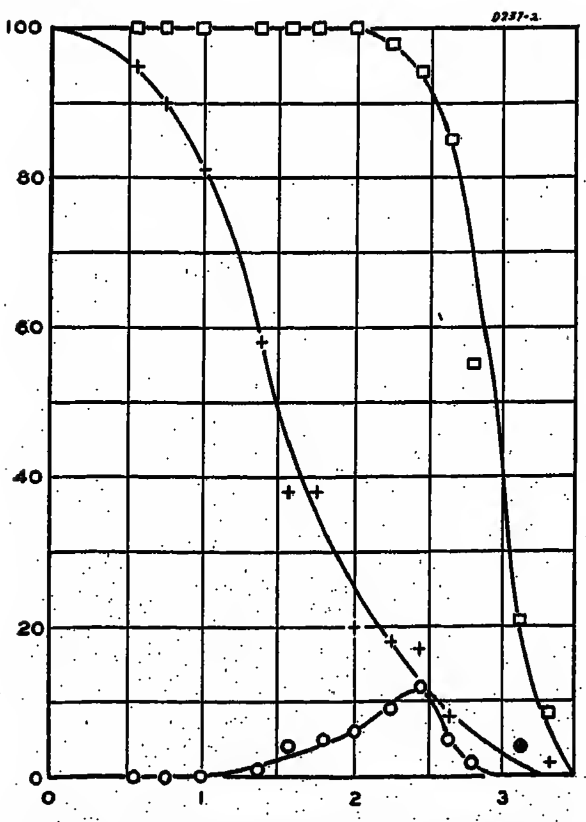

Figure 2. Stroke distribution in plane $B/h=0.5$, for span lengths of $2h$

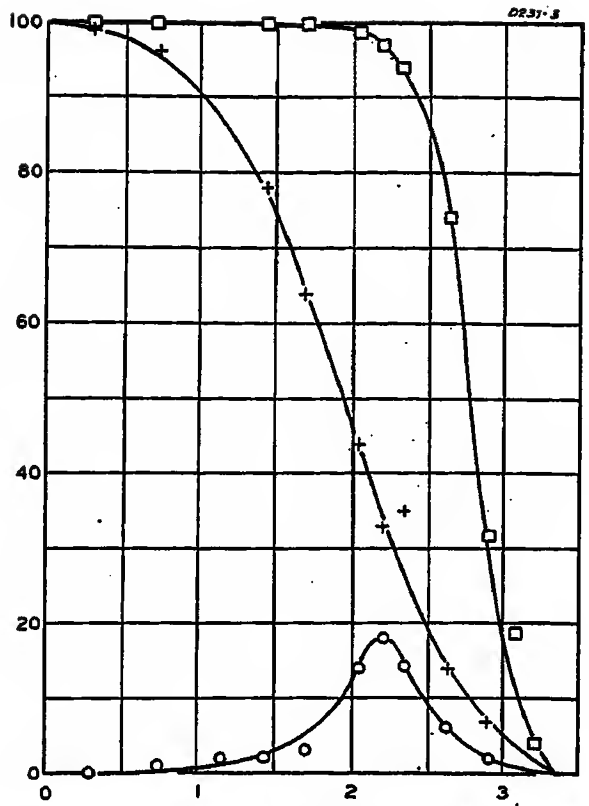

Figure 3. Stroke distribution in plane $B/h=1.0$, for span length of $2h$

With the cloud electrode in the plane of the tower, $B/h=0$, the distribution of Figure 8 of the paper was obtained for strokes to the system. With the cloud electrode in the plane $B/h=0.5$ (one-quarter the distance between towers) there was obtained the stroke distribution of Figure 2 of this discussion. In the plane $B/h=1.0$ (half the distance between towers) the distribution was found to be that shown in Figure 3 of this discussion. From the areas under these curves, Figure 4, showing the distribution of strokes along the span, was obtained.

The per cent added shielding, resulting from the presence of towers, is found by comparing Figure 4 of this discussion with Figure 21 of the paper, and equals 88.9 per cent for this span length. The result obtained from the investigation of longer spans, shown in Figure 24 of the paper, gave 80 per cent as the added shielding for this case, a conservative value which differs from 88.9 per cent by an amount which would have negligible effect upon the shielding calculated for an entire transmission line in which such short spans would be rare. Figure 5 of this discussion shows this correction to Figure 24 of the paper.

It is to be noted again that the results given in this discussion and in the paper apply quantitatively only for the 64-degree protective angle chosen for the test measurements, as stated in the paper. For other protective angles, the trends and relative

shielding effects of towers and line sag can be determined only qualitatively from these data.

R. W. Sorensen: The several papers of the session have each made a definite contribution to our knowledge of lightning and what to do with it in connection with the operation of electric power systems, and structures to be protected. In 1926, some costly fires due to lightning occurred in oil-storage reservoirs, and a rather hurried study was made to determine the value of rods or towers as a means of providing protection against damage by lightning. One result of that study was the erection in southern California and other places of well-grounded towers to serve as lightning rods around oil-storage reservoirs.

In general, the towers were located so that any spot to be protected came within a circle, such that the distance from the rod on the level of protection was within $2^1/_2$ times the rod height from the rod. In other words, each tower is expected to protect around it an area included within a circle having a radius of $2^1/_2$ times the tower height. It is obvious that such a tower could not be in the center of the structure whose protection is desired. Therefore, in each installation, several towers surrounding the object to be protected were used.

These towers were placed at considerable distance from the reservoir to be protected, to guard against side flashing from the tower to the reservoir.

Naturally, the protective circular areas for the several towers were made to overlap so that all parts of the object whose protection is desired will have the protection of one or possibly more rods. No guarantees were made that absolute protection could be provided by rods, but up to the present time (15 years have elapsed) all places provided with the protection planned have been free from damage by lightning. The statistical data are therefore favorable.

The paper, "Shielding of Substations," by Wagner, McCann, and Lear, adds greatly to the information that was obtained when the protective plan for the oil-storage reservoirs was developed. Their presentation, combined with the information contained in each of the papers presented at the session, well augment our knowledge as to what can be done in maintaining lightning protection by the use of rods—in some cases supplemented by connecting grounded conductors.

A comparison of the data presented in McMaster's discussion, which show some slight changes from the data in the original paper, indicates that the original data regarding the amount of shielding due to

towers and sag do not give an impression of more protection than might normally be expected in power lines with shorter spans.

With regard to the dependability of results as obtained from the tests on models as discussed in our paper, may I call attention to the fact that in studying actual lightning performances, as well as in the use of model tests, the results obtained are statistical. The probability law regarding the ratio of strokes that hit the rod, to strokes that hit elsewhere, holds both in model tests and in actual observation of lightning itself.

It therefore seems to me that, notwithstanding our inability to exactly duplicate all actual conditions with small scale models, the statistical measure of protection provided by the tests on models is well within the range of the statistical measure of protection upon which one can rely in using data as they apply to actual lightning. It therefore does not seem unreasonable to assume that we are fully justified in considering our model tests as indicative of actual lightning conditions, due regard, of course, being given to a reasonable engineering tolerance factor.

Lightning Investigation on 132-Kv Transmission System of the American Gas and Electric Company

Discussion and authors' closure of paper 42-18 by I. W. Gross and G. D. Lippert, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April section, pages 178–85.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The authors have presented a large amount of data accumulated over the last eight years during the course of their lightning investigations. These data should be very useful to the utilities as well as to the designers of equipment, since the large amount of data available and presented permit drawing rather definite conclusions as to the severity of lightning currents, the effectiveness of ground rods and counterpoises and the effectiveness of modern lightning arresters.

The authors mention, in connection with Table II, that the apparent line-surge impedance is of the order of 236 ohms or less when the calculation is based on the measured bus voltage and on the measured line current. Conversely the traveling wave voltage using line current at station and surge impedance of 400 ohms is of the order of from 800 to 6,000 kv.

I would suggest the following interpretation:

If traveling wave theory is used on a circuit represented by an incoming line and outgoing line with an arrester at the junction, and the arrester is represented by a resistance corresponding to its maximum IR drop, the effective station resistance R' is a parallel connection of outgoing line-surge impedance Z_2 and arrester resistance R or $R'=R\times Z_2/R+Z_2$.

In the case of the currents presented in Table II of the paper, the IR drop is of the order of 315 to 355 kv, the arrester resistance between 140 to 260 ohms, and the effective station resistance R' between 105 and 157 ohms if Z is taken as 400 ohms. The sum of the currents in the outgoing line and through the arrester is equal to measured line current.

$$i_R'=\frac{2E}{R'+Z}$$

where E is traveling wave voltage.

The current associated with the incoming traveling wave is $i_t=E/Z$; therefore, the ratio of traveling wave current to the total measured current is

$$\frac{i_t}{i_R'}=\frac{R'+Z}{2Z}$$

or

$$i_t=i_R'\ \frac{R'+Z}{2Z}$$

i_R' represents the sum of the incident and reflected traveling current wave which is measured as line current. R' and Z are known impedances, and, therefore, the traveling wave current, the traveling wave voltage, the current in the arrester and in the outgoing line can be calculated. Table I of this discussion shows these values for the five cases at Roanoke.

Therefore, the bus voltage represents the sum of the incident and reflected traveling voltage wave; likewise, line current represents the sum of the incident and reflected traveling current wave. Bus voltage divided by line current gives the value of the effective terminal impedance of the line.

The traveling wave voltages range between 560 and 800 kv which are reasonable values and are to be expected near a station on a 132 kv system.

The bus voltages measured are, of course, at least as high as the arrester-gap breakdown, which is 388 kv for AIEE lightning-arrester test. The IR drop following the arrester-gap breakdown is however, much lower for the low currents indicated in Table I of this discussion. The effective terminal impedance depends on the IR drop of the arrester rather than on the gap breakdown voltage.

The calculated and measured arrester current checks well for case 3 only. In all other cases, the calculated currents are higher than the measured values from 700 to 2,000 amperes. It is not stated whether the measured line current is the sum of the currents on the incoming and outgoing line. If it were the sum, then, of course, the calculated arrester currents would be considerably smaller. In case 3 for instance, the lightning arrester current would be 800 amperes instead of 1,400 amperes. In calculating Table I, line currents have been assumed to be measured on one line only.

The actual circuits involved in the terminal impedance at stations is much more complicated than the circuit used for these calculations. Especially if station capacitance is taken into account, the traveling wave current would be roughly one-half line current for relatively steep current waves, because the capacitance initially reacts as a short circuit to the incoming current wave with a consequent reflected wave of amplitude and polarity equal to the incident wave. On that basis, the calculated arrester currents check more closely the measured currents, and the traveling wave voltages will range between 400 kv and 640 kv for the examples in Table I of this discussion. A more exact calculation can be made when all the constants of the circuit are known.

The low bus voltage of 300 kv in the fourth case at Roanoke is indicative of a slow rate of voltage rise of the traveling wave. This is substantiated by the maximum rate of voltage rise of 92 kv per microsecond given in the table for this case, the calculated IR drop is 320 kv with an arrester current of 1,600 amperes. In the fifth case at Roanoke, the high line current and low bus voltage without arrester operation suggest that the incoming traveling wave was of the order of 800 kv or higher but of short duration, probably less than one microsecond. Such a wave could be reduced by the station and bus capacitance to the measured value of 233 kv and, therefore, would not cause arrester operation. It would be interesting to know whether records indicate a line flashover at the time this record was obtained. A short wave of only one-microsecond length would, however, have a relatively steep front of the order of 800 kv per microsecond or greater, while the wave-slope indicator indicated only 164 kv per microsecond.

Similarly, the high bus voltages shown for cases 1 and 2 at Roanoke would indicate high rates of voltage rise to exceed the arrester-gap breakdown voltage of 388 kv.

The rates of voltage rise indicated in the Table II of the paper for a few of the cases in Roanoke, therefore, seem to be too low to account for some of the other simultaneous observations in the station and on the line.

If a wave-slope indicator, such as shown on Figure 1A of the paper was used in this station, the calibration of the instrument would have a dual calibration on account of the 35-turn coil which probably has an inductance of the order of 13 microhenries and the fact that a protective gap is provided. With rates of rise producing inductive voltages with amplitudes smaller than sparkover of the gap, the calibration should be $de/dt=i/2C$. When the rates of rise are great enough to arc-over the gap, the current indication can be equivalent to several times the rate of rise indicated by the above equation.

On the basis of such calculations, it might be worthwhile to re-examine the records. Such an examination might show that a larger proportion of waves had steeper wave fronts. Due to the dual calibration characteristic, the correct rate of rise can be established only in such cases where other related data, such as in Table II of the paper, are available.

Finally, with respect to the authors' Table III, I would suggest a possible explanation for the apparent greater effectiveness of the tower legs to carry current than the counterpoise. If we analyze case 1 of Table III, we find that the tower-base voltages associated with tower leg, ground rod, and counterpoise currents are 360,000, 275,000, and 117,000 volts respectively if currents are multiplied by resistance. Obviously, the three voltages cannot exist simultaneously. Now we know from tests[1,2], that a counterpoise resistance varies between some 100 to 200 ohms initially to a value somewhat lower than the d-c resistance, provided the current fronts

Table I. Lightning Data at Roanoke Station as Calculated and Compared With Test Results of Table II of the Paper. $Z = 400$ Ohms

Measured Line Current (Amperes)	Measured Arrester Currents (Amperes)	Calculated Arrester Currents (Amperes)	Bus Kv Measured	IR Drop Calculated	Terminal Impedance Calculated	Traveling Wave Current (Amperes)	Traveling Wave Voltage (Kv)

2,000		No operation	233	314	157	2,000	800*

*Arrester did not operate. Indicates chopped traveling wave reduced to 233 kv by station capacitance.

are steeper than the length of travel of the current wave on the counterpoise. On the other hand, the 200 ohms resistance of the tower leg probably does not vary considerably since its length is short (ten feet) and the registered current of 1,800 amperes is relatively low. The resistance of the ground rod probably is initially higher than the d-c value, since its length of 60 feet is considerable.

Calculations based on these considerations would indicate a probable maximum rate of current rise of the total current to ground of 20,000 amperes per microsecond and an average rate of rise of 4,000 amperes per microsecond with a crest current of 10,000 amperes. In other words, the three current crests measured do not occur at the same time.

The rates of rise indicated above are well within the range of measurements made on the Empire State Building.[3] A rate of 20,000 amperes per microsecond or more was recorded in 36 per cent of the records. Since the values shown in Table III are undoubtedly the results of direct strokes, the results of such measurements seem to indicate a qualitative check to the measurements at the Empire State Building. If the data of Table III are interpreted in this manner, that the apparent high tower-leg conductivity indicates high rates of current rise, such measurements might be useful to obtain statistical data on rates of rise of lightning currents.

W. W. Lewis (General Electric Company, Schenectady, N. Y.): In Figure 10 of the paper by Messrs. Gross and Lippert are given curves of rate of change of voltage at stations. These curves are based on a certain interpretation of the wave-slope-indicator records.

In a paper by Lewis and Foust, entitled "Lightning Investigation on Transmission Lines—IV," which appeared in AIEE Transactions for August 1934,[1] Figure 1 shows the time to reach crest of 45 waves caused by lightning on the 220-kv Wallenpaupack–Siegfried line, as recorded at the end of the line by cathode-ray oscillograph, and Figure 3 gives similar information for 16 waves recorded at the mid-point of the line. I have taken the same data and calculated the kilovolts per microsecond of the wave front.

In Figure 1 of this discussion curve A shows kilovolts per microsecond as ordinates against percentage equal to or greater than ordinate for 44 waves recorded at the end of the transmission line near the station. Curve B gives similar information for the 16 waves recorded at the mid-point of the line. It will be noted that curve B lies considerably above curve A. Three points of small voltage amplitude but very short time to crest account for the upper part of curve B. A possible explanation for the difference in these curves is as follows: The transmission line was covered with two overhead ground wires for 20 miles near the end of the line. Most of the waves recorded traveled in toward the station from a long distance and consequently suffered considerable attenuation before reaching the oscillograph. At the mid-point of the line, however, there were no overhead ground wires and it is possible that the waves originated nearer to the oscillograph. Consequently, these waves were steeper than the waves at the end of the line.

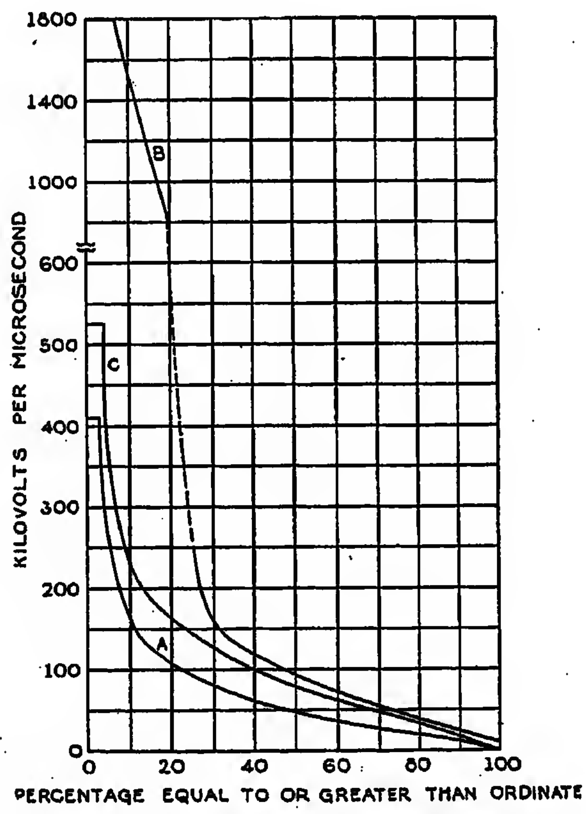

Figure 1. Comparison of wave-slope-indicator and cathode-ray-oscillograph records

Curve A. 44 cathode-ray-oscillograph records at end of Wallenpaupack–Siegfried line

Curve B. 16 cathode-ray-oscillograph records at mid-point of Wallenpaupack–Siegfried line

Curve C. 554 wave-slope-indicator records at stations on Glenlyn–Roanoke line

Curve C is plotted from 554 records secured on the Glenlyn–Roanoke line in 1939, 1940, and 1941, by means of the wave-slope indicator. These are the same data on which Figure 10 of the Gross-Lippert paper is based, but the data have been interpreted differently. The oscillatory surge interpretation has been used, making use of the data from all of the links.

The data of curves B and C were both taken under similar circumstances, that is, from traveling waves coming into stations on conductors shielded by overhead ground wires. These two curves check very closely and this circumstance gives considerable confidence in the wave-slope indicator and the oscillatory surge interpretation.

J. T. Lusignan, Jr. (Ohio Brass Company, Mansfield, Ohio): In commenting on the results of Table II of the paper the authors mentioned the apparent discrepancy in arriving at line impedance values. I assume that the bus voltage is measured next to the arrester so that applying this to the line current should result in a value for arrester impedance not line-surge impedance. Could that be a proper assumption?

In the paper I note reference to the use of $^1/_{16}$-inch-by-2-inch flat iron strap for counterpoise. What are the advantages of this section? I am wondering whether there have been any corrosion problems with such a section as yet.

Should the range of 15.6–180 per cent for relative conductivity of the ground rods not be 31–180 per cent? The last column of Table III leads me to believe this.

The field-investigation data described in this paper should prove most helpful not only to the operating engineer and line designer but also to the equipment manufacturer. I was very interested in the figures given by the authors for rates of voltage rise recorded at the stations. While it is comparatively easy to design line insulators to resist puncture under exceedingly steep wave fronts, it is rather costly to do so with such station insulation as bushings. Often some sacrifice of other worth-while properties must be made. So far we have designed to meet voltage rises in excess of 1,000 kv per microsecond. We note that the authors only measured a maximum of 600 kv per microsecond. I am wondering whether they felt that 1,000 kv are still a reasonable figure. It is not that we want to drop it any. We would just not like to have it hiked much higher.

C. M. Foust (General Electric Company, Schenectady, N. Y.): The wave-slope measurements of conductor voltages at substations included in the paper by Messrs. I. W. Gross and G. D. Lippert were obtained through an extension of our now extensively used surge-crest ammeter technique.[1] Sev-

eral steps in this adaptation, particularly as to details of calibration not included in the paper, are brought out in this discussion.

The general arrangement of field setup as shown in Figure 1 of the Gross-Lippert paper consists of magnetic links located in the ground connection to the coupling capacitors to measure maximum capacitor currents. The design of the coupling-capacitor wave-slope indicator is based on the following considerations:

1. A range of wave slopes from 25 to 5,000 kv per microsecond.

2. Measurements of capacitor currents reversing in polarity with a wide range of relative front- and tail-slope ratios.

3. Coupling capacitors of several capacitance values.

For a unidirectional voltage wave on the line the coupling capacitor current will reverse in polarity, and when the charging and discharging currents are of the same order of magnitude, a simple unidirectional current calibration for the magnetic links will be inaccurate, giving values generally below true wave slopes.

These considerations were provided for through the design of an eight-link recording station for each coupling capacitor with the links set in or adjacent to small coils in the ground connection of the coupling capacitor as shown in Figure 1A. The coil turns and link locations were designed to give a magnetization ratio of 2.5 to 1 between adjacent links. On a surge-crest ammeter of 100 divisions and proportional to magnetization current, this 2.5 to 1 ratio gives at least three adjacent link readings for each application of unidirectional current from 10 to 8,000 amperes. This range of current provides for wave-slope readings from 25 to 5,000 kv per microsecond with the available coupling capacitors ranging from 0.00025 to 0.0015 microfarad. Now with this overlapping of link magnetization, at the known link ratio of 2.5 to 1, an oscillatory calibration similar to those we have used for structure currents and checked by actual laboratory tests can be used to obtain crest-current values with reasonable accuracy.

On this basis of interpretation our field records range up to 525 kv per microsecond with the distribution of frequency of occurrence shown in Table II. These values do not depart greatly from those presented by Gross and Lippert in Figure 10 of their paper and based on a somewhat different interpretation.

As far as available records indicate, these slopes were the result of traveling waves incoming to the station from strokes to the line some distance out. For comparison with these distant strokes we have a direct-stroke oscillographic record made in 1930 of slightly under 2,000 kv per microsecond. This 2,000-kv-per-microsecond slope was a direct stroke to a high-voltage transmission line, the measurement having been made immediately at the point of a stroke to the line conductor of a 220-kv line. No overhead ground wires were in use at the time. The point struck was out on the line remote from the terminal stations, and no additional station capacitance was available to reduce the wave slope. This value of voltage wave slope, therefore, possibly ranges above that to be expected on well-protected lines at substations.

Table II

Wave Slope Kv Per Microsecond	Frequency of Occurrence Per Cent Above Magnitude of Column 1
525	Maximum recorded
220	10
150	20
100	40
60	60

1. Direct Measurement of Surge Currents, C. M. Foust and J. T. Henderson. AIEE Transactions, volume 54, 1935, April section, pages 373–8.

J. G. Hemstreet (Consumers Power Company, Jackson, Mich.): This paper presents very valuable information pertaining to the effects of lightning on high-voltage transmission systems. We compliment the authors on the splendid way that they have collected and presented such a large amount of pertinent data and concur on the conclusions that have been derived.

The statistical curves for lightning currents appearing in the various elements of a transmission system should be of interest to all concerned with lightning protection and performance of high-voltage transmission facilities.

The writer has been associated for the past five years with an investigation of the relative effectiveness of radial counterpoise and deep driven ground rods. This investigation has been conducted on towers situated on a sandy plane where tower footings and counterpoise offer very high measured resistances to ground. Deep driven ground rods extending to depths of approximately 100 feet below the surface offer very low measured resistances and are connected in parallel with the counterpoise to each tower. Counterpoise and rods are so equipped that contributions of each to the total tower current may be measured. It has been found in our investigation that where the measured resistance of the ground rods is very low as compared to that of the counterpoise, the ground rods contribute three to four times as much current as does the counterpoise, thus indicating that the deep driven ground rods are very effective for dissipating stroke currents. The ratio of per cent current to per cent conductivity of the counterpoise has been found to be as much as 8.6 or more when the same ratio for the combined tower footings and ground rods is in the order of 0.6.

Data presented in Table III of the paper for cases 1, 2, and 3, when rearranged to compare the counterpoise contribution with that of the ground rods and tower footings combined, give ratios of per cent current to per cent conductivity for counterpoise as 0.72 to 0.78, while the same ratio for ground rods plus tower footings is about 1.6 to 2.0. This differs somewhat from our experience and is probably due to the different conductivity relations of counterpoise and grounding system.

It is, therefore, possible that the counterpoise may contribute much more current than a measure of its conductivity would indicate, while means for grounding the towers directly by ground rods and tower footings would carry current more nearly in the order of their conductivities.

The writer is curious to know the general nature of the surface and soil conditions for the towers listed in Table III, since the measured resistances of the counterpoise are somewhat less than either tower footing or ground-rod resistances in every case.

W. G. Roman (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. In discussing Table *A* of the paper, the authors attempt to estimate the conductor voltage by multiplying the observed line currents by an assumed surge impedance of 400 ohms. This leads to erroneous results, as the current recorded in the line is not a single traveling wave current, but the totalized current consisting of all traveling waves including reflections from arresters, flashovers, and junction points, as well as the original traveling wave current. The actual line voltage is determined by the impedance of paths to ground particularly the tower and tower ground or the station arresters and ground.

2. The same comments apply to the attempt to calculate the line-surge impedance from the observed line current and bus voltage in Table II of the paper. The bus voltage is determined by the impedance drop through the station arresters, the station ground, and the drop from the bus to the arresters.

3. In Table II, there are discrepancies between the observed line currents and the arrester discharge currents. Is this due to currents leaving the station on other lines connected to the same bus? If so, are records of these currents available, and do the sum of all the currents into the station bus correlate with the observed arrester currents?

4. When a traveling wave enters a station, the rate of rise of voltage on the bus is not necessarily the same as would be measured on a line when the same wave passed. A typical station is a complex network of parallel capacitances from the bus to ground through leads of various lengths. These station constants determine the rate of rise of voltage on the bus for a given traveling wave entering the station. For a given traveling wave, the rate of rise will be higher in a small station having low capacitance to ground than in a large station having high capacitance to ground. Also, a station having more than one line connected to the bus will show lower rates of rise than a station having only one line on the bus. For these reasons, caution should be used in applying data on rates of voltage rise obtained in a given type of station to stations or equipment in general.

C. F. Wagner and **G. D. McCann** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): A single magnetic link can be used to determine the crest magnitude of a unidirectional current. When, however, the current is oscillatory or has values of opposite polarity subsequent to the crest, two or more links are required to estimate the crest magnitude of the current. The reason for this is the demagnetizing action of the current of opposite polarity.

A demagnetizing current of but one or two per cent of the original magnetizing current might produce an error of 25 to 50 per cent of the true indication, and larger currents larger errors.

The magnetic link in the wave-slope indicator described in the paper by Gross and Lippert will be magnetized by a current which is proportional to the rate of change voltage across a capacitor. The authors recognize the interference of switching surges in most of their links and limit their lightning measurements to the indications of a single link. Due to the complex nature of voltage surges, especially at terminal equipment, the magnetic links are, in all probability, subjected to demagnetizing influences subsequent to the maximum magnetizing force. This would, undoubtedly, throw considerable doubt upon the records so obtained. Most, if not all, of these devices were located adjacent to transformers protected by arresters. It is likely that the maximum rate of change of voltage occurs when the arrester gap breaks down. Curve I of Figure 10 of the paper is, therefore, more likely to be a measure of the rate at which the arrester breaks down, influenced, of course, always by the extent to which any subsequent rate of change of opposite polarity might affect the reading.

I. W. Gross and G. D. Lippert: In presenting the data given in this paper, the authors hoped that sufficient detail was included to enable others interested in the lightning field to analyze it and draw their own conclusions, which, it was recognized, might not in every case conform to that given in the paper. Comments along this line are certainly most welcome, as it is recognized, in exploring new fields in lightning field research with newly developed instruments and even with some of the older ones, there are discrepancies which have occurred and may continue to exist for some time to come.

Regarding the matter of correlating measured bus voltages with line currents and surge impedances, it is recognized that the technical solution of this problem involves complicated mathematics together with a knowledge of terminal constants which it is difficult if not impossible to obtain. In presenting data, therefore, such as given in Table II of the paper, it was realized in suggesting this analysis that complete correlation might not be obtained. However, it is impractical to attempt to calculate lightning voltages and impulses with any degree of certainty in a complicated network consisting, for example, of one incoming line, four outgoing lines—one being on the same tower circuit as the incoming, and, in addition, coupling capacitors, station capacitance, terminal equipment, and the like at the station.

Table II merely attempts to show what correlation, if any, does exist on a very simple basis. It is hoped that the presentation of the data in Table II and the discussions which have followed will lead to more extended work on this problem in an attempt to reach a much more simple and easy solution than now required by extensive mathematical calculations.

Mr. Hagenguth uses a relatively simple mathematical analysis which seems to have promise of placing a reasonable interpretation on the data. The currents recorded in the paper are actually measured currents in the line wires and are not a value obtained by the addition of currents in separate wires. In the fifth case of Table II, there was no evidence found that there was a line flashover associated with this record.

Regarding the possibility of the protective gap flashover affecting the results, there was only one field station where evidence of this gap flashing over was obtained.

The data obtained in our field investigation, when interpreted, give rates of current rise comparable to those obtained on the Empire State Building. It has always been a question in the minds of the authors whether or not it was possible to convert satisfactorily records in lightning strokes to a building such as the Empire State Building to practical application to an elevated transmission system such as a 132-kv line or circuit.

Dr. Lewis' comparison of rates of voltage rise measured at stations and out on the line with the data presented in our paper is most interesting, considering that they were obtained by two entirely different methods. We subscribe heartily to the suggestion that higher rates of voltage rise undoubtedly occurred near the region of the stroke. This means that on lines which are not shielded, higher rates of voltage rise may be expected than on lines partially or adequately shielded.

Regarding the use of galvanized iron strap for counterpoises on which a query has been made by Dr. Lusignan, this material was used on account of its low cost, expected freedom from theft, and the further belief that it would be reasonably unaffected by soil corrosion. Digging up and inspecting this material after some six years indicated that there was relatively no trace of any corrosion whatsoever.

The percentage range of 31 to 180 instead of 15.6 to 180 for the relative conductivity of ground rods is correct. Regarding the question raised by Dr. Lusignan as to whether the 1,000 kv per microsecond furnish a reasonable basis on which to design equipment, we believe that there is nothing in the picture as brought out from the data reported in the paper relative to natural rates of rise of natural lightning on transmission lines which would indicate that the 1,000-kv-per-microsecond figure is too low. Until further evidence is available, there certainly seems to be no justification for decreasing this value as a design basis.

The question of the method of determining rate of voltage change in the field with the surge-crest ammeter has been mentioned by Messrs. Wagner and McCann, and perhaps Mr. Foust's discussion has already cleared up this point. We recognize that this wave-slope indicator is a relatively new instrument in the field and will be subject to some scrutiny until records obtained therefrom have been correlated with other data obtained by different methods. Considering the relatively large amount of data that is obtainable by the use of this instrument at a reasonable cost, in comparison with a single cathode-ray field installation and the uncertainties coupled even with this more accurate measuring instrument, it is believed that the wave-slope indicator has yielded some very valuable information, although it may be later subject to some modification in the instrument itself or detailed refinement in calibration.

The results Mr. Hemstreet has mentioned in connection with his field work in measuring the effectiveness of driven ground rods, counterpoises, and tower resistances are interesting. The fact that they do not show the same trend as those reported by the authors may be due in part at least to different soil conditions. The conditions under which our reported measurements were made were in flat country with sandy loam-type soil. We hope to continue further investigation on this subject, and perhaps the results may show why there is a discrepancy between the grounding results shown in Mr. Hemstreet's field study and those reported by the authors.

Lightning Investigation at High Altitudes in Colorado

Discussion and authors' closure of paper 42-16 by L. M. Robertson, W. W. Lewis, and C. M. Foust, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, April section, pages 201–08.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper is very interesting from the point of view of extending lightning-stroke records into regions of high altitude. The conclusion is drawn that there may be no lightning strokes within regions of altitudes of 18,000 feet and above. I should expect that this conclusion is correct as far as currents of sizable amplitude are concerned. On the other hand, the existence of long continuous discharges of relatively long duration might be expected to take place between differently charged portions of the clouds, as well as between cloud and ground. Data are available. The fact that the terrain extends into the cloud should not preclude formation in the clouds, especially since air currents at such altitudes are frequently extremely violent.

It is interesting to note from Figure 1 and Table 1 of the paper that the average number of strokes per mile per year, over the whole section above 6,000 feet, is approximately 0.25; in the section 6,000–8,000 feet —0.43; 8,000–10,000 feet—0.1; 10,000–12,000 feet—0.17, and in the short section above 12,000 feet—1.75 strokes per mile per year.

In conclusion 2 of the paper, it is shown that of the 145 strokes registered, 56 per cent caused faults and 44 per cent caused no line disturbances. It would be interesting to know the distribution of faults with respect to the altitude on this line. From the data presented, it would appear that flashovers should occur frequently at altitudes, such as are attained by this line, because:

1. The number of strokes per mile is high.
2. The ground resistance of tower footing, and probably also of counterpoise, increases rapidly with altitude as shown in the paper.
3. The flashover voltage of the air decreases considerably at high altitude.

Therefore, the reduction in current amplitude should not have so great an effect on the fault record as would appear from the current data alone. I would appreciate

the authors' comments on this phase of their investigation.

Edward Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Robertson and his coauthors conclude that there is little likelihood of lightning strokes at altitudes of 18,000 feet or more. Although the data adduced in the paper are hardly complete enough to prove the case, there is some logic in the assumption that altitude influences lightning. Is it not likely that this influence varies with climatic conditions and geography? In the tropics, thunderstorms are reported to be of somewhat different nature than in the temperate zones, with a greater prevalence of strokes between clouds. This may be a manifestation of an effect as discussed by authors in so far as the freezing isotherms shown in Figure 10 of the paper are, no doubt, at higher altitudes than in the United States, so that the separated charges may lie at higher altitudes. It would be interesting if more data were made available on this subject.

Another factor that may color the distribution of the current records is the influence of earth resistivity and geology on the nature of the lightning currents that flow after the stroke has been established. Some lightning investigations and observations of arrester performance, as discussed before the Institute[1] last summer, indicate that such an influence exists. This is logical, since the earth, as well as the cloud, is a terminal of the lightning battery. In regions of ancient geology and high resistivity currents of lower amplitude may prevail. Such regions exist in Colorado, and the effect may be magnified on the tops of rocky mountains. The authors have mentioned geology, and continued investigation of its effect on lightning currents is of importance. This relates also to the paper by Messrs. Bellaschi, Armington, and Snowden, on impulse and sixty-cycle characteristics of driven grounds, presented at this meeting.

C. F. Wagner and **G. D. McCann** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): As stated by the authors, operating experience of transmission circuits at high altitudes over a period of 30 years has shown that there is less damage to equipment than at lower altitudes. The authors, from the data submitted, conclude that this is due to the absence at the higher elevations of lightning currents of large magnitude. It may be that the simple explanation is the less frequent occurrence of lightning strokes of all magnitudes; that is, the current distribution curve might be the same but the total strokes per season be fewer.

All the points obtained are tabulated in Table I and plotted in Figure 5 of the paper. For a given range in altitude, fewer records are obtained at high altitudes than at the lower altitudes. In the absence of information regarding the distribution of the number of instruments as a function of altitude, it is impossible to say whether this is due to fewer instruments at higher altitudes or fewer discharges per instrument. In any event, because of the statistical nature of such investigations, the number of records obtained above 8,000 feet is insufficient to warrant the conclusion that currents of large magnitudes do not occur. Had a larger number of instruments or a longer period of time been considered, currents of large magnitude might have been recorded.

The bench marks which form the points at zero elevation in Figure 5 were obtained from the low-altitude record of Figure 6 of the paper, the Lewis and Foust curve. The accompanying Figure 1 shows a similar curve obtained by Waldorf. If will be observed that this curve shows much smaller currents than that of the Lewis and Foust curve, and had the bench marks at low altitudes obtained from this curve been used, the straight lines of Figure 5 would have been entirely different.

In Figure 1 not only are the Lewis and Foust and Waldorf curves plotted, but also the mean curve for all the records of Table I, which represents data for altitudes in excess of 5,000 feet. Comparing this curve with the Waldorf curve shows that the effect of altitude is very small, the difference being much smaller than the difference obtained by different investigators at low altitudes.

Not being able to identify the particular points from which the different curves in Figure 6 were plotted, the authors replotted the data in Table I for the four ranges in altitude given. The results are shown in the accompanying Figure 2. These curves do not appear to indicate a very definite trend in the effect of altitude, the differences being smaller than are obtained from year to year or from season to season on the same line.

In conclusion, while the surmise of the authors may be correct that the magnitude of lightning strokes decreases with increase in altitude, the data presented appear insufficient to draw definite conclusions.

E. A. Evans (General Electric Company, Pittsfield, Mass.): The authors have stated in conclusion 1 that 36 per cent of the currents they measured were positive, while 64 per cent were negative. This is of considerable interest since, as they have also indicated, stroke currents measured on low-altitude transmission lines have been found to be roughly five per cent positive, and 95 per cent negative. They suggest as a possible contributing factor, the probability that the high-altitude lines may at times be within the clouds. Under this condition one might expect that the line would be nearer the upper positively charged portion of the cloud, and that it, therefore, would be more likely to receive discharges from it.

There is one section of the Shoshone–Denver line which I feel certain is seldom, if ever, within a thoundercloud. Therefore, a re-examination of the data on strokes to that part of the line will be of value in determining whether Colorado thunderstorms have charge distributions which differ from the distributions in low-altitude storms. The section referred to is that between 5,000 and 8,000 feet at the Denver end of the line. Judging from the authors' profile of the line, its length is about 27 miles.

This end of the line is subjected to the same types of thunderstorms which I studied from the top of Devil's Head Mountain, roughly 35 miles south of the line during the summers of 1930 and 1931. The two seasons were spent there, through the courtesy of the United States Forest Service, for the sole purpose of studying the phenomena occurring during thunderstorms.

Devil's Head Lookout is 9,348 feet above sea level, while the immediately surrounding country for some distance lies between 7,000 and 8,000 feet elevation. Although the lightning discharge centers of 37 storms passed within three miles of the lookout in 1930, and a number more in 1931, in no case was I within the thundercloud.

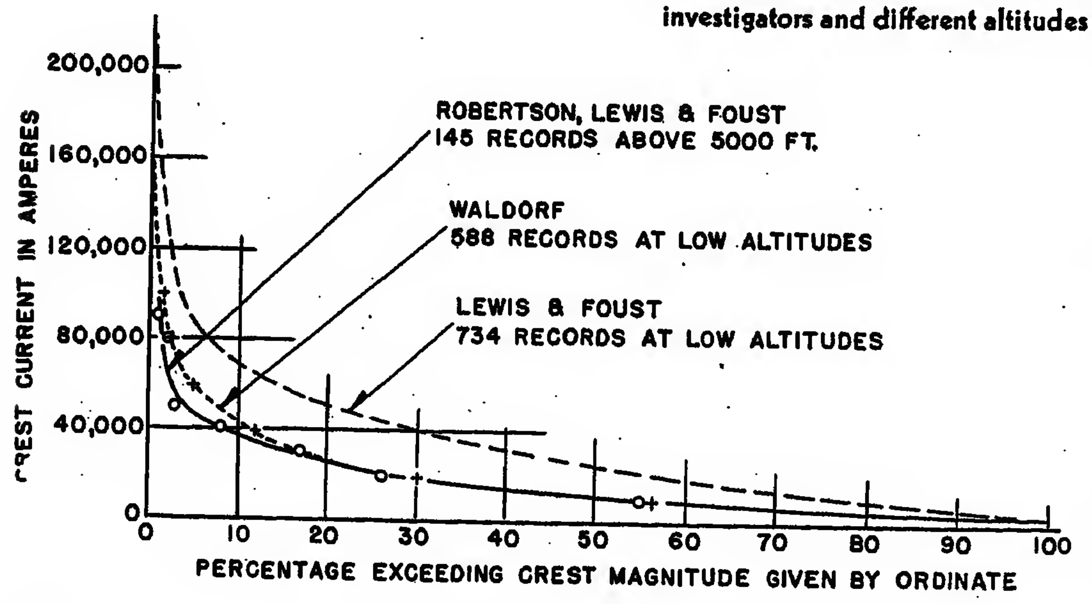

Figure 1. Comparison of current distribution curves for different investigators and different altitudes

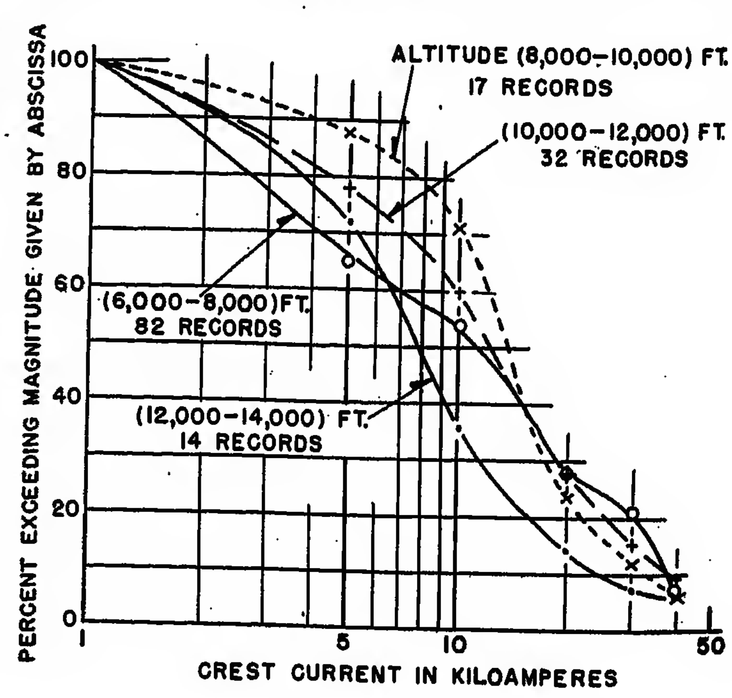
Figure 2. Cumulative curves of probable stroke currents as a function



Several measurements were made of the distance between ground level and cloud base. Most of these fell between 3,000 and 6,000 feet above the surrounding country and from 1,200 to 4,200 feet above the lookout. Only on very rare occasions were storms seen in which the cloud base appeared to be less than 1,000 feet above ground. These cases may have been optical illusions, for storms viewed at a distance, particularly when the rain area is dense, appear to be much lower than they actually are.

In view of this, it seems reasonable to assume that the section of line referred to was seldom within the cloud. Therefore, if a reexamination of data for it shows a considerably higher percentage of positive strokes than that obtained for storms at low altitude, a difference in charge distribution for low- and high-altitude storms may be indicated.

Based on my observations of thousands of lightning strokes, the shape of a number of which could be explained only by assuming that both positive- and negative-charge concentrations were present near the base of the cloud, and based on cloud field measurements, I am of the opinion that some of the positive currents measured by the authors were caused by discharges from centers of positive charge in the lower regions of the cloud.

Other positive records may have resulted from strokes which began as negative discharges from the base of the cloud to ground but ended as positive discharges, due to the discharge channels extending into the upper positively charged regions of the cloud. In Colorado on September 2, 1930, while watching a storm under conditions in which the cloud was clearly visible from its base to its top, I saw several discharges in succession which were probably of this type. In each case a stroke occurred from the lower part of the cloud to ground. Each stroke was followed by a progressive illumination upward through the cloud, which ended with several discharge channels visible near the top of the cloud. McEachron has recorded strokes to the Empire State Building[1] which started as negative discharges and ended as positive discharges. It is possible that the structure of Colorado mountain thunderstorms, resulting from their special conditions of formation, is such that this type of discharge occurs more frequently.

With regard to the decrease in current magnitude with altitude, the roughly sevenfold increase in tower-footing resistance between 7,000 feet and 11,000 feet possibly deserves some consideration. Using the tower-footing resistance as a crude measure of earth resistivity, a foot of counterpoise at 11,000-foot elevation should have of the order of seven times as much leakage resistance to ground as a similar length at 7,000-foot elevation. The difference in resistance offered to the discharge of a lightning stroke at the two locations will be less than this, due to breakdown of the air pores in the ground, but it should still be substantially higher at the 11,000-foot elevation. Considering the discharge of a stroke into a counterpoise (after Bewley[2]) as a combined leakage discharge and traveling wave phenomenon, the leakage resistance met by the stroke should be one that starts relatively high and continually decreases, as the surge travels along the counterpoise and thereby taps more and more paths in parallel to ground. Bewley's and Wade's[2] measurements of the velocity of propagation of an artificial lightning surge along a counterpoise indicate that after three microseconds between 900 and 1,000 feet of counterpoise should be picking up current from the earth. With this length of counterpoise in action, it appears doubtful that its resistance either at 7,000- or at 11,000-foot elevation would be high enough to substantially influence the maximum current of the stroke. Further evidence that a sufficient section of counterpoise probably comes into action quickly enough to offer a low-resistance path for the lightning current is given by one of the authors.[3] Still, in view of the nature of the ground under the Shoshone–Denver line at high altitude, ground resistance should not be entirely dismissed as a possible contributing factor toward the decrease in current with altitude found by the authors.

The authors' suggestion that decrease in temperature with altitude is a factor in limiting the formation of lightning is interesting. The rapid decrease[4] in moisture content of the atmosphere with altitude is also important. Based on the data given, it appears improbable that thunderstorms can form above an extended ground level of say 18,000-foot elevation, if the temperature at that level never exceeds 32 degrees Fahrenheit. Thunderstorms could, however, form at lower elevations and strike from the upper regions of the cloud to ground at that elevation as they moved toward it. Meteorologists believe, as shown by the generalized cloud diagrams in Figures 10 and 11 of the paper, that charge concentrations can occur in thunderstorms several thousand feet above the 18,000-foot level.

The study of corona discharge currents from points subjected to thundercloud fields appears promising as a means of increasing our understanding of the nature and strength of these fields. I would expect that refinements in calibration methods as the investigation proceeds will show the field strengths to be lower than those given in Table IV of the paper.

It should be possible to considerably increase our knowledge of the locations, polarities, and magnitudes of the charge concentrations causing thunderstorm fields by a continuation of the above measurements, combined with simultaneous observations of thundercloud position and characteristics, discharge center locations, and rain area locations. The records should also yield information on the charging processes going on within the storm cloud.

A few measurements of the discharge current from a 40-foot length of 0.011-inch-diameter bare wire, subjected to thundercloud fields, were obtained at Devil's Head in 1931. These yielded some interesting information on thunderstorm field characteristics. The maximum current which I measured was 314 microamperes. For this record a flow of positive electricity from wire to air was indicated showing that a negatively charged region in the cloud was dominating the field at the lookout.

L. M. Robertson, W. W. Lewis and C. M. Foust: Several of the discussers point out that the apparent decrease of lightning current with altitude may be due to causes other than those suggested by the authors, for example, climatic conditions and geography, influence of earth's resistivity and geology, and less frequent occurrence of lightning strokes of all magnitudes. Some or all of these points may have a bearing on the results.

Our data permit us to comment on the relative frequency of occurrence of strokes. All our results were obtained on the sections of line equipped with ammeter links, as indicated on Figure 1 of the paper, that is, on about 45 miles of the approximately 150 miles of line. With 145 total strokes recorded in four years, this would indicate about 0.8 stroke per mile per year. Bell[1] showed 356 towers flashed on the section of the Wallenpaupack–Siegfried line not equipped with overhead ground wires (about 36.9 miles) in a period of 13 years, or about 0.74 tower flashed per mile per year. Assuming each flashover represents a stroke, it will be seen that figures for high altitude in Colorado and low altitude in Pennsylvania are comparable.

In Mr. Hagenguth's discussion, he deduces from Figure 1 and Table I of the paper the average number of strokes per mile per year in the different altitude ranges. He overlooked the fact that data were secured only on about 45 miles of the line. The correct figures for strokes per mile per year would be approximately as follows:

Over the whole line	0.8
6,000 to 8,000 feet	2.05
8,000 to 10,000 feet	0.36
10,000 to 12,000 feet	0.4
Over 12,000 feet	1.17

Messrs. Wagner and McCann show a curve of lightning current against frequency plotted from Waldorf's data, and they compare this with the Lewis–Foust curve and with Figure 6 of the present paper. It is interesting to note that of the 734 records plotted in the Lewis–Foust curve, 457 records are from Waldorf's data on four systems. This is 62 per cent of the Lewis–Foust data and 78 per cent of Waldorf's 588 records plotted by Wagner and McCann. The remaining 277 records, or approximately 38 per cent of the Lewis–Foust data, are from four other eastern low-altitude power systems. From a comparison with various other curves we believe that the Lewis–Foust curve is representative of the range of current magnitude that may be expected at altitudes near sea level. It should also be noted, as mentioned in the paper, that 30 years operation indicated much less destruction, for example, shattering of wood poles and crossarms, at higher altitudes than at lower altitudes on the Colorado system.

We wish to thank the discussers for their interesting and constructive discussion.

We intend to continue our investigation and hope to secure additional data which will confirm or revise our present conclusions.

Large Adjustable-Speed Wind-Tunnel Drive

Discussion and author's closure of paper 42-65 by C. C. Clymer, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, March section, pages 156–8.

M. M. Liwschitz (The Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): Mr. Clymer recommends in his very interesting paper that the rotors of both doubly fed machines in the wind-tunnel drive described by him be connected in series with the synchronous machine, in order to introduce a source of positive damping in the circuit of the doubly fed machines. Were the rotors directly connected in parallel,

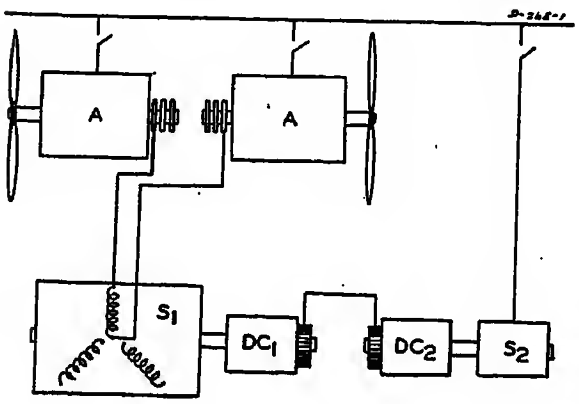

Figure 1

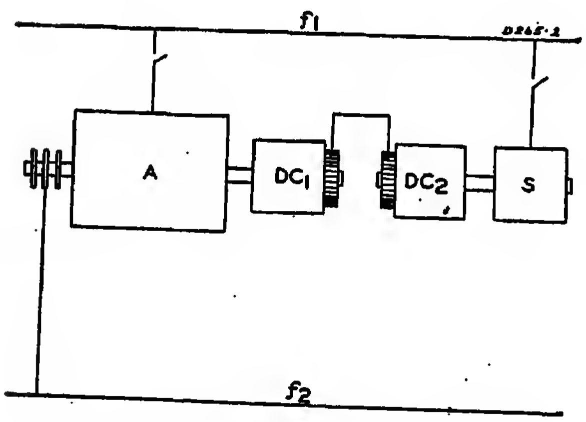

Figure 2

there would be only a negative damping in the circuit of the doubly fed machines, and these could oscillate independent of the total system without any restraining force.

This statement by Mr. Clymer is correct as far as normal doubly fed machines are used, machines having the damping characteristics shown in the paper "The Doubly Fed Machine," presented at the AIEE winter convention by Messrs. C. Concordia, S. B. Crary, and G. Kron.[1]

But there is a possibility to build the doubly fed machine by using special windings, so that its negative damping is considerably reduced, and so that the damping torque of the system, consisting of the doubly fed machines and the fans, is not negative but slightly positive in the range between about 12 per cent slip and standstill. Doubly fed machines built in this way do not need a source of positive damping between the rotors and can operate without danger of nonrestrained oscilla-

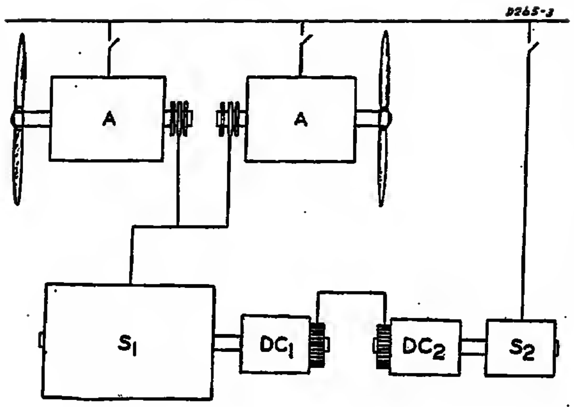

Figure 3

tions, when their rotors are connected directly in parallel.

There is another point in the paper by Mr. Clymer on which I would like to make a remark. Mr. Clymer recommends the variable-speed drive as described in his paper for the use as frequency converter. For this purpose also the arrangement can be used that is shown in Figure 2. Two sets of this kind I have described in the *Siemens-Zeitschrift* 1926. The doubly fed machine is used here as a frequency changer only. The motors that drive the fans or pumps will be connected to the secondary line having the frequency f_2 and will be synchronous motors.

There is no danger of negative damping here, since the doubly fed machine is connected on one side with d-c machines, which produce positive damping, on the other side with synchronous machines which have damper windings.

L. A. Umansky (General Electric Company, Schenectady, N. Y.): In reviewing these two papers, and in listening to the discussions, I was particularly impressed with one fact: a good and sound solution of an engineering problem depends not only on the kind but on the size of the equipment involved.

Take, for instance, the frequency changer described by Dr. M. M. Liwschitz. This arrangement is neat and probably is economical when the difference of frequencies between the two power supplies is small, and the capacity of the set is moderate. But suppose we must provide a 20,000-kw frequency changer to tie together a 60-cycle and a 25-cycle system. The d-c machines on the frequency changer and on the regulating set will be about 12,000 kw each. The high resulting cost is obvious; each d-c machine will have to be subdivided into three or four units. The whole arrangement will not be practical.

Or, let us take the remark made by Mr. Kilgore in reference to the slip-regulator control as a feasible application for wind-tunnel drives. Undoubtedly, for smaller drives of this kind, say of a few thousand horsepower, such control can be considered, particularly if a low efficiency is not a factor. But, for a 30,000-horsepower or a 40,000-horsepower drive, the matter of efficiency cannot be disregarded, and some means of slip-energy recovery should be provided. Furthermore, the slip-regulator control for a 40,000-horsepower drive will not solve the problem of starting current inrush which the described drives have successfully solved.

The system discussed here and first suggested by Mr. Clymer is not at all the Kraemer system. In the latter, as we all know, the slip energy of the main induction motor is converted into d-c power by means of a synchronous converter. Could this be done in case of 40,000 horsepower with a 6:1 or greater speed range? The capacity of the converter would be an equivalent of 30,000 kw; would have to be split into six or more units, and the problem of hunting, load division and so on, would be aggravated. Starting of the main drive would be just as difficult (considering the power system) as with a slip regulator.

C. C. Clymer: Mr. Liwschitz makes some very interesting observations concerning the possibility of obtaining damping on doubly fed machines operating in parallel. The use of a series connection for the rotor is, of course, only one way of achieving stability. There are other ways. For example, a six-phase synchronous machine, and the use of inductive coupling. The series connection is, shall we say, an economical and convenient method since it permits the use of perfectly standard induction motors with simply a reconnection of the synchronous machine.

Since Mr. Liwschitz does not describe the connection by which positive damping may be obtained with parallel rotor connections, a discussion on the various methods is not possible, however intriguing the subject may be.

Variable-Speed Drive for United States Army Air Corps Wind Tunnel

Discussion of paper 42-63 by A. D. Dickey, C. M. Laffoon, and L. A. Kilgore, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, March section, pages 126–30.

L. A. Umansky: See discussion, this page.

Equivalent Circuits for the Hunting of Electrical Machinery

Discussion and author's closure of paper 42-3 by Gabriel Kron, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 290–6.

S. B. Crary (General Electric Company, Schenectady, N. Y.): Kron's equivalent

circuits for the damping and synchronizing coefficients of rotating machines already have been used in our company for many problems, and we can attest to their practicability and usefulness. We have obtained results which would never have been realized by ordinary numerical methods. Numerical methods may rapidly become impractical from an engineering standpoint when the number of factors to be taken into consideration increases only moderately. It may take more time to make an analysis in such a manner than it does to build the apparatus. This difficulty of the analytical method can be largely removed by methods which eliminate or simplify the numerical work. Network analyzers and differential analyzers provide means by which this may be accomplished.

The circuits developed by Kron for use on an a-c network analyzer may be used for an important class of problems: specifically, for the determination of the damping and synchronizing torques over the range of system conditions and design parameters. These parameters may include the frequency of oscillation, the effect of circuit elements to which the particular apparatus being studied is connected, and the effect of change in the design details of the apparatus or equipment itself. The method using damping- and synchronizing-torque coefficients allows a study of a particular part of the system and for particular modes of oscillation separately, without introducing the additional complexity of all of the other elements and all possible modes of oscillation at once. This then allows for a best design to be obtained for this particular element as it may be applied to different systems and under varying conditions. If necessary, additional tests for the stability and performance of the whole system may be made by using Routh's criterion, or a differential analyzer solution. The use of the circuits developed by Kron does not replace the use of other stability criteria and methods of analysis, but rather they increase their value by making them more easily applied.

Banesh Hoffmann (Queens College, Flushing, N. Y.): In his paper "Equivalent Circuits for the Hunting of Electrical Machinery," Kron transforms the nonsymmetric impedance of a machine to a symmetric form, which is then taken to be the impedance of an equivalent network. The manner of bringing Z to symmetric form has certain interesting features which seem worthy of discussion.

The process used by Kron has two essential steps:

A. The introduction of complex quantities, and the application of a symmetric components transformation.

B. The subsequent multiplication by a diagonal matrix n'^{-1}.

Let us discuss B first. In one place Kron regards this as the process of dividing each component equation of the vector equation of voltage by an appropriate scalar. In this form it has no tensor significance. I wish to show that the operation may actually be regarded as a valid tensor transformation, employing a well established tensor device known as a *mixed reference frame*.

Let the equation of voltage after step A has been performed be

$$e_a = Z_{ab} i^b \tag{1}$$

and denote the real, diagonal matrix n'^{-1} by $N_\lambda{}^a$. Since equation 1 is a vector equation, we may transform it to a new reference system using $N_\lambda{}^a$ as the transformation matrix. The tensor law of transformation gives e_a the new components

$$e_\lambda' = N_\lambda{}^a e_a \tag{2}$$

The *vector* $(Z_{ab} i^b)$, treated as a unit, will have the new components

$$(Z_{\lambda b} i^b)' = N_\lambda{}^a (Z_{ab} i^b) \tag{3}$$

It is thus a valid tensor transformation to write equation 1 in the form

$$e_\lambda' = N_\lambda{}^a Z_{ab} i^b \tag{4}$$

If we define

$$Z_{\lambda b}' \equiv N_\lambda{}^a Z_{ab} \tag{5}$$

we may write equation 4 in the form

$$e_\lambda' = Z_{\lambda b}' i^b \tag{6}$$

It is this quantity $Z_{\lambda b}'$ which Kron takes as his symmetric impedance. A full tensor transformation on equation 1, applying to each individual tensor therein, would give

$$e_\lambda' = Z_{\lambda\mu}' i'^\mu \tag{7}$$

with

$$Z_{\lambda\mu}' = N_\lambda{}^a N_\mu{}^b Z_{ab} \tag{8}$$

and

$$i'^\mu = N_b{}^{-1\mu} i^b \tag{9}$$

In equation 6 the e has been transformed to a new reference frame, the i has been left in the old, and the Z has been placed partly in one frame and partly in the other. The quantity $Z_{\lambda b}'$ is merely the impedance tensor Z_{ab} expressed in a mixed reference frame. Since $N_\lambda{}^a$ happens to be diagonal, the effect of the above transformation is merely to change the scales along the individual reference axes so far as the e's are concerned, while leaving the scales for the i's unaltered.

At this point let us recall the well-known theorem of tensor analysis which states that an unsymmetric tensor is unsymmetric in all reference frames. This theorem effectively prevents the transformation of Z to symmetric form by means of a full tensor transformation. But it is inoperative if we use a mixed reference system, and there seems no theoretical reason why the use of a mixed reference system should not alone suffice to bring Z to symmetrical form. On the other hand, in step A, by his introduction of complex transformations, Kron automatically takes the problem out of the restricted realm of tensor analysis into the more general one of spinor analysis. The impedance, when regarded as a spinor, has one dotted and one undotted index. For such a spinor symmetry is not an invariant property, the symmetry theorem being replaced by one which states that a hermitean spinor is hermitean in all reference frames, and a nonhermitean spinor nonhermitean in all reference frames. Thus, the introduction of spinors could theoretically alone suffice to bring Z to symmetric form. Nevertheless Kron uses step A merely to simplify the appearance of Z and makes Z finally symmetric by means of the mixed reference system introduced in step B. It would thus seem that he has been lavish in the theoretical resources used to combat the asymmetry of Z, since either the introduction of a suitable complex full spinor transformation alone or else the introduction of a suitable mixed tensor reference frame alone could theoretically make Z symmetric. When p is replaced by $j\omega$, and so on, the Z of a rotating machine and the Z of a network become alike in being nonhermitean, and this is an invariant characteristic, while the property of symmetry is neither invariant nor common to both. The use of a mixed reference frame obscures this invariant similarity. Therefore, in view of Kron's statement that only tensors (or more generally spinors) can be represented as measurable quantities in the equivalent network, it might ultimately prove of practical value to investigate the possibility of reducing Z to symmetric form by the use of a full spinor transformation only. The calculations required, though, would be of considerable length. Kron's main object was actually to make Z symmetric, and this he has done not only with elegance and real economy of labor, but also, as I have shown above, by the use of legitimate spinor operations.

The following remarks are the fruits of correspondence with Mr. Kron. They concern the reasons why the method by which Kron reduces Z to symmetric form is actually successful in accomplishing its purpose.

Initially we have equation 16 of Kron's paper, with R and L symmetric. If we apply a spinor transformation we are liable to destroy the symmetry of R and L. And if we do happen to preserve this symmetry under step A, we are liable to destroy the symmetry of R on multiplying it by n'^{-1} in step B. Clearly, therefore, the method of reduction cannot be generally valid. The following calculations show that it is actually made exactly to measure for the problem in hand.

By matrix multiplication we have

$$\begin{vmatrix} 1 & j \\ 1 & -j \end{vmatrix} \begin{vmatrix} a & c \\ c & b \end{vmatrix} \begin{vmatrix} 1 & 1 \\ -j & j \end{vmatrix} = \begin{vmatrix} (a+b) & , & (a-b)+2jc \\ (a-b)-2jc & , & (a+b) \end{vmatrix} \tag{10}$$

Thus only a diagonal spinor, originally symmetric, will remain symmetric under step A. Now R is always diagonal, provided there are no resistances common to any meshes, and L will be diagonal if there are no mutual inductances. But the transformation to symmetrical components is always applied to the d and q axes of a layer of winding, and since these are taken at right angles they have no mutual inductances. Thus step A does not disturb the symmetry of R or L. It does however change them from diagonal to nondiagonal form, as equation 10 shows. This is important since R', the new R, is multiplied in step B by the diagonal matrix n'^{-1}. By matrix multiplication we have

$$\begin{vmatrix} x & 0 \\ 0 & y \end{vmatrix} \begin{vmatrix} a' & c' \\ c' & b' \end{vmatrix} = \begin{vmatrix} xa' & xc' \\ yc' & yb' \end{vmatrix}$$

Thus $n'^{-1}R'$ will be symmetric only if either n'^{-1} or else R' is a multiple of the unit matrix. Now on the rotor it is assumed

that the windings are symmetric. This means that R, and thus, by equation 10, R', is a multiple of the unit matrix, so that the condition is satisfied. On the stator, however, there may be asymmetries, and R is generally not a multiple of the unit matrix. But on the stator we have $v=0$, and this makes n'^{-1} a multiple of the unit matrix, thus fulfilling the condition in the other possible manner. Any asymmetries on the rotor, such as from an outside load, would destroy the effectiveness of the method.

Gabriel Kron: Mr. Crary's discussion brings out rather emphatically the fact that analytical methods of investigating engineering structures become, from a practical point of view, valueless just when these studies are most needed, unless the method offers a means also for quick numerical solution. The need for and usefulness of calculating devices and models such as the a-c network analyzer is attested by the fact that the number of such devices is increasing, and in our company the analyzer is being worked two shifts.

The limitation of the hunting equivalent networks, as presented here, is that they are restricted to one frequency of oscillation. However, these circuits may be transformed so as to be valid for all frequencies, that is, for transients, such as the sudden short-circuit and acceleration phenomena of machines and interconnected systems.

Professor Hoffmann's points are all well taken. It is an excellent suggestion that the multiplication of Z and e with n'^{-1} should be considered as a transformation to a mixed reference frame, in which the transformation consists in changing the scale of the voltages.

That the use of symmetrical components takes the problem out of the restricted realm of tensor analysis into the more general one of spinor analysis, as stated by Dr. Hoffmann, is indicated also in the introductory equations 1-4 by the use of barred indices.*

The question whether the two steps A and B can or cannot be replaced by one spinor transformation must be left open. I have tried repeatedly to discover such a single transformation, but did not succeed.

There seems to be no agreement as yet among authoritative mathematicians whether the word "tensor" should include physical (or geometrical) entities that are functions of both real and complex variables or whether it should be restricted to functions of real variables, while the word "spinor" is introduced to denote physical entities that are functions of complex variables. Personally, I prefer to use the expression "tensor" for all physical entities.

That R and L both must be of special form in order that the method of symmetrical components should reduce them to symmetrical form is, of course, well-known. There is a real need in electrical engineering for transformations that reduce more general types of tensors to symmetrical form, and, if possible, to diagonal form. So far Fortescue's method is the only workable tool available. Professor Hoffmann, because of his immense background of transformation theory, may be of help to electrical engineers along these lines of development.

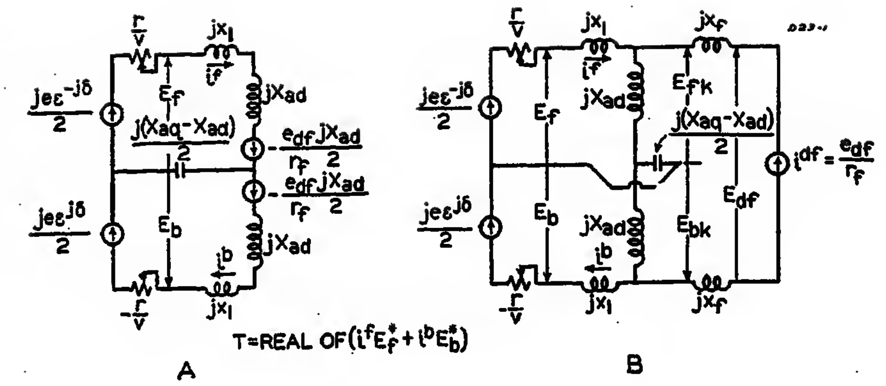
* See reference 7 of the paper, May 1935, page 239, where the method of symmetrical components has already been presented as a full-fledged spinor transformation.

Figure 1. Two forms of the equivalent circuit of the salient-pole synchronous machine

T real of $(i^f E_f{}^* i^b E_b{}^*)$

A—With impressed field voltage

B—With impressed field current



He correctly points out that R must be a multiple of the unit matrix along the reference axes, in which the equivalent circuit is to be established, if it is to be brought to a symmetrical form. That condition is not satisfied with unbalanced load on the rotor even for the reference axes under discussion, and Z then becomes hopelessly asymmetrical.

However, it must be emphasized that it is not at all necessary that Z should be expressible by a symmetrical matrix in order to represent $e = Z \cdot i$ by a stationary network. The only necessary (though not sufficient) condition that Z should be representable by a stationary network, is that Z should be a tensor (or rather a spinor). The condition of symmetry only enters if the requirement is to use a mesh network. But if one cares to use an orthogonal network (a network with both impressed voltages and currents) the symmetry of Z is not a necessary condition.

As an example, let the steady-state equivalent network of a salient-pole synchronous machine Figure 2a of the paper be considered reproduced in the enclosed Figure 1A. The original equation $e = Z \cdot i$ in which Z is not symmetrical has been given in reference 5, equation 14 (dividing row f_a by v and b_a by $-v$) as

$$e = \begin{array}{ccc} d_f & f_a & b_a \\ \hline \multicolumn{1}{|c|}{e_{df}} & \multicolumn{1}{c|}{0} & \multicolumn{1}{c|}{0} \\ \hline \end{array}$$

$$Z = \begin{array}{c|c|c|c|} & d_f & f_a & b_a \\ \hline d_f & 4r_f & 0 & 0 \\ \hline \frac{1}{4}-f_a & 2jX_{ad} & \frac{2r}{v}+j(X_d+X_q) & j(X_d-X_q) \\ \hline b_a & 2jX_{ad} & j(X_d-X_q) & -\frac{2r}{v}+j(X_d+X_q) \\ \hline \end{array}$$

Even though this matrix with three rows and two columns is not symmetrical, it can be represented by the equivalent circuit of Figure 1B containing three meshes in which an impressed field current i^{df} also exists. That current remains constant while the speed v changes.

The disadvantage of the circuit of Figure 1B is that on the network analyzer, the generator supplying i^{df} has to be adjusted each time v varies, while on the circuit of Figure 1A, all generators remain unchanged as v varies. On the other hand Figure 1B with its constant field current corresponds more nearly to the physics of the actual machine. In fact, it gives the resultant flux E_{df} linking the field winding, that could not be represented on Figure 1A.

In the problem of connecting a synchronous machine to a transmission line Z is asymmetrical and E_{df} has to be known. Hence the circuit of Figure 1B must be employed then and not the simplified form Figure 1A, in which the row and column of d_f (and the corresponding mesh) had been eliminated.

Temperature and Electric Stress in Impregnated-Paper Insulation

Discussion and author's closure of paper 42-10 by J. B. Whitehead and W. H. MacWilliams, Jr., presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 10–13.

L. J. Berberich (Westinghouse Research Laboratories, East Pittsburgh, Pa.): Doctors Whitehead and MacWilliams have shown that oil-impregnated paper subjected to high stress and temperature undergoes large increases in power factor in a relatively short time. They offer the explanation that this behavior may be caused by electrolytic dissociation of the oil and the effects of temperature and stress in accelerating this dissociation.

This problem can be viewed somewhat more broadly when the behavior of oil-impregnated paper is contrasted to that of the modern capacitor dielectric which consists of paper impregnated with chlorinated diphenyl. It is common practice to operate capacitors at voltage stresses in the neighborhood of 400 volts per mil and temperatures only a little lower than the 80 degrees centigrade used by the authors are reached in service. Little or no increase in power factor over long periods of time is observed under these conditions, which appear to be disastrous for oil-impregnated paper.

What is the explanation for this difference in the observed behavior of the two dielectrics? As for the synthetic impregnant used in capacitors, it has a greater residual electrolytic dissociation than oil which is reflected in a greater ion content and conductivity. This dissociation is probably equally well accelerated by voltage stress and temperature. The answer may lie partly in the fact that the dielectric constant of the synthetic material is greater than that of oil, and consequently there is less stress on the liquid component in the case of the capacitor dielectric for the same over-all voltage

stress. The rest of the answer may possibly lie in the fact that there is some evidence that the synthetic liquid has a greater affinity for paper than oil because of its polar nature. Both the higher dielectric constant and the greater interfacial tension between the synthetic liquid and paper should make the formation of gas pockets less likely than in the case of oil-impregnated paper.

At this point I should like to ask the authors if they have any definite evidence which would exclude the formation of gas pockets and the ensuing gaseous ionization as another possible cause of the behavior they observed? This evidence may be difficult to obtain, because even if dry spots exist in the paper while stress is being applied, reimpregnation may take place before they can be found by dissecting the sample. However, if the test is run for a long time, sufficient X wax should be formed to become easily visible. Assuming that gas pockets can form in some way, explanation of the observed behavior on the basis of gaseous ionization is easy. It is known[1,2] that gaseous ionization can cause a rapid increase in ion content of the oil which is reflected in an increase in conductivity and power factor.

Even assuming that gaseous ionization may be a possible cause of the power-factor increase, there still remains to be explained why the effect is less at lower temperatures. This may be simply a matter of greater viscosity of oil, making it more difficult for the oil movement to take place which is necessary for void formation. It would be particularly interesting to repeat this work with a lower viscosity oil which should answer some of the questions raised. It should also throw further light on the mechanism proposed by the authors.

Figure 9 of the paper shows a very large accelerating effect of temperature on the power factor increase. I should like to ask if the power-factor data for the various points were all determined at the same temperature?

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): At the beginning of the third paragraph of this paper it is stated that "Little attention has been paid to the study of the long-time effect of combined high temperature and high stress." Then the paper proceeds to give the results of tests of durations up to about 100 hours with stresses of 400 volts per mil on the impregnated-paper insulation.

In Figure 4 of my 1939 AIEE paper, "Load Ratings of Cable,"[1] are given power factor data obtained in a series of tests on experimental high-voltage oil-filled 132-kv cable installed in conduit. The maximum stresses on this cable ranged from 220 to 259 volts per mil, which are somewhat above the highest stresses on commercial oil-filled cable in this country. The duration of the test was several years, as indicated in the 1939 paper, and the maximum total duration of voltage application to the termination of the tests was over 60,000 hours. The copper temperatures were 80 to 95 degrees centigrade average for the 1,000-foot lengths for total periods of 9 and 24 months on two samples, respectively, and in some portions of the cables the copper temperatures were 120 and even as high as 140 degrees centigrade, in contrast with temperatures of up to 80 degrees centigrade in the paper under discussion.

In addition, we have been conducting, in our high-voltage laboratory, tests of oil-filled cable with maximum stresses of 294 volts per mil and with heating up to 100 degrees centigrade. The tests have been going for many months, and only small changes in power factor have occurred.

On the other hand, the Whitehead and MacWilliams paper gives data showing a very high rate of increase in the power factor (nearly 0.04 per week) for insulation subjected to 80 degrees centigrade and voltage stress of 400 volts per mil. Then, after giving other data, it is stated in conclusion 1 that deterioration of impregnated-paper insulation due to temperature and stress may begin earlier and increase more rapidly than commonly supposed. An exhaustive study of stresses of impregnated-paper insulation in operation, not only of cable but of capacitors, together with a study of the enormous amount of data obtained with experimental cable, indicates definitely that for the temperatures and electric stresses in effect in normal operation of impregnated-paper insulation, deterioration and chemical instability do not start anything like as early as indicated in the article. Perhaps there is some phenomenon that is peculiar to higher stressing, that is, at about 400 volts per mil, such as was used by the authors.

Long-time tests of oil-filled cables in Chicago showed little effect of superimposed voltage during heating periods upon changes in power factor as compared with similar periods of heating without voltage. In fact, it was found that application of voltage produced a decrease in power factor for hours or even days, while removal of voltage caused corresponding increases. This finding appears to be in contrast with the conclusions from test 3. However, Figure 7 of the paper seems to indicate further increase with power factor after removal of the voltage. We tried to explain the phenomena found in Chicago by assuming that application of voltage causes a shift in the balance of oxidation or deterioration products. Further careful studies of these phenomena should give valuable information on the mechanism of deterioration of insulation.

The conclusion is drawn from tests 6 and 7 that oxidation plays a relatively small role in the deterioration process. This conclusion is in contrast with the results of studies of oil-filled cables in Chicago and with the results obtained in the research project on insulating oils and cable saturants at the Massachusetts Institute of Technology under the auspices of The Engineering Foundation and AIEE. It should be noted, however, that the reported amount of oxygen of 0.7 per cent by volume is small, and the length of the test of about five days is very short. In aging tests of oil-filled cable in Chicago it took for one sample about one year and for another more than three years before considerable increases in power factor developed due to presence of some oxygen.

From the results of power-factor measurements of the individual layers, the conclusion is drawn that there was no chemical action from the electrodes. These tests were made at room temperature. Studies in Chicago showed that radial power-factor curves at room temperature show very little variations, while at 60 degrees centigrade they may show significant changes.

In order to obtain a better understanding of the processes involved in the power-factor changes observed, careful studies should be made of the effect of such variables as electrode materials, purity of the paper, oxygen content, and purity of the oil.

Robert J. Wiseman (Okonite-Callender Cable Company, Inc., Passaic, N. J.): I have read with considerable interest the paper by Dr. Whitehead and Dr. MacWilliams. They show that when their samples of impregnated paper, without oxygen or electric stress present, are heated for a week at 80 degrees centigrade, practically no change in power factor results; when tested without oxygen and with stress, there is a change in ionization with temperature and stress; and with oxygen and stress present, about the same results are obtained. These results are of interest, but it would have been helpful if the authors had been able to continue their time of tests for many weeks instead of one week. Each of us has our particular method of testing impregnated paper for its power-factor stability, and we find it is possible for the first few days to show a decrease in power factor and then a slow steady increase or even a very large increase, depending upon the type of oil being tested and the kind of metal used as electrodes. Perhaps at some time Dr. Whitehead will repeat his tests, varying the oil and kind of electrodes with samples under a high temperature for two to three months.

I like the explanation offered by the authors for the increase in power factor with stress, namely, possibly due to electrolytic dissociation; yet I wonder if it is actually dissociation—that is, is it a permanent change in the oil? We have made tests on samples of impregnated paper which we are quite certain permitted no chance of gaseous ionization to take place, and yet we did find a change in power factor with stress. It has been customary to assume that when there is a change in power factor, voids are present and gaseous ionization takes place. Dr. Berberich has referred to this condition in his discussion of the paper. I do not believe Dr. Whitehead's samples had gaseous ionization. Where we believe that there is no chance of gaseous ionization, and we do find a change in power factor for want of a better term of what happens, we call it "electrolytic ionization." The change in power factor is usually very much lower than takes place when gaseous ionization takes place. As we view it, it takes place due to the ionization by impact of free ions as the electric stress is increased, if one will accept the assumption that there are free ions present in oil. Perhaps Dr. Whitehead's electrolytic dissociation and our electrolytic ionization are synonymous.

R. W. Atkinson (General Cable Corporation, Bayonne, N. J.: During one period we tested a large number of impregnated-paper condensers in communication with the body of oil used for saturation of the paper. Like the condensers of the authors, these were subjected to voltage stress at an elevated temperature. We finally concluded that our tests were seriously affected by diffusion of oil between the condensers and the surrounding oil body which was freely exposed to oxidation and absorption of oxygen from the air. Altogether different results are obtained on condensers (such as a cable) when the dielectric is completely sealed from any communication with the atmosphere. I believe the authors should give careful thought as to the possibility that their results may also have been influenced by interdiffusion of oil between the saturant of the paper and the surrounding oil body.

Hubert H. Race (General Electric Company, Schenectady, N. Y.): The conclusions drawn from the data presented in this paper are quite contrary to information obtained either from service or other experiments on miniature cables. In my opinion, the reason is that the authors failed to recognize that when specimens are tested at 80 degrees centigrade in an open oil bath, oxygen is present in sufficient quantity to produce oxidation products in sufficient concentration to account for the results obtained.

At high temperature in an open bath the rate of transfer of oxygen from the air to the specimen is increased greatly because of convection currents set up in the oil bath. No doubt the specimens were prepared substantially oxygen-free but as soon as they were opened to air and submerged in an open bath of oil they started to absorb oxygen. Oxidation products of both the oil and the paper would contribute to increased power factor.

For this reason I believe oxidation was the cause of the results presented in Figures 1–5 which were marked "no oxygen" just as much as for the subsequent experiments in which a limited amount of oxygen was purposely admitted at the beginning of the experiments. For both types of experiments the observed time rate of increase in power factor probably is determined largely by the rate of diffusion of oxygen into the specimen. This would account for the fact that the authors found little difference between the specimens which contained no oxygen at the beginning and those to which oxygen was admitted before the heating and measurements started.

In Figure 9 the authors state that *in the absence of oxygen* they have found a rate of increase of power factor at 80 degrees centigrade of 0.02 per cent per hour or about 0.5 per cent per day. At the 1939 summer convention I presented a paper[1] summarizing life tests on oxygen-free miniature oil-impregnated-paper specimens *assembled, evacuated, impregnated, and tested in glass* in which the five specimens having longest life had been tested at high voltage between 400 and 800 days before failure. Up to July 1937 these specimens were heated to 60 degrees centigrade for about 20 hours each day and afterwards to 100 degrees centigrade. After dissembly, the oil-soaked paper taken more than 1 inch from the breakdown path in these specimens had a power factor of only about one per cent. Furthermore, many specimens had practically constant power factor throughout their life. These data are not consistent with those presented by Whitehead and MacWilliams. The differences are reconciled, however, if it is understood that continuous oxidation was possible in their specimens.

In the paper to which I refer we point out unexpected metal migration and concentration in the region of highest stress adjacent to the electrode surfaces. My explanation has been that under conditions of *high electrical stress* and elevated temperature, chemical reactions occur which would not otherwise be possible. Therefore, I am in complete agreement with Whitehead and MacWilliams in believing that the electrical stress is a very important factor in deterioration resulting from heating and oxidation.

1. Tests on Oil-Impregnated Paper—IV, Mechanism of Breakdown, Hubert H. Race. AIEE Transactions, volume 59, 1940, pages 721–9.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): It is well-known from accelerated aging tests of cables that electric stress causes a deterioration power factor at a rate which increases rapidly with rise of temperature above 60 degrees centigrade, but these tests do not indicate rates even approaching those shown by the authors' tests. It has generally been assumed that this action has been due entirely to the increase of ionization caused by vacuums resulting from oil contraction after thermal expansion. That this is the main reason for the temperature effect is obvious from the fact that when precautions are taken to prevent voids, the deterioration of power factor is practically stopped at temperatures even higher than that used by the authors. The authors claim an effect apart from and additional to that caused by ionization of voids.

As load cycle tests are usually conducted at stresses of one half, or less, of the stress employed by the authors, the phenomenon they report must be peculiar either to the high stresses used or to their test method.

I cannot dismiss the test method, because I note from the characteristics of the oil used to impregnate the samples that, unless there is an error in the viscosity figures, the oil is of naphthenic base, and therefore while its power factor is not greatly susceptible to change by oxidation under the given test conditions, its power-factor stability against electrical discharges would be greatly impaired by the presence of oxygen. In view of the nature of the oil, I do not consider that the open tank method of test used by the authors is a satisfactory guarantee against *electrical instability* due to oxygen.

We have tested a well-known naphthenic base cable oil in the electric discharge cell described on page 209 of AIEE Transactions, volume 60, 1941, and have found the results shown in Table I.

This may be the key to the authors' data.

It must be remembered that a paper-insulated cable is a completely enclosed device and that it is unsafe to draw conclusions about cable behavior especially in relation to power factor from tests on unenclosed specimens.

At Mr. Halperin's suggestion I made some load cycle tests with heat periods lasting over days instead of hours and found some increase in power factor during the 80 and 115 degree centigrade test periods, but the magnitude was not of the order found by the authors.

The other alternative is that something happens at stresses of 400 volts per meter that does not happen at 200 volts per meter,

Table I

Condition of Oil	Power Factor at 100 C Before Discharge Cell Test	Power Factor at 100 C After 1,000-Minute Discharge Cell Test at Room Temperature
New	0.86	2.2
Partially oxidized	5.00	Unmeasurably high at or over 80 C

that is something different in kind, rather than in degree. The authors suggest that this may be "electrolytic dissociation." Undoubtedly a number of free ions dissociated from impurities in the oil, if not from the oil itself, will increase with increasing stress, because ions of opposite sign tend to segregate and so reduce the rate of recombination without reducing the creation of new ions.

It is also true that heat will further this action by agitation, but I can see nothing new happening at 400 volts per meter which does not happen although in less degree at 200 volts per meter, nor can I see why the agitating effect of 80 degrees centigrade should be vastly greater than that at 60 degrees centigrade, a difference of only six per cent in absolute temperature.

K. W. Wagner's AIEE paper of 1922[1] shows characteristic curves of impregnated-paper insulation in which, at high current densities the stress actually decreases with increasing current density, or to put it another way, the current density increases even with decreasing stress. Does this condition indicate a combined electrical and thermal instability, under extreme conditions, such as the authors assume?

I do not believe that the authors have given us sufficient data to permit us to give a final evaluation of their work.

The series of papers on impregnated-paper insulation which Dr. Whitehead and his associates have brought out over a number of years should be regarded as parts of a unit which is not yet complete. I hope that the experiments which are described in the present paper will be amplified in the light of the discussions offered, for some future number of the series.

1. Physical Nature of the Electrical Breakdown of Solid Dielectrics, K. W. Wagner. AIEE Transactions, volume 41, 1922, pages 288–98.

J. B. Whitehead: The results reported in the paper have been criticized as showing a temperature plus stress increase of the power factor of impregnated paper much higher than that found in load cycles on impregnated-paper power cables, and also in labo-

ratory tests. The most important points made are:

(*a*) The relatively small values of power-factor increase found in long load-cycle tests on cables.

(*b*) That the results found by the authors are probably due to oil oxidation, the oxygen entering the sample by diffusion, since the tests are conducted under an oil bath with air at atmospheric pressure above it.

The principal data on (*a*) are those given by Mr. Halperin from the well-known and valuable cable stability tests conducted by his company. The particular results he cites are the tests on oil-filled cables; and from a large array of data on such cables he has selected a few in which the increase in power factor in long load-cycle tests is relatively small. In response to this it should be pointed out that from the same data there are a number of cases in which substantial values of power factor increase are evident. The text of the paper itself points out a number of such cases, and, in particular, Figure 1 of Mr. Halperin's paper shows results on a solid cable in which there is an excessive rise of power factor due to combined temperature and stress. Moreover, in many of the load-cycle tests the temperature cycle is 24 hours, which is scarcely long enough for the detection of power-factor increases such as we have reported.

Load-cycle tests on finished cables such as those of Mr. Halperin are not of the best type for investigating the combined influence of temperature and voltage. Tests on finished cable and under the usual load-cycle programs introduce many variables other than those here in question. It is quite probable that the oil-filled cables referred to by Mr. Halperin have good temperature-voltage stability, due either to the properties of the particular oil they contain, or perhaps due to the oil-filled type of construction. It should be noted that our own tests were made with a solid cable oil. Incidentally, the increases reported by C. F. Proos, referred to in our paper, were found in load-cycle tests on oil-filled cables, and the author emphasizes the noticeable effect of combined high stress and high temperature, an effect which is absent under the same stress at lower temperatures.

As to (*b*), the suggestion that our results are due to excessive oxidation, the principal comment is that by Dr. Race who suggests that within the six-day period of our test, enough oxygen will diffuse into our 0.04-inch thick sample to account largely for the rapid rise in power factor we have reported, as an oxidation process. In reporting our results we have assumed that a comparison of behavior of two samples, one practically entirely free of oxygen, and one containing over 500 times as much oxygen, would be sufficient to test a possible influence of oxygen on our results. In the latter case, the results did indeed show a substantially higher rate of increase due to high temperature alone, but not by any means comparable in amount to the increase of power factor found in both these samples when under combined influence of temperature and stress. However, Dr. Race goes further and states that it is possible that the amount of oxygen absorbed in the test in an open bath is so great that it completely masks the difference observed in our two samples, and that both samples are substantially the same in the matter of oxygen content.

We do not concur with Dr. Race in this view, and fortunately we have available the results reported by T. B. Jones, AIEE Transactions, volume 56, 1937, page 1492) who, working with the same apparatus and a similar oil measured the time increase of power factor of impregnated paper for samples in which the oil had been saturated with oxygen at pressures up to 76 centimeters of mercury, and temperature up to 80 degrees, saturation having taken place before admission to the sample, and saturation of the paper taking place at the same temperature in an atmosphere of oxygen. The results of Jones show that the rise of power factor due to the absorption of oxygen from the bath open to the air is of the order of up to 0.01, that is, little greater than those reported in our paper for the oxygen sample, and the value observed at the end of one day in our combined voltage-temperature test. These values are on the assumption that the sample has become completely saturated with air from the bath, which fact we seriously question. It is also to be noted that in Jones' experiments on samples containing different amounts of oxygen, the measuring cell was evacuated immediately after each power-factor measurement and therefore remained throughout the test at the particular pressure corresponding to the amount of contained oxygen, except for the brief intervals in which power factor was measured.

Incidentally I may also mention that we have allowed cylindrical impregnated-paper specimens such as used in our accelerated life tests, to stand for weeks at a time submerged in an open bath, and have found no material change in the value of power factor measured immediately after impregnation.

Most important in the present work, however, is the difference in behavior we have found when the specimen is subjected to stress and when it is not. If our power-factor increases are due to oxidation alone, they should certainly show up in the absence of stress, and this they do not do. Is it possible that Dr. Race has overlooked this important fact?

With reference to Dr. Wiseman's preference for the term "electrolytic ionization," no serious objection can be taken to it. The word "ionization" has been overworked to such an extent that it applies to almost any unfavorable phenomenon in a cable. The word "ionization" arose first, I believe, from the phenomena in gases, and it was therefore natural that the term should be introduced to describe the phenomena going on in gas spaces in cables. However, it has always seemed to me undesirable to use this word when describing the behavior of liquids and solids, particularly those in which there is no free gas. Moreover, "dissociation" is a well-known term applying to all electrolytic solutions, and many authors consider that insulating liquids including oils have an inherent electrolytic dissociation. Dissociation in this sense, of course, means the continuous process of the separation of molecules into ions and the recombination of the latter, there being, however, on the average, always a certain number of free electrolytic ions. It is this type of ion that we have invoked in our suggested explanation of the phenomena reported in our paper.

We are glad to note that there is general admission that there may be conditions under which combined temperature and stress may lead to unlooked for increases in power factor. We heartily agree in the general comment that the matter should be investigated further with a variation of materials and other obvious variables. We recognize freely that we have tested only one oil and one paper, but we emphasize again that if *any* insulating oil presents the behavior such as we have noticed, attention should be called to it.

Field Investigation of the Characteristics of Lightning Currents Discharged by Arresters

Discussion of paper 42-17 by I. W. Gross, G. D. McCann, and Edward Beck, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 266–71.

E. R. Whitehead (Duquesne Light Company, Pittsburgh, Pa.): This paper is another valuable contribution aimed at rounding out our knowledge of lightning and protective systems by filling in a vital gap concerning the wave shape of natural surge currents.

The difficulty of obtaining such data has been overcome by persistence and resourcefulness, and if we add patience we shall in time accumulate a firm foundation for sound design and application of lightning protective devices.

The low magnitudes and slow rates of rise so far measured explain the highly satisfactory over-all performance of modern lightning arresters. There is, nevertheless, a number of instances in which failure to provide protection demands currents whose rate of rise and magnitude greatly exceed those indicated. None of us is satisfied with such inferences, however, and it is to be hoped that some light will be thrown on this question by the authors in the course of continued investigations. It should be realized that direct strokes quite close to stations are required to produce such currents, and for this reason these data may not be secured for some time.

In many instances it is possible to plan economical protection for discharges of this character and if application engineers give this problem appreciative attention, we may expect protection methods to keep pace with fundamental research.

W. J. Rudge (General Electric Company, Pittsfield, Mass.): The data contained in this paper are a valuable addition to the basic information essential to the economic design and application of protective devices. It is hoped that the authors will continue their investigation in the future.

In Figures 3 and 9 of the paper, the authors compare the results obtained with those obtained by Gross and McMorris. It is pointed out that the difference in the two results may be due to the difference in instrument sensitivity. This is apparently true as the surge-crest-ammeter links used

by Gross and McMorris were set to have a threshold of measurement at 300 to 400 amperes; therefore, discharge current below this value would not be recorded. In Figure 9 of the paper by Gross, McCann, and Beck, it appears that currents as low as 100 amperes or perhaps less were recorded. Since low currents occur more frequently than high currents, it is natural to expect that with a lower threshold of measurement a larger number of discharges will be obtained.

It is of particular interest to note that the highest current measured in this investigation is 9,600 amperes, although five of the installations described in Table I were on wood-pole construction with no overhead ground wires where one would expect the highest discharge currents to be measured. The highest discharge current recorded by Gross and McMorris through a single arrester pole was 15,000 amperes with a probable maximum of 18,000 amperes (if the currents were added in two arrester poles on the same phase). In view of these results, it appears that the lightning arrester subcommittee reports, publishing the performance characteristics of arresters available to the industry up to discharge currents of 20,000 amperes, cover the range of lightning currents most frequently encountered on high-voltage transmission systems.

H. A. P. Langstaff (West Penn Power Company, Pittsburgh, Pa.): The West Penn Power Company has had the equivalent of five to six years experience with fulchronograph installations on our 25-kv system, the first of three being installed August 1939. A number of records have been obtained, one of which I understand is the maximum rate of rise obtained to date: namely, 7,800 amperes per microsecond. From a total of 40 surge recorders on this same system during this past year we have obtained 11 records varying from 4,500 to 10,000 amperes; nine between 10 and 20,000 amperes; one between 20 and 30,000 amperes; three between 30 and 40,000 amperes, and one over 40,000. All arresters involved were of the line type, and a number of them were of the 20-kv rating. The one discharge over 40,000 amperes destroyed the 25-kv arrester. One 20–30,000-ampere discharge was through a 20-kv arrester with no resulting damage. We are continuing our application of 20-kv arresters on the 25-kv system with desirable economical results, and most all of the line-type arresters are mounted on suspension, thereby allowing all damaged arresters to clear the circuit and allow service to be re-established.

Loss-of-Field Protection for Generators

Discussion and author's closure of paper 42-20 by G. C. Crossman, H. F. Lindemuth, and R. L. Webb, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 261–6.

S. B. Griscom (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper brings out an interesting point in connection with the stability of metropolitan power systems. On transmission systems when stability is a serious problem, it is usually due to such factors as large initial phase-angle displacements, low inertia factors, reduction of synchronizing power by switching out lines, and large reductions of generator output by line short-circuits. These considerations are practically never a factor in the stability of metropolitan systems because of the close proximity of generating capacity and loads, the multiplicity of transmission circuits, and the inherently better stability characteristics of steam turbine generators compared with water-wheel generators.

As may be expected, general instability of metropolitan power systems is very rare, possibly occurring at intervals of from 5 to 20 years on any given system. When instability does occur, it is more apt to be caused by some major apparatus failure, or to an operating error. In other words, with metropolitan systems, the problem is not improvement of stability, but the elimination or neutralization of incidents which might cause instability. The most frequent causes of instability of metropolitan systems have been prolonged short circuits at points of high-power concentration and loss of generator excitation. Recent advances in bus differential and backup protection systems have largely solved the short-circuit problem, and the loss-of-field protection system described by the authors appears to satisfactorily solve the excitation problem.

The combination of an undervoltage relay with the reactive current relay is of particular interest in that it gives double assurance against false tripping. In the minds of most operators, this requirement is probably paramount.

Harold A. Bauman (Brooklyn Edison Company, Brooklyn, N. Y.): Those of us who are operators of generating stations are primarily concerned with improving the reliability of our service by reducing the possibility of serious system disturbances.

These loss-of-field protection relays were welcomed by all of our operators as filling a gap in our generator protection. The first installation, at Hudson Avenue station of the Brooklyn Edison Company, proved the extreme reliability of this equipment. The only maintenance required has been the half yearly operation check.

Tests made by actually tripping out the field of one of our generators while on the bus carrying load proved that the protective relays functioned so well that even the high board operators could hardly observe any disturbance on their station meters.

We are confident that this new loss-of-field protection will prevent serious system disturbances and that a long wanted need has been filled in our system protection.

Earle Wild (Commonwealth Edison Company, Chicago, Ill.): The use of this relay for locating complete or partial loss of excitation on a turbogenerator should be very valuable, as this is a rather rare and often a difficult type of trouble for an operator to analyze. This relay would remove any doubt in the operator's mind as to the cause of the severe oscillations on his generator. It should be pointed out, though, that it is neither desirable or necessary in the metropolitan operating company to remove the generator from the system. The ability of nonsalient pole turbogenerators to resynchronize themselves is very pronounced and the correct procedure would be for the relay to indicate by alarm the nature of the trouble. By either reducing the steam input or restoring the field, the generator would very quickly come back to synchronous speed. In the short interim the speed has been increased considerably to the slip speed of an inductive generator. On large systems the reactive requirements of an induction generator are met with only a slight drop in voltage for the few seconds before an operator could act.

This conclusion is based on the analysis of approximately 18 cases of trouble and tests on the Chicago system which were made over ten years ago and reported in a paper in the December 1931 TRANSACTIONS of the AIEE.

E. E. George (Ebasco Services, Inc., New York, N. Y.): The scheme of relay protection outlined in this paper seems to provide satisfactorily for a reasonable range of operating conditions and to be adaptable in principle to different sizes and types of units.

Apparently, the scheme always operates to disconnect the generator if the field is lost or is reduced so low that predetermined conditions of voltage, current, and phase angle prevail. It is not clear whether any consideration has been given to reducing the turbine throttle opening so as to lower the generator kilowatt output and prevent instability in those cases where no hazard to equipment is involved in continued operation.

On hydroelectric machines it has been found possible to clear up an out-of-step condition in which the generator was slipping poles rapidly by merely reducing the turbine gate opening. This procedure was satisfactory even in the case where the field was completely removed from the generator, and it permitted the field to be restored without ever opening the generator oil circuit breaker.

There would seem to be cases in some systems where reduction in generator kilowatt loading might be preferred to opening the generator oil circuit breaker. This provides further argument for the idea of position limit interlocking between the generator voltage regulator and the turbine throttle or gate opening.

G. C. Crossman: In reply to Mr. George's comments on reducing turbine throttle opening to lower generator kilowatt output and thus prevent instability during loss or material reduction of generator field excitation, the authors would like to point out that such throttle control has been considered. However, since the system with which the authors are connected is designed to stand the loss of capacity represented by the disconnection of any one unit in any station, it has been felt that the added complication of such control could not be justified, especially in view of the speed with which serious voltage reductions can occur with loss of field on this system.

Mr. Wild has indicated that on the Chi-

cago system it has not been felt desirable or necessary to remove an unexcited generator from the system since only a slight voltage drop is experienced for the few seconds before the operator could act to reduce generator load or restore field. As indicated in the paper, the authors recognize that there are some systems where loss of field may occur without serious voltage disturbance and where corrective measures may be taken without disconnecting the generator from the system. However, studies and experience indicate that on the New York metropolitan system serious voltage disturbances can occur within a relatively short time, sometimes as short as one or two seconds. Furthermore, when such a disturbance does occur, and the unexcited machine loses synchronism, it is often very difficult for the station operator to determine which machine is in difficulty and what that difficulty is. Several years ago loss of field occurred on a 160-megawatt 25-cycle unit. A serious voltage disturbance resulted over the entire 25-cycle system, with considerable equipment damage. Due to the confusion produced by the fluctuations occurring in practically all the station instruments, considerable time elapsed before the operator was able to identify the machine in trouble and remove it from the system.

In connection with Mr. Wild's comments as to restoring field without disconnecting the generator from the system, it should be pointed out that probably the majority of excitation system troubles cannot be corrected without removing the machine from the system. Of the six cases of complete loss of field which have occurred on the New York system, only two resulted from opening of excitation system breakers, while the other four resulted from such various causes as: field rheostat control circuit trouble; pilot exciter rheostat open circuit due to over travel and contact trouble; and contact failure of a pilot exciter brush during replacement of the paralleling brush.

At the time the paper was written, there had been no operating experience with the loss-of-field relays described in the paper. Subsequently, however, on the evening of January 23, 1942, loss of field occurred on a 65-megawatt, 60-cycle, 3,600-rpm unit equipped with these relays. The unit was carrying a load of 60 megawatts. Through an operating error in shutting down another machine, the pilot exciter breaker on this machine was tripped, causing complete loss of field. The relays quickly disconnected the machine from the system without appreciable disturbance in bus voltage.

Linear Couplers for Bus Protection

Discussion and authors' closure of paper 42-40 by E. L. Harder, E. H. Klemmer, W. K. Sonnemann, and E. C. Wentz, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 241–8.

C. D. Hayward (General Electric Company, Philadelphia, Pa.): Bus protection continues to be a most popular subject at the protective-relay sessions. Fortunately for the relay designer, the attention of interested engineers continues to focus (and rightly so) on the current transformer rather than on the relay as the piece of equipment most susceptible to improvement.

The paper on transient characteristics of current transformers during faults by Messrs. Concordia, Weygandt, and Shott[1] today clearly demonstrates the impracticability of using standard current transformers for generator bus protection.

At the Toronto convention last summer Messrs. Kennedy and Sinks[2] showed that a nonsaturating transformer with linear characteristics was necessary, if adequate bus protection was to be provided. They chose the air-gap-core current transformer in preference to the nonmagnetic-core or linear coupler, as described by the present authors, because of the higher level of power which it affords to operate the relays.

The nonmagnetic-core transformer, or linear coupler, is by no means a new device. The interesting magnetic properties of toroidal coils which make them attractive for use as current transformers have been known for a long time. The mathematical demonstration of the complete freedom of the ideal toroidal coil from mutual coupling effects has been used as a textbook example in volumes on electricity and magnetism[3] for many years. It has long been common practice to use toroidal loading coils in telephone circuits to reduce inductive "cross talk."[4] The use of air-core current transformers for differential protection was covered by United States patents[5] issued ten years ago.

The chief stumbling block which discouraged the use of air-core transformers, or linear couplers, in the past was the low amount of power which could be obtained from them to operate the relays. This trouble has been overcome in the air-gap-core current transformer by making the air-gap portion of the core just long enough to prevent saturation of the remaining iron portion on the highest fault currents to be encountered, but no longer, so that the power delivered is not unnecessarily reduced. Since the maximum power which can be obtained from a given sized current transformer on a given primary current is proportional to the square of the effective permeance of its total core magnetic circuit, and since the air gaps in a typical air-gap-core current transformer constitute only about one sixth of the total magnetic circuit, it will be evident that a current transformer with an air-gap core can deliver about 36 times as much power under optimum conditions as it could if its core were all air.

The authors of this paper have apparently accepted the low power level of their linear couplers as inevitable and have been forced, therefore, to use delicate low-energy relays in order to obtain pickup on acceptably low values of internal fault current. The much higher power level afforded by the air-gap-core current transformer makes it possible to use standard-type sturdy reliable relays and to obtain operation on lower fault currents.

The air-gap-core transformer due to the greater power available, can also readily be used with standard types of relays having a small percentage of through-current restraint where minimum settings for internal faults are desirable, whereas the extra burden of restraint coils and connecting leads would probably be excessive for the linear coupler. With the air-gap current transformer only a small percentage of through-current restraint is required, just enough to overcome the tendency to operate on the small differential current due to the slight mismatching of the mutual reactances of the transformers. It is not necessary to have a separate restraint magnet on the relay for each bus circuit, as it is nearly always possible to group the circuits so that the three separate restraints available on standard relays are sufficient for busses having any number of circuits. With this arrangement the tendency of the relay to operate on heavy through faults is entirely eliminated, leaving the sensitivity of the relay as the only limitation on the minimum fault setting. Thus with standard relays and the air-gap-core transformer, the setting can be made low enough for any practical bus installation.

Since theoretically the linear coupler should be free from mutual coupling effects of external fields, it would be interesting to know whether the authors have any explanation to offer for the seemingly high error of 1.6 per cent given as due to astatic effects, especially when the air-gap current transformer without its shielding case was only one per cent and was too small to be accurately determined with the shielding case in place.

Also the linear coupler would appear to be easier to manufacture with close tolerances than the air-gap transformer; hence, we are disappointed to see the authors state that the couplers can be built with an accuracy of plus or minus 1.5 per cent which is no better than that given for the air-gap transformer at the summer convention.

Since no greater accuracy is claimed for the linear coupler, and since its power level is very much lower than that of the air-gap-core transformer with similar linear characteristics, it would appear that considerably more development would be necessary before the linear coupler can be accepted as a desirable transforming means for bus differential protection.

G. Camilli (General Electric Company, Pittsfield, Mass.): The authors have described an interesting application of the linear couplers to the operation of differential relays for bus protection. Unfortunately, the output which can be derived from the toroids described in this paper is very limited and requires highly sensitive relays.

It might be of some interest to those not familiar with the art to know that linear couplers have been used in the past for the measurement of losses at low power factors (see: Method of Measuring Losses in Reactors at Low Power Factor, by K. G. R. Wilkinson & T. W. Carter), *BEAMA Journal*, May 1939, pages 145–50.

As in the paper under discussion, in this case also, the purpose of the toroids is to obtain a voltage which is directly proportional to the primary current.

The scheme of measuring losses is quite accurate, because practically no load is derived from the toroids. The voltage across their secondaries is balanced with the voltage obtained across the apparatus to be tested in a potentiometer network.

Careful adjustments and very accurate calibrations are necessary when couplers are used to supply even very limited loads.

W. R. Brownlee (The Commonwealth and Southern Corporation, Jackson, Mich.): A bus-protection scheme, having the well-known advantages of differential protection and yet being free from transient effects, should be highly useful in overcoming the reluctance of many operators to install any bus-protective equipment. This reluctance is not too difficult to understand, in view of the fact that if one false operation of a bus-protective equipment occurs, perfect performance must then be secured for many years, if the scheme is to have as good an operating record as conventional transmission-line relays. Also the seriousness of an incorrect bus clearing is such that false operations are next to intolerable. Accordingly it is well to consider carefully whether a setting margin of six per cent is sufficient to take care of an expected manufacturing tolerance having a three per cent spread, assuming that there are no other possible sources of error.

In considering the desirable operating range of bus-protection relays, another factor in addition to the range of normal maximum and minimum connected generation is of importance. Particularly in the case of outdoor busses, it may be highly desirable after a bus-protection operation to make a brief inspection and then energize the bus from a single generator. The bus-protection relay should, of course, operate with positive margin for this condition.

The lower operating limit given by the authors for the low energy plunger relay is 1,500 amperes or about $7^1/_2$ volts. For a high voltage system (such as 138 kv), this setting amounts to some 360,000 kva which may not be low enough. The sensitive polar-type relay apparently has an available setting of about one third of this value. What is the opinion of the authors on the necessity of any special precautions in control cable elements to prevent the possible induction of some two volts in the high impedance relay circuit?

Mention is made of adjusting the mutual reactance of the couplers to the correct value after they have been wound. Details of the adjusting method would be of interest.

E. L. Harder, E. H. Klemmer, W. K. Sonnemann, and E. C. Wentz: The discussion by Mr. Hayward indicates that he believes that the paper on "Transient Characteristics of Current Transformers During Faults," by Messrs. Concordia, Weygandt, and Shott, clearly demonstrates the impracticability of using standard current transformers for generator bus protection. The wave forms and error currents calculated in the paper referred to are quite interesting in that they do not appear to be too much out of line with what is to be expected. However, to interpret the results of that paper in such a way as to conclude that generator bus protection using standard current transformers is impracticable is entirely out of line. It has been clearly shown by calculation, test, and operating experience, that the principle of utilizing variable percentage characteristics in relay design, together with utilizing fault current for restraint, is and has been quite feasible. Furthermore, standard current transformers are used, selected so that they meet well-established criteria with respect to a-c performance which are neither difficult to specify nor hard to meet. It should be borne in mind that the whole story is not given when a study of current-transformer characteristics shows that a false differential current will flow during certain external fault conditions. The picture is only completed when a satisfactory relay design has been evolved to meet these conditions, or when the problem is given up as being hopeless. The situation, as it exists today, is that the limitations in current-transformer performance under transient conditions have been satisfactorily offset by adequate relay design.

Mr. Hayward puts emphasis on the fact that the toroidal coil is not new. The justification for his attention to this point is probably the fact that in our paper we stated that a new principle was applied to bus differential protection. What the authors meant, of course, was that while the toroidal coils in themselves are not new, the application to bus differential protection is new in that it has not been done before. The fact that the principles involved in the accurate performance of air-core toroidal coils are not new is a positive advantage in that it adds an unquestioned background of accuracy fully justifying the application of these devices.

The fact that a limited amount of energy is available from the air-core transformers or linear couplers has undoubtedly been a deterrent against previous investigation on a serious basis. However, close examination of the facts brings out the interesting point that the difficulty anticipated in the past was a great deal more fancied than real. To substantiate this point, let us consider the relative values of energy levels required to operate several standard relay designs as shown in Table I.

The standard-energy close–open relay operates at 17 volt-amperes at tap value, and this is a figure with which most of us are familiar. The plunger-type relay and the polar-element relays were the ones used in the tests described in this paper. Both of these elements are standard designs as are found in many Westinghouse relays. The figures given for the type *D*-2 relay are rather startling because of the low energy level indicated, but this is easily verified from published information. For example, the resistance of the moving coil is given as 0.213 ohm, and a contact setting requiring only one millivolt across the coil for operation is easily made. From these values of volts and ohms the figure of 0.0000047 volt-ampere results.

Reviewing the above, it is seen that practical relays operate over a range of energy requirements of 3,620,000 to 1, this range being obtained by dividing 17 by 0.0000047. The most sensitive relay used in our tests was the polar-element relay requiring 0.02 volt-ampere, and this is 4,250 times the amount of energy required by the type *D*-2 relay. With this tremendous range in relay energy requirements to pick from, it seems to the authors to be rather pointless to make a vigorous effort to fill a portion of the magnetic circuit of the coupling device with iron, particularly in view of Mr. Hayward's statement that the best that can be done is to obtain a 36-fold increase in power level. Furthermore, when iron forms any part of the magnetic circuit, it introduces its characteristics into that part of the magnetic circuit so that the d-c saturation problem is not at all voided. The parameters of the circuit are merely moved to higher current levels, which merely give the current-transformer designer a little more freedom in certain respects, but which introduce other complications. For example, a parallel circuit must be used, bringing in such complications as temperature errors inherent in the application of modified current transformers of this type and the necessity for a multiplicity of adjustable impedances for impedance-matching purposes.

Mr. Hayward indicates that with the air-gap-core transformer there is plenty of energy to energize restraining coils of the differential relay in those cases where it may be desirable. In this respect, there is no difference whatever between the two schemes. Restraint is necessary only when the accuracy of the device is not sufficiently high to cover the desired range between maximum external fault and minimum internal fault. Experimental work has been carried out to a sufficient extent to show that should it become desirable to add restraint to the linear-coupler relay, the linear couplers can furnish the energy required without difficulty.

Table I

	Volt-Amperes
Standard energy close–open relay	17
Plunger-type relay	0.5
Polar-element relay	0.02
Type *D*-2 relay	0.0000047

Attention is called to what Mr. Hayward feels is a seemingly high error of 1.6 per cent given in the paper. If the authors could have made this test at a total error of three per cent, it would have been done. Actually, the only way we could get the maximum error of 1.6 per cent was to deliberately adjust the position of the poorest coupler of the entire lot for maximum error. A total of three per cent error would have been used as stated above for this test, if a number of couplers just meeting the limits which we have reserved of ±1.5 per cent had been available. Actually, the only way to operate under the maximum error of three per cent, in practice, would be to have all of the couplers in the circuits carrying current into the bus in error a maximum amount in one direction, and the linear coupler in the circuit carrying the current away from the bus in error the maximum amount in the other direction. For example, if on a six-circuit bus the linear couplers in five source circuits were 1.5 per cent high in their response, and the remaining linear coupler in the faulted circuit was 1.5 per cent low in its response, then the maximum error of three per cent would be obtained. The probability of the linear couplers being so disposed is very remote; furthermore, not all of them will be in error on either side by the maximum of 1.5 per cent.

Perhaps experience will show that the authors have been unduly pessimistic in assuming that 1.5 per cent is a normal level of error to be experienced in economic manufacture of these devices. It is fully appreciated that similar devices are made much more accurately for use in precision testing; hence, they could be made just as accurately for bus differential protection. With such increased accuracy, however, the cost of the device would obviously be increased, and it was felt that at the present time the best compromise between high accuracy and reasonable cost would be met at the level of ±1.5 per cent error.

Mr. Camilli points out that "careful adjustments and very accurate calibrations are necessary when couplers are used to supply even very limited loads." In this case, the loading on the couplers is of minor consequence with regard to accuracy and comes into play only for the tripping operation on minimum internal fault. If the linear couplers are out of calibration by 1.5 per cent, then the minimum pickup point of the relay would be slightly affected. Actually, the variation between individual couplers as well as the fact that the relay will not be provided with an infinite number of taps for 100 per cent accurate impedance matching makes it obvious that slight errors in individual linear couplers are inconsequential with regard to the minimum pickup adjustment. A check between calculated pickup current and actual pickup current is given in the test results. What Mr. Camilli has undoubtedly overlooked is the fact that during external fault conditions when the relay must not operate, the linear couplers are performing effectively on open circuit, without loading, because their voltages are in opposition in a series circuit.

Mr. Brownlee wonders if a margin of six per cent is sufficient to take care of an expected manufacturing tolerance having a three per cent spread. The margin given is entirely adequate in that the three per cent spread made up of ±1.5 per cent errors includes all errors which may appear in the couplers, astatic or otherwise. In view of the considerations pointed out above, it is expected that the theoretical maximum error of three per cent will never occur, but even if it did, the safety factor of 2 to 1 would still obtain, which is adequate.

In Mr. Brownlee's second paragraph, our interpretation is that under certain conditions, a minimum of connected generation may exist which is lower than the usual or expected minimum. The problem is, then, to determine what is the real minimum in any application before determining the range between maximum and minimum fault currents.

With regard to the induction in the control cable, the relative disposition of the various parts of the circuit should be considered. In the linear coupler itself, a large number of turns surround an area of several square inches placed as favorably as possible with respect to a primary conductor for the induction of voltage. The control cable between linear couplers and the switchboard should consist of two wires in the same conduit or duct. This cable run will consist of only one turn with a minimum of area between the two wires permitting flux to link the circuit. As long as the two wires are run in the same duct or conduit, it is obvious that the problem is of minor consequence, particularly where the cable is in iron conduit. In one instance, for example, the pickup in the leads amounts to less than one per cent of the minimum voltage used for relaying. Where the exposure to induction is very severe, however, the solution is to use conductors in twisted pair in iron conduit.

In response to Mr. Brownlee's question about the method of adjusting the reactance, the more obvious way is to add or subtract turns until the proper reactance is obtained, and then rewind the last layer so that it is uniform around the circle. A better way more suited to production is to have a section of the winding which is uniformly wound for coarse adjustment, which can be connected in addition or opposition with smaller sections of the winding, also uniformly wound for finer adjustment with one turn taps in one of these sections for the very finest adjustment of all.

Current-Transformer Performance Based on Admittance-Vector Locus

Discussion and author's closure of paper 42-11 by A. C. Schwager, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 26-30.

E. C. Wentz (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): It is to be feared that the multiplicity of methods for calculating ratio and phase angle which have been presented during the past few years has served to confuse, rather than aid the application engineer, who should be the one particularly benefited. The design engineers are taking such a great interest in the problem because they hope that a single set of $F\cos\theta+M\sin\theta$ saturation curves or an admittance-vector-locus curve or a nomogram, or equivalent, will be accepted by the application engineer in lieu of a huge number of ratio and phase-angle curves. At one stroke the designer is saved a great deal of work, and the application engineer gets more fundamental information. He can get all the possible ratio and phase-angle data, if he is willing to make a few simple calculations. Yet it is doubtful that the great majority of relay application engineers have thus far been impressed.

It should help to correlate these schemes in the minds of application engineers if we sort out the points on which the designers agree, though they say different things, and discuss briefly the points on which they disagree, even though what they say sounds the same.

Those who start with Agnew all agree on fundamental principles, as Agnew and they evade the "internal reactance" or "leakage-flux" hurdle. Mr. Sinks[1] went back further than Agnew and showed conclusively that Agnew's simple vector diagram will not work if considerable leakage flux is present. However, the author of this discussion worked out a method[2] by which the Agnew formula can be applied, if one is willing to accept a definition of internal reactance in terms of a certain measured value of leakage flux. Yet at this time it is not possible to say that a single simple method for including leakage flux or internal reactance will soon be generally accepted as a standard method.

However, recognizing that leakage reactance may often be neglected, there is fundamental agreement among the designers. The obstacle to calculation is that Agnew's formula contains that pair of trigonometrical bugaboos:

$$F\cos\theta+M\sin\theta$$
$$M\cos\theta-F\sin\theta$$

and that these lead to too much arithmetic. "Simplification" of these bugaboos has been the object of Wiggins, Woods and Bottonari, Wentz, and finally Mr. Schwager. The number of these simplifications may have caused confusion, but it must be remembered that the solutions are all the same in the end; the only reason for preferring one method over the other is that one likes it better. (This is not quite true when Woods and Bottonari suggest that $F\cos\theta+M\sin\theta$ may be equal to $\sqrt{F^2+M^2}$ as this is simplification by sacrifice of accuracy.)

The two principal methods of accurate simplification are then Mr. Schwager's, which, in effect, plots $F\cos\theta+M\sin\theta$ and $M\cos\theta-F\sin\theta$ simultaneously as a vector locus, and the author's,[2] which plots them separately as a family of curves. In either type of curve volts or volts per turn can be plotted against admittance or admittance for one turn (Mr. Schwager's) or amperes or ampere turns (the author's). Both can be particular or general.

It is not possible to say that either method is better. Whatever method is easier to use is better; the decision is up

to the application engineers. However, the benefits of general use of either one of the methods and accompanying data are so important to both design and application engineers that it is to be hoped that the application engineers will study both methods and endeavor to make a decision, perhaps through an appropriate AIEE committee, recommending one method and an accompanying standard form in which manufacturer's data are to be submitted.

3. A PROPOSED METHOD FOR DETERMINATION OF CURRENT TRANSFORMER ERRORS, G. Camilli and R. L. Ten Broeck. AIEE TRANSACTIONS, volume 59, 1940, September section, pages 547-50.

P. O. Langguth (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. The author has presented a unique method of determining the performance of current transformers and represents a new viewpoint not previously considered for popular use. It is interesting to note that in the past several years, the diversity of problems in relaying has brought about a score of methods, all aimed toward the simplification of voluminous performance data, yet flexible enough to meet the demands of present-day relaying problems.

2. The paper very clearly illustrates the progressive steps normally considered by the designer and is of equal interest to the relaying engineer. Familiarity with the saturation characteristic of apparatus associated with magnetic devices, I believe, is universally understood by the designer and relay engineer alike. The direct values obtained from these data represent a popular yardstick for current transformers. The quantity of admittance as brought forth in the paper is also a useful measurement with perhaps greater appeal to the designing engineer.

3. The writer, however, believes that many characteristics are immediately apparent from the saturation curve based on induced voltage and excitation data. These data may easily be obtained from the completely assembled transformer and interpreted for many varying conditions such as diversity of burden, ratio, and current. Inspection of a saturation curve reveals the so-called linear range which may suffice for many ordinary relaying problems. In such cases, the marked ratio may be considered ideal over this range. A further extension of the curve beyond the so-called "knee" will provide the application engineer with sufficient data for most applications.

4. For greater accuracy, the vector conditions with relation to the transformer output and excitation components must be considered. Mr. Schwager's method has combined the effect of the exciting component by determination of "admittance-vector loci" and has the advantage that the path of this two-dimensional vector of excitation has been definitely established for a given transformer. It also reveals what proportion of ampere turns will finally be left for the output.

5. Considering the use of the saturation characteristic directly from test data, I would like to suggest here another method which is based directly on an earlier AIEE paper by Messrs. Woods and Bottonari. It consists essentially of the combination of the vector diagram and the saturation data into a functional diagram and has the advantage of being relatively a simple and direct graphical solution. Such a scheme is illustrated in Figures 1 and 2.

6. Basically, these charts represent a graphical solution of the transformer vector diagram. The variable element, for example, the excitation of the transformer is obtained from the saturation curve plotted in Figure 1. This is combined vectorially in Figure 2 with the secondary current under consideration to obtain the ratio and phase-angle error of the transformer. An example is worked out in Figure 2, and the graphical steps are indicated by the dotted arrow lines.

7. It is my feeling that this idea or a similar one could be standardized to the extent whereby the charts could be made available on standard AIEE forms. Figure 1, for instance, could be so prepared that the originator of the transformer would merely draw the two curves on the form. Figure 2 would be a standard graphical form for computing the ratio and phase-angle error directly from data obtained by use of Figure 1.

8. In conclusion, Mr. Schwager has presented an interesting method that reveals many functional details of a current transformer. He has demonstrated how a large amount of transformer information can be expressed in one chart as compared to the voluminous number of ratio and phase-angle curves normally experienced in practice today. Since this paper evidences a continuing interest in this general subject, I suggest that the relay subcommittee arrange to prepare some simplification of cur-

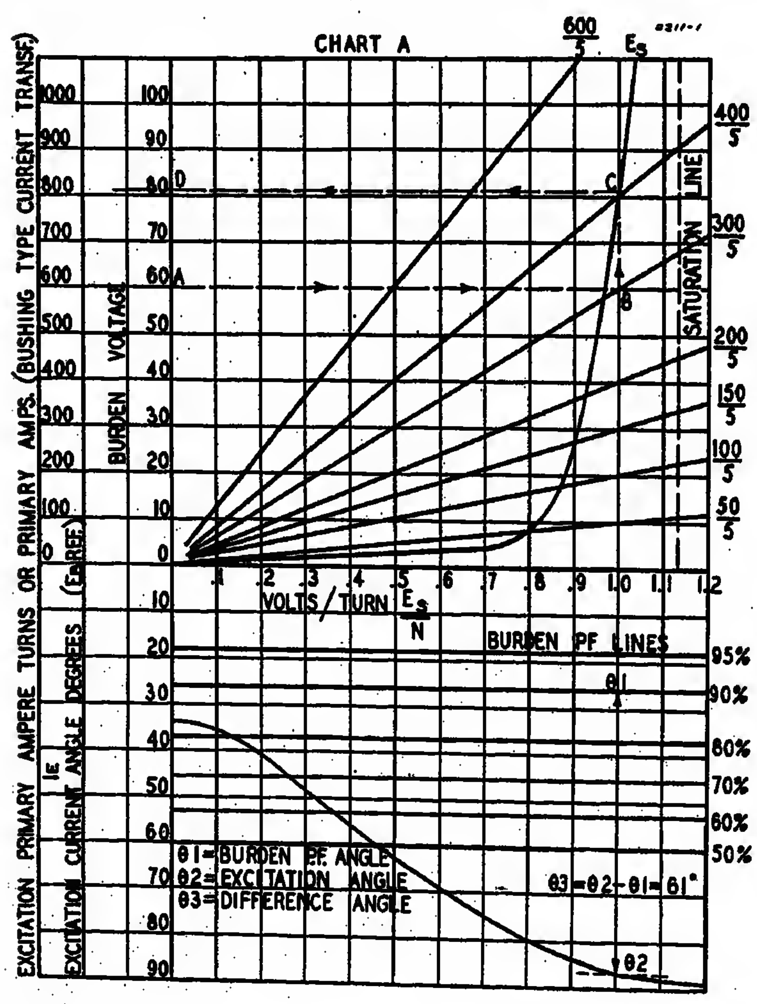

Figure 1

rent-transformer data and have its use adopted in standard form in the near future.

Otto A. Knopp (Pacific Gas and Electric Company, Emeryville, Calif.): Through his paper, "Current-Transformer Performance Based on Admittance-Vector Locus," Mr. Schwager has performed a valuable service in having perfected a method of presenting the characteristics of a current transformer in an exceedingly simple and ingenious way. Such a method was badly needed by the manufacturer of such transformers.

The writer, who has always had a great fascination for current transformers of all types, principally for methods of testing them and testing with them, has always felt as a utility engineer that the automatic calculation by test is the simpler procedure for determining the ratio and phase angle of a current transformer, rather than the calculation of these errors from the electric constants of the iron core by the methods originally developed by P. G. Agnew.

For manufacturers the calculating method has, no doubt, great advantages for selecting the size and type of core, ampere-turn value, size of conductors, and so forth. Mr. Schwager, working for a manufacturing concern, was, therefore, interested in this calculating method, and he succeeded in developing new and useful graphical methods which not only reduced the calculation work materially, but furnished an excellent method of presenting the basic characteristics of the current transformer from which all other performance data can now be quickly determined any time they are needed, without subjecting the current transformer to new tests. This is particularly useful when the individual transformer has been sold by the manufacturer and is no longer available to him for test.

The writer, working for a public utility, is naturally more interested in using direct test methods such as described in his AIEE paper, AIEE TRANSACTIONS, May 1936,[1] for error determinations, as the transformer to be tested is in his possession and remains in his possession. Therefore, a simple test under the existing conditions, is the best approach toward getting accurate results and avoids tedious calculation and the necessity of many tests for determining the necessary constants needed for the calculation. More time would be consumed in the determination of the value of the various burdens and their power factors than in determining the ratio error or phase-angle error directly, since most utility laboratories are well equipped for testing ratio and phase-angle error of circuit transformers. However, there may even be good use for Mr. Schwager's approach in the utilities, if the manufacturer who supplies the current transformers furnished their characteristics in the form Mr. Schwager suggests. The engineering department in the utility, confronted with the problem of selecting current transformers for certain relay operations, can select a current transformer more precisely by the Schwager method than by referring to a few specific ratio and phase-angle error curves which may not apply to the particular condition.

Another application would be the use of the "admittance-vector locus" for setting up current-transformer standards, replacing the XYZ standards or the new standards proposed: B–0.1, B–0.2, B–0.5, and so forth. Another, and, in the writer's opinion, the most useful application of the "admittance-vector locus," would be by its use in the reverse. It should not be difficult, with the accurate methods and equipment available in the utility laboratories for determining ratio and phase angle of current transformers for all kinds of burdens, to determine the "admittance-vector locus." Thus, it may be possible in the utility laboratory to determine this locus as a matter of record more accurately that way than it could be determined by making measurements of the iron loss and other electrical constants of the core.

Such cores are, in most cases, rather small, requiring especially delicate instruments. Where bushing-type current transformers are involved (and I presume Mr. Schwager was mostly concerned with these), the cores are large, making the determination of the electrical constants simple and accurate. The errors of these transformers are large, making a graphical method such as Mr. Schwager's particularly well-adapted. The adaptability of the method to modern compensated current transformers, where the errors are of the order of 0.1 to 0.3 per cent and one to three minutes phase angle, is not as good. There the reverse method may be helpful.

1. SOME APPLICATIONS OF INSTRUMENT TRANSFORMERS, Otto A. Knopp. AIEE TRANSACTIONS, volume 55, 1936, May section, pages 480–9.

J. A. Elzi (The Commonwealth and Southern Corporation., Jackson, Mich.): The users of current transformers have a definite need for performance data covering a wide range of conditions which cannot be adequately covered by the usual ratio and phase-angle curves. It therefore appears that the user must be provided with basic data from which any desired characteristics can be determined, and, since most of the users are not transformer designers, it is important that these data be presented in a readily usable form. In this paper the author presents a means by which this can be accomplished and has analyzed step by step the method of arriving at this curve.

Since the admittance-vector locus is a function of the characteristics of the steel used in the transformer, it would appear that any one manufacturer would need to provide only a few such curves to adequately provide data for an entire line of current transformers. It would be interesting to have the author's opinion regarding this point.

The values for the points corresponding to various ratios of E_2/N in Figures 7 and 8 of the paper are not linear, and extrapolation between points is not possible. This at first appears to limit the usefulness of the curves. However, it might be pointed out that, for a given burden and turn, ratio values of secondary current can be chosen such that ratios of E_2/N corresponding to points given on the curve will result, and performance characteristics for intermediate values for secondary current can then readily be obtained. It might also be of interest to note that since the admittance-vector locus is located with respect to the unity power-factor line, it is very easy to investigate performance at burden power factors other than those shown in the figures by simply drawing in lines for any power factor desired.

G. Camilli (General Electric Company, Pittsfield, Mass.): The author's paper is timely in presenting a novel method of determining the performance of current transformers. The new American Standards Association Standards on instrument transformers recognize the fact that characteristic data of bushing-type current transformers for relay applications can be calculated from exciting current and core-loss data. By the method developed by Mr. Schwager, these excitation data can be incorporated in his admittance-vector locus, from which the final ratio and phase-angle errors can be derived.

This graphical method should be welcomed by both the designers and by the application engineers, because, in contrast with the standard procedure, it gives a more functional picture of the performance of the transformer. It is hoped that this method, together with other graphical analyses which have been proposed, may form the basis for a future ASA Standard for the calculation of current transformers for relay applications. The proposed method may be advantageous in all those cases where either the designer or the operating engineer is interested in complete characteristics at different burdens and at different power factors. However, it is doubtful whether the scheme reduces the amount of work involved over the standard procedure when only a small amount of data is required.

A. C. Schwager: Messrs. P. O. Langguth, E. C. Wentz, and G. Camilli point out the usefulness of the admittance-vector locus for the designing engineer; the question, however, is raised as to whether the method is practical for the use of the operating engineer when only a small amount of data is required. It appears that the author has not sufficiently emphasized the importance of Figures 9 and 10 in his paper. These figures represent the ultimate simplification of the vector-locus graph. Figure 9 shows that for a given burden power factor the ratio error of a multiratio bushing-type transformer can be represented by one single curve, provided $N^2/Z>1{,}000$. Figure 3 of this discussion shows a chart applying to an actual transformer from which the ratio for any total burden power factor between 0.5 and 0.7 can be easily computed as indicated for any practical value of N^2/Z.

The author intended to convey the existence of such simple charts in Figure 9 of the paper. Chart Figure 3 applies to a 600 to 5 multiratio transformer with the ratios as indicated. The top curve applies for a total burden power factor of 0.5 and the three lower curves apply to a burden power factor of 0.7 and varying N^2/Z values. A logarithmic abscissa of two different logarithmic rates for the E_2/N values greatly increases the accuracy over the entire range.

The practical result of Figure 10, on the other hand, is a simple chart Figure 4 of this discussion from which the ratio error can be read off directly in function of the

500/5	B-E	100	10,000
600/5	A-E	120	14,400

primary current. N^2/Z is the parameter of the various curves; in a practical chart additional N^2/Z curves and scale subdivisions would be included. As shown in the paper, the individual curves in Figures 3 and 4 of the discussion can be readily obtained from the excitation characteristics of the steel, or from a sample of the transformer if available for test, the latter giving the more accurate data.

In view of the simplified charts Figures 3 and 4, the author considers it unnecessary to refer to Figures 7 and 8 of his paper or to the methods outlined by Mr. Wentz and by Mr. Langguth, except for design purposes or for application investigations of a more general nature. It might however be worthwhile to analyze some of the features of the above three methods.

Since we are primarily concerned with determining the ratio (complex) of the transformer, it appears that curves whose ordinates are equal to the actual error, except for constants of the transformer and burden are simpler than curves which are not proportional to the error. The admittance-vector locus represents the error, whereas if the magnetization curve is used, the error is obtained only after a division of the exciting current by a variable (I_2). In addition, the admittance-vector locus has increased reading accuracy over the magnetization curve.

In comparing Figure 5 of Mr. Wentz's paper with the author's charts, it must be realized that these charts are equivalent to the author's Figure 8 and do not cover the low-ratio bushing-type transformer represented in Figure 7, since Mr. Wentz uses a simplified equation for the ratio error.

The interesting charts A and B (Figures 1 and 2 of this discussion), which Mr. Langguth has submitted, correspond to Figure 7 of the author's paper. It appears, however, that Mr. Langguth's method requires considerable computation and drafting effort, in addition the range covered by the abscissa is only one per cent of that covered by author's Figure 7, and its practical value for multiratio transformers seems thereby seriously limited.

Since standardization of current-transformer data has been frequently mentioned in the various discussions, the author would like to summarize his suggestions; the final decisions as to the merits of the various proposed methods will, as pointed out by Mr. Wentz, have to be made by the application engineer.

It is proposed that two charts be furnished only.

1. **Admittance-vector locus as shown in Figure 5 of the discussion, or a chart showing the admittance vector components in a rectilinear co-ordinate system, with E_2/N as abscissa in logarithmic scale.** Figure 5 of this discussion permits the calculation of the exciting current for idle transformers and if desired can be used as the basis for any detailed investigation as described in the paper.

2. **Ratio error curves as shown in Figure 3 or 4 of this discussion. Either of these curves permits the determination of the entire ratio data without complicated calculation or construction and require no knowledge of the operation of the transformer proper.**

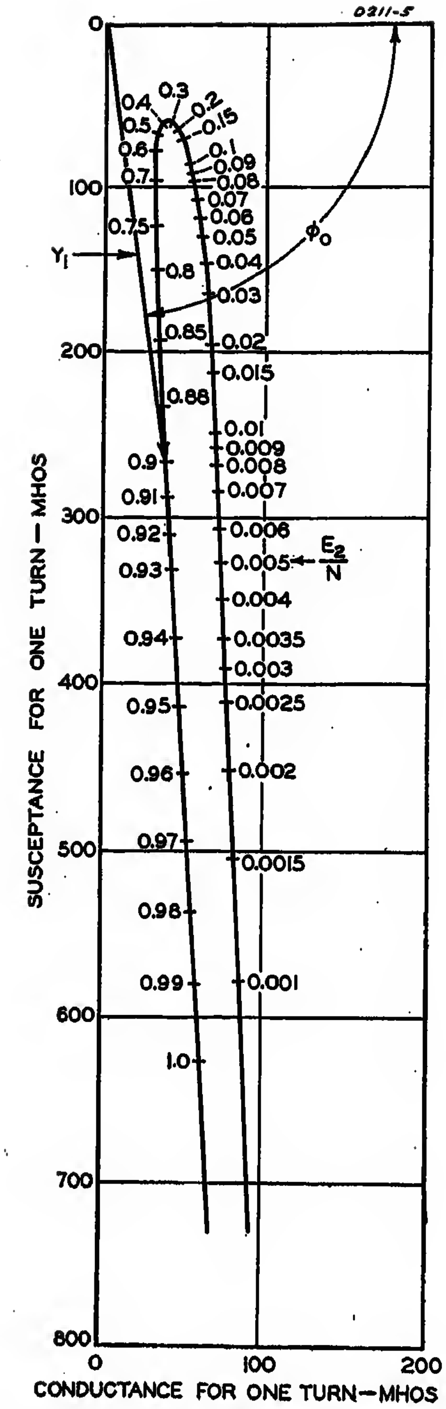

Figure 5. Admittance-vector locus for one turn for 23-kv bushing current transformer

Internal reactance negligible

Internal resistance $R = 0.0022N$

$Y_N = Y_1/N^2$

Mr. Elzi points out an interesting further simplification which might have particular merit for design purposes. The admittance-vector locus can be rescaled so that $Y_{1(B)} = y_{1(B)}D/A$, where $Y_{1(B)}$ is unit admittance, A is the cross-sectional area of the core, and D is its mean diameter. Instead of a parameter of volts per turn, flux density B is used, or E_2/NA if preferred.

This basis will give values of sufficient accuracy for design purposes, even with cores of somewhat different proportions, and close values if the cores have equal outside-to-inside diameter ratios, because of similarity of flux distribution.

Mr. Elzi's concern about the difficulties encountered in interpolating E_2/N values on the admittance-vector locus might be reduced by referring to the proposed practical curves Figure 5, or by plotting the admittance-vector components on a rectilinear co-ordinate system as suggested above under standard data.

That the admittance-vector locus method is readily accepted by a utility laboratory is particularly appreciated. Mr. Knopp confirms the wide field for which the new method might be applicable. The deter-

mination of the vector locus in reverse, as suggested by Mr. Knopp, opens up a considerable field of applications. The method consists of measuring ratio error and phase angle for a known secondary burden and plotting them in a rectilinear co-ordinate system, the resulting curve being geometrically similar to the admittance-vector locus for one turn. This test curve, therefore, fully represents the transformer and permits the calculation of the various important constants, such as turn compensation and secondary leakage reactance.

Multichannel Carrier-Current Facilities for a Power Line

Discussion and authors' closure of paper 42-13 by P. N. Sandstrom and G. E. Foster, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 71–6.

W. R. Brownlee (The Commonwealth and Southern Corporation, Jackson, Mich.): The protective features of the carrier-current installation described by the authors provide an excellent example wherein the use of special, and sometimes so-called "complicated," protective measures are a principal factor in making possible important savings in major equipment (in this instance, the high-voltage oil circuit breakers). The value of such savings may be many times the cost of the additional protective equipment. The presence of continuous automatic supervision should add materially to the over-all reliability of the protective scheme.

Although the transferred tripping arrangement was provided primarily to permit clearing both power sources from a faulted transformer bank, the inherent abilty to clear both ends of the transmission line simultaneously is quite valuable. It is assumed that some form of distance relays is used for the phase protection in this connection. If so, is any special provision made to prevent operation of the distance relays during system oscillations, especially those which do not result in an actual out of step condition? Perhaps the multiple tone system described will lend itself rather well to an "out-of-step blocking" arrangement.

The protection of a three-terminal line or "Tee-tap" involves problems which sometimes cannot be solved by the simple addition of distance relays to a conventional carrier-current system. Have the authors made any study of the possible application of their transferred tripping arrangement to three-terminal lines?

P. N. Sandstrom and G. E. Foster: In answer to Mr. Brownlee's discussion, his assumption is correct that distance-type relays are used for protection against phase-to-phase faults. The particular type employed is the high-speed impedance type. No special provision has been made to prevent the operation of these relays during system oscillations. With the present method of operation there is very little chance for instability.

With reference to the question of protection of a three-terminal line with distance relays in conjunction with conventional carrier-current system, the authors have had contact with an installation of this type. This installation has given satisfactory service for over two years.

The authors have not made a complete study of the possible application of the transfer trip arrangement to a three-terminal line. One method of extending this transferred tripping method to a three-terminal line would be by means of a carrier loop consisting of three carrier frequencies. The first frequency connects station A to station B; the second frequency connects station B to station C, and the third frequency connects station C to station A. At each station only one transmitter and one receiver would be needed. The blocking loop would be extended over this carrier loop. Tripping would be accomplished by breaking the blocking loop at any point and starting the tripping frequency at that point. Since a loop is formed, the tripping signal would go to the other two points, giving almost simultaneous opening of all three terminals.

Transient Characteristics of Current Transformers During Faults

Discussion and authors' closure of paper 42-39 by C. Concordia, C. N. Weygandt, and H. S. Shott, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 280–5.

E. C. Wentz (Westinghouse Electric and Manufacturing Company, Sharon, Pa.) and **W. K. Sonnemann** (Westinghouse Electric and Manufacturing Company, Newark, N. J.): In the opening paragraph of this paper, the authors indicate that very little quantitative data on the transient performance of current transformers have been published. It is agreed that a complete set of transient-performance curves covering all existing designs of current transformers has never been issued. Such a set of curves would involve volumes. Apparently, this paper intends to present data which may be considered quantitative through the use of the so-called size constant of the transformer. In this respect, however, we do not feel that the paper has made any great strides forward over the Wentz-Sonnemann paper mentioned as reference 2. In the reference paper, the authors have presented formulas for the calculation of current-transformer performance in terms of design constants and secondary circuit resistance. In Mr. Harder's discussion of that paper, he reduced the design constants to terms of the saturation curve which puts the necessary design information in a form which can be obtained much more readily in many cases, and which can be used more easily.

We feel that the size constant as given in the paper is not too good a criterion of transformer excellence for the following reasons.

1. We believe that the factor, l, representing the length of the magnetic circuit, is unduly stressed, and tends to lead to erroneous conclusions. For example, if the factors l and A are both increased to, say, double their given value, the size constant is unchanged, but the transformer will, in practically every case, give better performance for any given application. This improvement results from the increase in area and not from an increase in length, as indicated in the author's conclusion 1. The reason for this is that the amount of flux in the core necessary to circulate a given current in the secondary circuit is independent of the length of the magnetic circuit. Once the flux reaches the saturation point, the error current begins to flow in the differential relay. If the area of the core is doubled, the time to reach saturation is increased, thus allowing an increased time interval for the d-c component of the fault current to diminish with a consequent reduction in the magnitude of the error current when it appears.

2. The factor, r_2, should and does include the resistance of the secondary burden. It inevitably follows that any one design of transformer does not have a single size constant in itself. Its size constant can only be determined after the secondary burden for the particular application has been ascertained.

The authors intimate that it is still necessary to consider each application of bus differential relays on its own merits. While this is true to a certain extent for some schemes, and where there are special considerations, it does not give a true picture of the situation as it has existed since the advent of the variable percentage differential relay. Sufficient study of the transient characteristics of current transformers and sufficient tests to verify the conclusions reached have been made so that in the usual bus-differential application, it is possible to apply the variable percentage differential relay without exhaustive engineering research. Such research is avoided through applying the relay in line with certain well-established criteria. These may be explained as follows:

1. The current-transformer ratio should be so chosen as to keep the maximum secondary fault current within reasonable limits as determined by a practical relay design.

2. On multicircuit busses, it is sometimes necessary to use two relays per phase in order to provide an adequate number of restraining elements.

3. The current transformer should not saturate on the maximum symmetrical fault current to which it will be subjected. This does not mean that it will not saturate on asymmetrical fault current. Instead, the saturation caused by the d-c component will usually be severe, giving rise to a substantial error current. However, the use of the variable percentage characteristic as well as an adequate number of restraining elements prevents the relay from false tripping for external faults.

C. Concordia, C. N. Weygandt, and H. S. Shott: On reading over the discussion by Messrs. Wentz and Sonnemann, we note such a very great difference in viewpoint that it will be somewhat difficult to find a common ground for discussion. Messrs. Wentz and Sonnemann seem to feel that enough had already been done on this problem so that all the significant questions are readily answered, but we cannot agree with this opinion. To our knowledge the only quantitative results previously published have been from spot tests and often, as in the case of the paper by Messrs. Wentz and Sonnemann, without any means of identifying the transformer.

Referring to the first paragraph of the discussion, it is not merely by introducing the concept of size constant that our paper intends to present quantitative data, but also in a much more exact representation of the saturation curve. It seemed desirable, in view of the complexity and importance of

the subject, to attempt as rigorous a solution of the problem as practicable, rather than to continue to oversimplify it.

Referring to the second paragraph of the discussion, we infer that Messrs. Wentz and Sonnemann cannot have given our paper the attention which we feel it perhaps deserves. As stated in conclusion 1: "Of two transformers having the same size constant the one having the longer magnetic circuit will give better performance for the same value of primary current." This statement is true, and to say, as the discussers have, that it is not the longer magnetic circuit which accounts for the improvement, seems to us to be quibbling. We do not subscribe to the discussers' arguments about the area; in fact, it could just as well have been the length l and the secondary resistance r_2 which were changed, instead of length and area, and conclusion 1 would still hold. The performance curves as shown by Figures 9–12 are all related to the "amperes per inch of core length." Thus, if length and area are both doubled, the size constant will remain the same, but the same value of primary current will result in half the ampere turns per inch, and, hence, the performance will be shown by a different point on the curves. Regarding the discussion of r_2, we refer the discussers to the definition of r_2 following equation 1 of the paper. Both the size constant and performance of any transformer depend on its secondary burden.

Referring to the discussion of the variable percentage differential relay it seems desirable to point out that such a relay would have severe limitations when used with conventional bar-type current transformers even when the current is only five times normal, as indicated by Figure 9.

Progress Report of D-C Testing of Generators in the Field

Discussion and authors' closure of paper 42-1 by E. R. Davis and M. F. Leftwich, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 14–18.

Charles F. Hill and L. J. Berberich (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Messrs. Davis and Leftwich have found with others that spot readings of insulation resistance were not as effective in determining the condition of the insulation as insulation resistance-time curves. Absorption or insulation resistance-time curves periodically determined have been used by many operators with some success. This success for the ordinary low-voltage determinations (500–1,000 volts) has, however, been limited to:

1. Detection of moisture in insulation.
2. Determination of leakage over the end windings due to moisture, dirt, oil, and combinations of these.
3. Studying the curing of the insulation in a new machine which is illustrated by the data in Figure 8 of the paper.

Low-voltage d-c testing on the other hand, has not been of much value in the location of damage to the insulation due to mechanical causes.

A number of operators have also attempted to locate mechanical defects by means of other tests such as power factor and ionization detection with negative results, in general. It had been our opinion that rather high-voltage d-c testing should be more effective in detecting mechanical deterioration in such insulation, but attempts by some operating engineers did not give positive results. It is, therefore, encouraging to see that the authors have achieved some measure of success with such high-voltage d-c tests.

The EEI subject committee on generator insulation testing (AIEE TRANSACTIONS, volume 60, 1941, p. 1003) reports some tests with high-voltage d-c on several machines which were about to be rewound. They were not always successful in locating deliberately inflicted mechanical damage. They did find, however, that insulation resistance may be considerably less when measured at high-voltage than when measured at a low-voltage in a machine known to have a defective winding. We have made many measurements of insulation resistance on sections of good coils insulated for 13.8 kv of both the older and the newer types over a range of voltage from 500 to 25,000 volts. These showed that the insulation resistance was substantially unaffected by voltage. Therefore, when a voltage effect is found, some insulation defect may be indicated. This should be investigated further.

The authors have logically started at lower voltages and gradually stepped up the voltages in their testing program, until now a voltage of 14,000 is used on machines of the higher-voltage ratings. We believe, however, that still higher voltages could be used. We have made a number of tests of the a-c and d-c breakdown strengths of both the older and newer type of insulation and have found that the d-c breakdown strength corresponds very closely with the a-c peak breakdown strength. The EEI subcommittee already referred to obtained the same result on old machines. It is, therefore, indicated that d-c voltages at least as high as the permissible a-c peak-test voltage on old apparatus could be used in testing without damage to good insulation. This would correspond to voltages up to 20,000 or 25,000 for a 13.8 kv machine which is somewhat higher than the maximum voltage used by the authors.

Messrs. Davis and Leftwich have indicated that many of the failures are due to mechanical causes. They have shown that high-voltage d-c has definite value in detecting this type of insulation defect. Table II of the paper shows that many of the breakdowns on test have occurred at d-c voltages far below the a-c peak-operating voltages. The authors state that some of these breakdowns have occurred on coils near the neutral. We would like to ask if all coils which broke down on test at voltages below the a-c peak operating voltage were far removed from the line end in the phase group.

The authors have apparently kept a record of service and test failures over a long period of time. Such records are of considerable value, not only to the operator, but also to the manufacturer for improvement in design may be suggested. These records are summed up in Table IV of the paper. One would expect that the real value of a testing program should be indicated by a reduction in failure rate in service. While Table IV does not give the service failure rate before the testing program was started, it does not show any consistent improvement in failure rate in service as experience was gained in testing. We would like to ask if the authors have any explanation for the lack of a definite improvement in service failure rate since the testing program was begun.

There is a possibility that machine voltages themselves are locating defects which develop on coils nearer full-phase potential, leaving only those on coils near ground potential for the d-c tests. If this is true, then the use of much higher d-c test voltages might be very useful to anticipate or eliminate service failures.

C. T. Weller (General Electric Company, Schenectady, N. Y.): During recent years, an important activity of the Institute has been the co-ordination of insulation. This involves testing methods as well as values, so it is gratifying to have a "Progress Report" on a d-c method to supplement the usual a-c methods. The use of high direct voltage for commercial routine testing dates from about 1916, when the development of our d-c cable-testing sets was started. These were developed

1. To provide equipment of greater portability than the ponderous a-c equipment then required for testing cable lengths.
2. To determine if impending cable failures could be anticipated from the time-current curves of the insulation.

The question of test equipment portability (1) does not ordinarily arise in the case of generators, but the question of impending failure detection (2) is always pertinent. After a long investigation, a ratio of 2.4:1 between the d-c crest and a-c rms test voltage values for cables was arrived at. A corresponding test-voltage ratio for apparatus apparently has not been established, so arbitrary values are sometimes used.

The effect of direct voltage on insulation is indicated by some of our experiences with the early cable-testing sets in the laboratory. We attempted to use sphere gaps to determine approximately the drop across the rectifier but found that the polarity of the direct voltage had an effect on the arc-over voltage. In view of the well-known limitations of sphere gaps from the standpoint of accuracy, we built an electrostatic voltmeter for use as a d-c–a-c transfer instrument; this was rated 100 kv (crest a-c or constant d-c value) and was of the oil-insulated, reflecting, repulsion type. The voltmeter worked beautifully with alternating voltage, but with gradually increasing direct voltage became more and more erratic, until it was impossible even to estimate what the deflection might be; the performance indicated that the leakage was both large and variable but no arc-overs occurred. In order to simulate cable lengths we built up a capacitor of glass-tinfoil units mounted in a wooden frame carefully treated with paraffin. As the direct voltage across the capacitor to ground increased, leakage through the seams in the wood finally caused smoke to appear, so additional insulators

had to be provided. The direct-voltage values involved were much higher than those under discussion today, but the results were first responsible for our conclusion that direct voltage constitutes a much more severe test on insulation than alternating voltage when leakage is present. Variable leakage occasionally occurs in cable circuits and some very erratic arc-overs have resulted. However, it should be emphasized that cables, because of their uniform insulation and resulting voltage stresses, are ideal subjects for d-c testing, but such is definitely not the case for apparatus. It is evident that the authors were wise in proceeding with caution. It appears that many additional "Progress Reports" will be necessary before a proper d-c–a-c test ratio can be established for apparatus.

P. H. McAuley (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The author's results show that high-voltage d-c testing of insulation, which amounts to a combined dielectric and Megger test, is very effective. The following data may help to explain some of the results given in the author's Table III and Figure 8.

Table I of this discussion shows the results of tests at 500 volts d-c on four fractional horsepower 440-volt motors of a type which has given good performance in service. The tests were designed to determine the variations in resistance likely to be encountered on machines. The readings were at one minute after voltage was applied, but in most cases resistances were still increasing after 15 minutes. The corresponding currents may be obtained by dividing the voltage (500) by the resistance values shown. First, note the remarkable consistency in the performance of the four different motors. The first test was made at room temperature just as the motors were received from the factory. In a 48-degree-centigrade oven the resistances dropped slightly. However, with the oven at 75 degrees centigrade and later at 95 decrees centigrade, the values are practically the same as the original room temperature values. Upon cooling to room temperature the insulation resistances increased in about a 100 to 1 ratio. The last column shows the effect of standing around under summer air conditions plus an overnight cooling cycle in a refrigerator. All values, of course, are well up in the range regarded as indicative of insulation in good condition.

The apparent explanation of the behavior of the insulation is moisture absorption.

Table I. Insulation Resistance in Megohms After 1 Minute at 500 Volts D-C on 4 Small 440-Volt Motors at Controlled Oven Temperatures

Motor	28C	48C 5 Hr	75C 20 Hr	95C 19 Hr	22C 23 Hr	25C (18 Days) 5C (15 Hours) 25C (7 Hours)
1	460	125	430	415	22,000	27
2	475	119	400	445	65,000	16
3	455	99	340	360	42,000	25
4	495	106	310	340	38,000	31

When these motors were stored following the varnish bakes, a long slow process of moisture absorption followed under summer humidity conditions. Capacity and power-factor measurements also show this process rather well. At the higher temperatures moisture is being driven off and resistances do not change much. But when the motors cool again, insulation resistances in the dry condition at room temperature are very much higher. Exposure to room air plus a cooling cycle conducive to condensation soon reduces the readings to $^1/_{1,000}$ the former values. In spite of the varnish treatment, moisture influences leakage currents. Also, in these particular tests, the results were influenced in part at least by the leads which touched the frames at places in the terminal boxes. It has been found that rubber-insulated leads are no guarantee of high insulation resistance in the leads. In general, leads can have a great influence on indicated insulation resistances.

These results apply, of course, to machines which stand idle for long periods and are subjected to high humidity conditions. On samples and on motors subjected regularly or continuously to high operating temperatures, insulation resistances usually increase with aging. It has been noticed that measurements at room temperature show about a 10 to 1 increase over considerable periods of time.

Individual values of insulation resistance above the range of values due to dirt or moisture can hardly be regarded as significant. However, similar machines seem to perform very consistently. If a given type is well-classified, insulation resistance readings may prove of some value in evaluating the condition of individual units. Admittedly we have a good deal to learn before this is possible.

B. Van Ness, Jr. (Pennsylvania Water and Power Company, Baltimore, Md.): In recent years there has been a growing interest in the development of a nondestructive method of checking the condition of generator insulation. The increasing demands upon standby and reserve equipment during the present emergency stress the need for a solution to the problem—which is complex and difficult—and one requiring the attention of many investigators. Therefore, the present paper is particularly timely.

Insulation troubles may be classified roughly under two headings:

1. Temporary—in which some outside agent temporarily reduces or impairs the insulation strength. In this class of trouble may be typed insulation affected by moisture and surface dirt.
2. Permanent—in which the dielectric strength of insulation is permanently reduced by mechanical breakage, electrical rupture, and so on.

The distinction between these two classes of insulation trouble is not always appreciated.

In general, the more commonly recognized nondestructive methods employed in machine insulation testing will rather definitely pick out the temporary types of machine insulation weakness introduced by moisture or dirt, but as yet they are not at all definite in the location of permanent types of insulation difficulties. Therefore, it is encouraging to see the fresh viewpoint presented in the paper by Messrs. Davis and Leftwich and the progress they are making in field testing. With the exception of destructive a-c high-potential testing, theirs is the first method reported to definitely pick out incipient insulation faults of the permanent type. In many cases of their checks it was not necessary to test to failure to detect faults, but in some cases the faulted winding actually failed during testing. This method of testing, therefore, does not as yet completely meet the desired ultimate of nondestruction, but it is a definite approach toward that goal. Winding damage is localized and the hazard of widespread trouble from service failure is eliminated. Furthermore, it is very possible that the test breakdowns occurring at the inception of the program might have been averted, had testing been under way when the insulation was first affected.

The higher test voltages offer interesting possibilities. It is hoped that the authors will find it possible to extend the method to the 13,800-volt class at comparable test voltages and with equally successful results.

E. R. Davis and **M. F. Leftwich**: The interest shown by those presenting discussions is greatly appreciated by the authors.

Dr. Hill and Dr. Berberich mention that some of the generator armature breakdowns on test occur on coils near the neutral. In checking our records, we find that many of the failures on test occurred approximately halfway between line and neutral coils in the phase group. The test voltage of failure usually exceeds the a-c peak operating voltage. However, at the beginning of the test schedule many of the incipient failures were located near the generator neutral at comparatively low test voltages so that no "standard" test voltage could be determined until these defective coils were located and removed.

Referring to the rate of failure in service as shown in Table IV, we wish to point out that the average age of generators prior to beginning of tests was 7.78 years as compared with 13.45 years to January 1, 1942. These ages take into account additional capacity added to system and machines which have been rewound. Further checking of records reveal that in the 10-year period immediately prior to test schedule, a total of 403,650 kva failed in service as compared with 360,115 kva as shown in Table IV. This difference of 43,535 kva is very encouraging, because the average age of windings during this 10-year period was increasing. It is believed with the newer test apparatus and additional testing experience this downward trend will continue and perhaps exceed the rate of decline in kilovolt-amperes failing in service as noted.

The difficulties which Mr. Weller encountered in accurately measuring high d-c potentials are easily understandable, although our problem was not so difficult, because we are using a comparatively low voltage. However, by keeping comparative records on individual generators, a slight inaccuracy of test potential as recorded by instruments would hardly be evident, providing the same test set and instruments are used.

The effect of moisture on insulation when a comparatively high d-c voltage is applied, as described in Mr. McAuley's discussion, is very interesting. We have used a d-c voltage of 5,000 on large 6,600-volt generator

armatures while being dried prior to initial installation and have obtained similar results. However, a much longer interval of time was required to obtain a change in insulation resistance.

We hope that many high d-c voltage tests will be made in the near future, particularly on armatures of the 13,800-volt class. The compilation of such data may eventually lead to definite test standards. At least, as Mr. Van Ness, Jr., states, the higher test voltages offer interesting possibilities.

Measurement of Maximum Demand

Discussion and author's closure of paper 42-15 by P. M. Lincoln, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 57–62.

Perry A. Borden (The Bristol Company, Waterbury, Conn.): The soundness of the theory of measuring demand on a logarithmic basis has already been well taught by Dr. Lincoln in his earlier papers; and his original form of the instrument, even with the inherent errors which he has now pointed out, demonstrates the practical application of this theory and provides probably a truer basis for determining the limits of electrical apparatus than is found in the mechanical instruments of the block-interval class. I believe that those utilities who have adopted the thermal demand meter have found its use to be economically sound and are satisfied that such slight departures which it may possess from the theoretically correct values are insignificant as compared with the inherent departures of those values from being a true criterion of the actual limits of the apparatus. That demand measurement can never be reduced to an exact science is an admitted fact—and is probably the only fact which can account for the toleration of measuring methods which may show such vast discrepancies as have long been recognized and have been vividly brought to light in Dr. Lincoln's Ithaca tests.

In the development of the new form of thermal meter there has obviously been encountered the same problem that is met wherever the measurement of temperature is involved, namely, that of making sure that the temperature as indicated by the sensitive device is the same temperature as that in which we are interested. In this case, however, since temperature is but one link in a chain of energy transformations essential to the final measurement, the various loading and compensating devices appear to have succeeded not only in taking care of such discrepancies but in utilizing the time lag of heat transfer to simulate the temperature response characteristic of the electrical plant.

From an engineering standpoint, and even from an economic standpoint, the thermal demand meter would seem to approach as closely as possible to the ideal method of obtaining the desired measurement. The main objection to its use seems to be, now as heretofore, that of providing to the customer a satisfactory explanation of the engineering soundness and economic fairness of its readings. There has been raised against the use of thermal demand the argument that is readings are difficult to define and to explain in comprehensive terms to the nontechnical user. This objection probably has some foundation and would not in any way be removed by the adoption of the suggested modification in which, with the adoption of a longer characteristic time period, the meter is deliberately designed to depart from following a true logarithmic law. These objections, however, appear to be principally academic, and should not introduce more difficulty in the work of the rate maker than is found in the incorporation of a power-factor clause in charges for electrical service. Here, it is admitted that the possibility of several definitions might form a basis for controversy; but, as in most other instances of formulating definitions, a certain amount of compromise must be tolerated in the interests of ultimate simplicity. This attitude is well brought out in Professor Karapetoff's contribution, "A Parable About the Mean Radius of the Ellipse," published in the AIEE JOURNAL, volume 39, 1920, page 732. (I here take the opportunity to recommend that this parable be reprinted for the edification of the younger members of the Institute.)

The secondary importance of the actual value of the selected time interval in demand measurement has long been realized and was confirmed in the tests under actual load conditions as described in my 1920 paper on demand measurement (AIEE TRANSACTIONS, volume 39, page 1847). Dr. Lincoln, in his discussion of that paper, pointed out many of the features of demand measurement which have been brought to a head in his present paper. While in 1920 we were hardly so audacious as to suggest anything like the universal adoption of a 60-minute time interval, it now appears that such a period, especially if incorporated in a logarithmic meter of the suggested form, might fill a very large place in the measurement of demand.

W. J. McLachlan (General Electric Company, Schenectady, N. Y.): The condemnation of the block-interval meter in Mr. Lincoln's paper appears practically to incriminate the prevailing practice in this country. This allegation at face value is alarming. That it is not, is evidenced by the fact that the same theoretical shortcomings of the block-interval type were expounded, before the Institute, quite thoroughly by Mr. Lincoln in 1915, again in 1918, again in 1934, again in 1939, and now are repeated in 1942.

Surely, there must be some reason behind the continuing use of a device whose shortcomings have so long been so well understood. In fact, there are many reasons. Among them are:

1. Any measurement of demand constitutes not an exact, but rather, only a rough approximation of the proportion of the system investment cost incurred in supplying that demand. This has been recognized practically since the conception of demand rates.

2. Since no demand allocation method known is exact, there has been a preference for a measurement basis which is simple to understand and explain. This is a definite advantage of the arithmetic average of the block-interval type as contrasted to the logarithmic characteristic.

3. "Peak splitting" is of significance only on load peaks of short duration, which occur singly during the billing period or which repeat at an interval exactly equal to the "block interval" or a multiple thereof. Probability states that random repetition of peaks within the billing period, which is the usual case, will minimize the "peak-splitting" effect.

4. Short-duration loads, where peak splitting can possibly have any effect, and where advantage is claimed for the logarithmic characteristic are a problem unto themselves, because the ability of the system to supply such loads is limited generally by voltage drop and not the thermal ability of the system. The voltage-drop effect is instantaneous, and its import cannot be measured by any of the time-interval demand measurements now used, be they logarithmic or arithmetic.

5. While heating of system equipment follows a logarithmic characteristic, the time constants involved in the various equipments are so radically differing in themselves, and different from those of the logarithmic meters now employed, as to make any claims for advantage in this respect at least open to question. For instance, a transformer may require six to seven hours to reach 90 per cent of ultimate temperature, as contrasted to the one-hour meter characteristic. Actually, an arithmetic curve much more nearly approximates the heating of such an equipment during a one-hour interval than does a one-hour logarithmic meter curve.

6. The fact that one type of meter follows the heating curve of equipment, at one fixed value of load, more closely than another is of little significance when it is considered that the response of both meters, to differing values of load, is in accordance with the first power of the current (since the measurement is in kilowatts, kilovolt-amperes, or reactive kilovolt-amperes) whereas the heating of equipment is much more nearly proportional to the square of the current. Thus the basic measurement is not in accordance with the thermal loading of equipment.

7. Testing convenience has been a predominant advantage of the block-interval type.

The discusser holds no brief for the block-interval meter. It is the manufacturer's business to build the types of equipment which the trade chooses to desire. The purpose of this discussion is to record the fact that there are factors which should be considered in arriving at this choice which do not appear in Mr. Lincoln's paper.

P. M. Lincoln: I take positive exception from the comments submitted by Mr. W. J. McLachlan. The indication of maximum demand as registered by the thermal demand meter is completely exact and not a rough approximation as Mr. McLachlan would have us believe. Its only departure from complete exactness is due to the impossibility of causing heat to diffuse instan-

taneously throughout the masses of matter that are being heated or cooled during normal operation. By careful design, this departure from complete exactitude can be made negligible.

May I ask Mr. McLachlan why he advocates an admittedly inaccurate method of measuring maximum demand when an exact method is available?

I would also disagree with Mr. Perry A. Borden's statement "that demand measurement can never be reduced to an exact science is an admitted fact." This statement is quite true when applied to an arithmetic average, but almost entirely false when applied to a logarithmic average. I, for one, make no such admission. The thermal demand meter as described in my paper is absolutely exact except in so far as its indication is influenced by the impossibility of causing heat to diffuse instantaneously. Apparently, both Mr. McLachlan and Mr. Borden fail to recognize the basic difference between a continuous and discontinuous function of time. The indication of the thermal wattmeter is absolutely exact except in so far as above indicated.

My paper is, perhaps, more unique for what it omits than for what it contains. For instance, in column 4, there appears a mathematical expression for the difference in the amount of heat that enters the two elements of the thermal wattmeter during normal operation. This expression is incomplete. The factor cos ϕ should be added where ϕ is the phase angle between E and I. Instead of $2EIr$ as given it should read $2EIr$ cos ϕ. In other words, the thermal wattmeter is a true wattmeter independent of power factor. I did not include the factor cos ϕ in my paper because of the many questions which such an inclusion might have raised. For instance, at power factors other than unity, what is the best relationship between the factors E, I, r and cos ϕ? At unity power factor, the best relationship is to make the influence of the factors E and I approximately equal. However, we must bear in mind that at 50 per cent power factor, the influence of the factor I is twice that at unity power factor; at 25 per cent power factor, four times; at 10 per cent power factor, ten times. This naturally raises the question what is the best relationship between the factors E, I, r and cos ϕ for the usual conditions of service that are met in normal operation. If all these questions had been discussed to the extent their merits dictate, my paper might have lengthened to many times its present length, and, in my opinion, it is already long enough. In view of this undue possible lengthening, it seemed better to omit the factor cos ϕ from the expression in column 4.

Freedom from power-factor error is obtained only by exceeding care in the design of the small transformer used. The capacity of this small transformer is very small. In any transformer there is a phase difference between primary and secondary. The smaller the transformer, the greater, in general, is this phase difference. By careful attention to transformer design, I have been able to keep the phase difference in this transformer down to a matter of two or three minutes of phase angle. This phase angle is small enough so that the resulting power-factor error is negligible even on very low power factors. It is worthy of note that exceeding care must be taken in this small transformer design.

In column 14 there is given a mathematical expression for the indication of the thermal wattmeter. Due to my own inadvertence, the text of paper does not sufficiently explain the full significance of this expression. This expression gives the indication of the thermal wattmeter when a given amount of energy (watt-hours or kilowatt-hours) is passed through the meter in a given time t. Also, this expression holds true only if the wattmeter is indicating zero at the time the load is applied. If the meter indication is other than zero at the time of load application, the final meter indication is vastly different than if its indication is zero. If the rate of load application is lower than the meter indication at the instant of load application, the demand wattmeter indication actually decreases. Also, the expression holds true only if heat diffusion is assumed to be instantaneous.

I wish to call particular attention to the last sentence in my paper. I am strongly of the opinion that the time interval for demand measurement should be standardized. I see no reason why John Jones should be assessed for maximum demand on the basis of a time interval that differs from that of Jim Robinson. The real object of any demand assessment is to assess the service user an amount that will reimburse the utility for its fixed charges. It is perfectly true that if John Jones has a perfectly steady load, while Jim Robinson takes his load at a rate of ten times or 100 times that of John Jones, but during only a small fraction of his time interval, then Jim Robinson should pay more for his service than John Jones. The thermal-demand wattmeter automatically recognizes the difference between John Jones' method of taking service and Jim Robinson's. The standard block-interval meter does not.

It is further my opinion that the standard block-interval demand meter must be scrapped. When it is possible for a service user to reduce his maximum demand assessment to one-half his actual maximum demand, the method of maximum demand measurement by which this becomes possible must be scrapped. This is particularly true since it is quite possible for the service user to accomplish this end without the utility even becoming aware that it is being done. In my opinion, this scrapping should have occurred back in 1917 when the thermal-demand wattmeter first appeared. During this 25 years, the public utilities of the United States have expended something of the order of $100,000,000 for demand-metering equipment. However, perhaps there has been no large loss by the public utilities of the United States in this delay of 25 years in scrapping date since much has been learned concerning the character of the thermal-demand wattmeter during this 25 year period. For instance, in 1917 when the thermal-demand wattmeter was first produced, there was no known means of adjusting its time interval. The thermal-demand wattmeter was introduced into Canada about 1919 and has become the standard demand wattmeter of Canada. In Canada, however, the time interval is approximately 15 minutes—the time interval of the thermal wattmeter as first produced. The longer time intervals have not yet been introduced into Canada. In my opinion, 15 minutes is much too short a time interval for demand measurement. As indicated in my paper, I favor adoption, as standard, the maximum time interval now being used, 60 minutes. If the thermal type of demand wattmeter had been adopted as standard in the United States in 1917, the time interval would unquestionably have been 15 minutes and we in the United States would have found ourselves in the same position as Canada now is—too short a time interval.

In adopting a standard time interval we must also give due consideration to ammeters as well as wattmeters as pointed out in my paper. Shall the one-hour thermal-demand wattmeter be the one that arrives at 90 per cent of final in one hour, or 81 per cent? Although I have never actually produced a thermal-demand wattmeter that will arrive at 81 per cent of final indication in one hour, my experimental work has clearly indicated that there will be no difficulty in producing such a meter. I personally believe that it would be preferable to keep the wattmeter's time interval at the time to arrive at 90 per cent of final and change the ammeter's to 95 per cent, but my opinion on this question is not so fixed as upon some of the other questions discussed herein.

It might further be pointed out that the thermal-demand meter may readily be so connected as to indicate vars or kilovars as well as watts or kilowatts. It may thus be used to take account of the power factor of the load under measurement. I think rate makers will generally agree that at the present time, the power factor of the load is not recognized to the extent that it deserves. By the measurement of vars or kilovars as well as watts or kilowatts, power factor can be recognized to whatever extent the rate maker may think advisable.

In my paper, as well as in this closure, I have expressed some rather pronounced, perhaps radical, opinions. If anyone commenting thereon wishes to disagree with any of those opinions, here is the place, and now is the time to express those disagreements. I have quite often found myself in disagreement on the matters discussed herein, and a few more added to those disagreeing with me will be received with complete composure. Let me urge those disagreeing with any of my expressed opinions to have no hesitation in saying so.

The Acceleration-Oscillogram Method of Motor-Torque Measurement

Discussion and authors' closure of paper 42-5 by C. R. Atkinson and E. G. Downie, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, January section, pages 7–9.

R. W. Ager (Cornell University, Ithaca, N. Y.): I wish to welcome the paper by Messrs. Atkinson and Downie to the litera-

ture on acceleration testing. Every method has its own inherent advantages. The main advantage of the method using the velocity-time curve as suggested seems to be in the use of standard equipment and in the speed with which calculations can be made. However I would like to ask the authors what accuracy can be obtained by this method. The authors have not shown how widely scattered the calculated points might be, nor do they indicate how successive calculations made from the same film might check if, perhaps, made by different calculators.

I wish to call attention to the differences in the shapes of the two curves of Figures 6 and 7 of the paper. These were taken from tests[1] made at different voltages and, therefore, some difference in shape might be expected due to saturation. While in my tests I found some differences in curves taken with a similar spread of voltage, the curve shapes were not as varied.

The authors' curves show a dip in the torque slightly above 50 per cent synchronous speed. Similar results have been found in my tests on some motors. A dip can be caused by dissymmetry in the electric circuit of the rotor as indicated by Figure 2 of my paper. This curve was for a wound-rotor induction motor operated with an unsymmetrical controller. Pronounced dips were also found in the curves taken on a 15-horsepower synchronous machine. The three large synchronous motors tested, however, showed no indication of having such dips in the torque curves, although the accuracy of the tests was such that even slight dips would have been recorded had they been present.

The torque pulsations indicated in these tests can occur due to two causes. These are:

1. The salient pole structure of the magnetic circuit.
2. Any dissymmetry of the electric circuits on the two axes.

Both of these cause pulsations of the same frequency, namely twice slip frequency. A comparison of the pulsations indicated in Figure 3 of the paper with those indicated in Figures 1, 2, and 4 will show that the latter are much more pronounced. In Figure 3 the speed curve does not show a negative slope until synchronous speed is reached. From an electrical point of view there seems little reason for this difference.

A careful examination of Figures 1, 2, and 4 will show that in these tests the frequency of the pulsations did not vary greatly. Also, the same period was indicated for the torque transient at starting (except in Figure 4 where the transient was too small to show clearly). Figure 3 indicates a different behavior. The starting transient shows only slight pulsations, and the main pulsations between half and full speed have a continually decreasing frequency which is exactly twice that of the field discharge current. The pulsations of Figure 3 check with the expected performance, the others do not. In taking the curve of Figure 3 the motor was operated without the added inertia of the second machine which was used in the other tests. With the second machine coupled to the motor, a torsion pendulum was formed which was set in vibration by the sudden application of the starting torque and also by the torque pulsations when the latter were of the proper frequency. This resonance effect probably accounts for the building up of the large swings noted in the tests. The high shaft torques corresponding to the indicated values might be present in generator sets driven by synchronous motors. That they are so well shown in these tests would indicate an application for this type of testing.

John F. H. Douglas (Marquette University, Milwaukee, Wis.): This paper is of interest to my colleague, Mr. E. A. Halbach of Marquette University, and myself, because we have been trying to perfect a generator and oscillograph which will measure and record torque-time and torque-speed curves. We submit two oscillograms, among our best, but still with too much ripple due to defects of generator construction. The first is the torque-speed oscillogram of a five-horsepower century induction motor started from the line. The second is the torque-time oscillogram of a synchronous motor. This shows in sequence the 50 per cent speed-torque dip, the increased torque on changing to full voltage, and the hunting pulsations caused by closing the field switch. We consider our oscillograms superior to oscillogram $5B$ of the paper, but inferior to those published by Dannath and Redfearn.[1] Dannath and Redfearn took extraordinary pains to build a ripple-free tachometer generator. Most of the other writers[2] on this subject also attribute the ripples to defective generator construction. When a Prony-brake retardation test of any motor is taken, and the ripples show up prominently, it is a good indication that the device is not sufficiently developed to measure real torque ripples of smaller magnitude.

The writers have undertaken a very difficult subject. While they furnish but little data on the device, it must be remembered that it would take a 500-microfarad capacitor, with a 100-volt tachometer, and a standard oscillograph, to record the acceleration of a motor starting in one second.

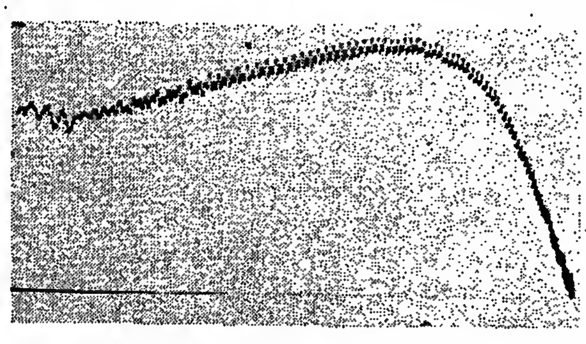

Figure 1

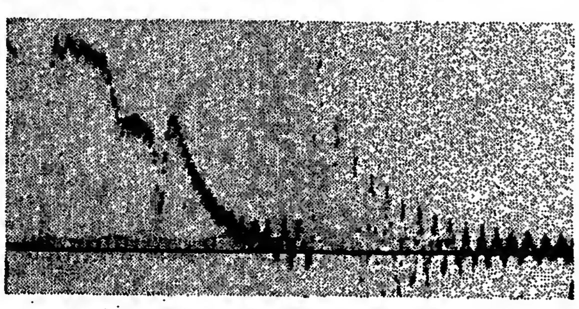

Figure 2

We believe the authors should furnish constructional features, the resistance and inductance, of the generator, the capacitance of the capacitor used, the sensitivity, resistance, and time constant of the oscillograph, if their generator is superior to Dannath's. In any case they should publish a sample Prony-brake retardation oscillogram to demonstrate that their system is free from undue ripples inherent in the tachometer generator. It is hoped that the discussion on this paper will bring out desirable specifications for an instrument or system of the type described.

L. A. Finzi (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The determination of speed-torque characteristics of motors from acceleration oscillograms seems to deserve broader application on test floors. When average torque values are being considered, the calculation of acceleration by graphical differentiation of speed-time records may be sufficient. But for instantaneous values a direct electrical differentiation method is desirable.

Many methods including the one suggested by the authors have been used for this purpose. The authors record the charging current from a d-c tachometer to a capacitor. Errors are caused by the resistance and losses of the circuit. A more serious objection is the voltage pulsations from the tachometer collectors, which are difficult to smooth out and sometimes cause misleading ripples in the oscillographic record of the capacitor current. Other methods use mutual inductances to give secondary voltages proportional to the variations of the voltage applied to the primary.

Very good records may be obtained by applying the tachometer voltage to a D'Arsonval galvanometer, which has a second coil wound on the moving frame. The voltage induced in this second coil is recorded with the oscillograph. If α is the deflection produced in the galvanometer by a given instantaneous value of tachometer voltage, the voltage induced in the second coil by its motion in the field will be proportional to $d\alpha/dt$ and hence to the acceleration of the motor shaft. The construction of such a galvanometer (originally developed by Heiles at Karlsruhe University around 1924) requires certain care, as the inertia of the moving parts must be

kept low, and quite a number of turns are required on the secondary coil. However, the adaptability of the instrument, when used according to the proper galvanometric technique, and the smoothness of the curves obtained make it very useful, especially when instantaneous peculiarities of torque curves are to be investigated.

Finally as a variation of the capacitor method, a small freely rotating d-c motor, with constant field and with the armature fed by the tachometer voltage, may be used. A change of speed of the tachometer causes a transient current which is again proportional to the acceleration or deceleration of the main motor shaft. In view of the comparatively large currents available in the measuring circuit, this method may be useful for such applications as acceleration governors. References 1 and 2 of this discussion may be of interest.

Victor Siegfried (Worcester Polytechnic Institute, Worcester, Mass.): The method proposed in this paper of using the acceleration speed characteristics to translate back into torque data is a very good and powerful one. Many things are being learned by it, but up to now the limitation has been in obtaining faithful speed indications. The authors are to be complimented on being able to produce usable records of speed through the means of their special tachometer generator. The use of such a generator will doubtless eliminate difficulties of other devices which introduce large losses of their own and thus mask the effects being sought. The direct acceleration record, through the charging current to a capacitor in parallel with this generator is especially interesting. The application of this generator to deceleration tests will extend the potentialities of that method to smaller machines. Another application which suggests itself is induction machine torque-speed tests, where torques that depart from conventional theory are only recently being recognized.

Of particular interest to this discusser are the torque curves obtained on small educational motor-generator sets, and their peculiarities discussed in appendix C of the paper. The peculiarities at about half speed which the authors found difficult to believe heretofore are altogether too common on small machines, and are particularly evidenced by the sounds which accompany this acceleration period. In the electrical engineering laboratory at Worcester Polytechnic Institute, most of the small sets exhibit some dips at half speed but usually pass by this point without difficulty. One machine, however, a 12.5-kva AHI synchronous motor, has shown particularly bad characteristics. At reduced voltage the machine would lock in at 58 per cent of synchronous speed and not accelerate further until thrown over to full voltage, even then being reluctant to pull up to full speed from that point. Incremental torque available for further acceleration was apparently zero at that speed.

Investigation of the factors giving rise to this extreme dip indicated that they relate to:

1. Applied voltage.
2. Resistance in the field circuit.
3. Temperature of windings.

The last factor only aggravated conditions on repeated tests, and so will not be discussed further. The circumstances of this machine were that it had recently been converted from use as an independent synchronous motor into a unit of a motor-generator set. The additional demands on its starting characteristics now made the problem acute where it had been only bothersome before.

Voltage taps were then changed from 65 per cent to 80 per cent of rated applied voltage with beneficial results but still with a long hesitation as it passed through the critical speed. Line-start procedure was then employed. These results indicated that voltage was not alone at fault, as the improvement was not in proportion to that expected from the voltage-square relation.

The field discharge resistor was 25 ohms originally. In desperation, it would sometimes be opened to permit the machine to accelerate. Obviously, this procedure was undesirable, but it proved the source of the trouble to be in the phase relationship between air-gap flux and rotor-circuit currents controlled by the short-circuited field. The resistance was changed successively to 50 and then to 75 ohms, the current at starting remaining substantially constant at six amperes. Improvements thus obtained indicated that the currents at standstill were being swung from nearly 90 degrees to nearer 45 degrees lagging with respect to the flux. The machine would thus accelerate easily through the dip point, which was raised to 60 per cent speed, and groans caused by torques were considerably reduced. The conclusion of this exploration would be that field circuits on synchronous motors should be not short-circuited but closed through the highest resistance that can be tolerated without endangering the insulation.

There is considerable similarity between synchronous-motor starting and induction-motor performance, and they are subject to similar methods of analysis. Torques are produced by components due both to fundamental frequency fluxes and to the harmonic fluxes which give rise to stray load loss. The resultant torques obtained by this complex pattern would seem to this discusser to permit resolving them into positive sequence (forward) torques due to the amortisseur winding and field circuit currents, and negative sequence (reverse) torques due to harmonics and other field circuit effects. Below half speed the positive torques predominate, being aided by field effects. At half speed, certain of the forward factors become reversed and aid the negative torques until, at some speed slightly above 50 per cent, the two opposing torques produce only enough resultant torque for the requirements of that critical speed, with none remaining for acceleration.

It is to be hoped that the "tools" developed and the interest aroused in this subject will lead to a clarification of the factors involved in a-c motor starting torques, as well as the many other studies which this acceleration-oscillogram technique will make possible.

R. M. Saunders (University of Minnesota, Minneapolis, Minn.): It would be interesting for the authors to point out the differences between their method of torque measurement and the acceleration method outlined in the "Proposed Test Code for Synchronous Machines" (1937), page 20, paragraphs 130 and 131.

In Figures 6 and 7 of the paper the authors show a disagreement of as high as 100 per cent in the torque measurements on the machine under test and suggest that these errors are due to heating of the armature and amortisseur windings. If this were true, the resistance of the amortisseur winding would be approximately doubled, and the temperature rise associated with this doubling of the resistance would be in excess of 250 degrees centigrade. This seems to be out of line with the usual industrial practice in regard to limitation on the temperature rise of cage windings. The writer would like to ask the authors if some other errors, such as transient effects, could not have crept into the other torque measurements.

In using the authors' form of the acceleration method, the accuracy depends upon two factors: the WR^2 and the readings of tan θ. In regard to the former, variations in the casting of spiders often make the calculation of the WR^2 subject to variations of as much as ten per cent. Extremely accurate calculations may be made and the result should be within five per cent. In regard to the latter quantity, the values taken from an oscillogram are apt to be in error due to the small physical measurements, the width of the trace, and the actual calibration of the oscillograph. In the writer's opinion these could easily amount to a ten per cent variation in the final result, even if the observers were careful. With the Prony-brake method an experienced test floor man can duplicate his results within ten per cent. Hence, the Prony-brake method should be equally accurate and somewhat more direct, which seems to make it preferred on machines up to 500-horsepower.

C. R. Atkinson and E. G. Downie: Interest has been shown in the exact electrical characteristics of the d-c tachometer generator used in our acceleration torque tests. The machine has a resistance of 51.7 ohms, inductance of 0.512 henry, and generates 0.155 volt per rpm. When running at 1,700 rpm, generating 263 volts d-c, it was found to have principal ripple voltages of 0.25 volt at 56 cycles or double rotational frequency, and 2.3 volts at 680 cycles commutator frequency. A ten-microfarad capacitor reduces the commutator ripple voltage to 0.04 volt (invisible on the speed trace), yet does not affect the amplitude of generated frequencies below 40 cycles. To get a reasonably smooth trace of capacitor charging or acceleration current requires 100 microfarads across the tachometer generator output, in addition to the smaller capacitor in series with the galvanometer. Response is satisfactory then, only to frequencies of 20 cycles and less. Slightly higher frequencies are amplified by series resonance, and still higher are greatly reduced.

We have been interested in the average

torque curves of synchronous motors, and have found the speed curve with slope measurement simpler to take and satisfactory in results. All calculated points fall almost exactly on the curves as drawn in Figures 6 and 7 of the paper. Torque pulsations are averaged out of the speed curve before scaling. The over-all accuracy should be ten per cent or better. We question the possibility of equal accuracy or even the practicability of full-torque-curve Prony-brake tests on motors up to 500 horsepower, as suggested by one discusser.

The oscillogram of Figure 5 of the paper was taken with 12 microfarads in series with the acceleration galvanometer, and a 100-microfarad filter capacitor. Resonance in the tachometer-capacitor circuit is calculated at 21 cycles, with maximum capacitor ripple voltage rise of 31 per cent over the generator voltage. The oscillation frequency of the acceleration trace, at its maximum amplitude, agrees with the synchronous-motor pole slip frequency, and also with the double rotational ripple frequency of the tachometer. This agreement, with proximity to circuit resonance does leave the amplitude of the acceleration oscillation questionable. We have noted with interest the methods of acceleration indication described by discussers and intend to investigate their possibilities.

We are pleased to note the agreement of discussers with our findings of the synchronous-motor torque dip at 60 per cent speed. Mr. Ager's explanation of the increased torque pulsations in Figure 2 of the paper, over those in Figure 3, appears very plausible. The homopolar generator used by Dannath and Redfearn is doubtless the most ripple-free yet devised, but the required d-c amplifier considerably complicates the system. Absolute linear response of the amplifier must be assured, or any deviation known and corrected for.

Design of Long-Scale Indicating Instruments

Discussion and author's closure of paper 42-70 by A. J. Corson, R. M. Rowell, and S. C. Hoare, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, June section, pages 318–27.

M. S. Wilson (General Electric Company, Schenectady, N. Y.): The development of the complete line of long-scale instruments represents an outstanding accomplishment in the measurement art.

The goal the instrument designer is continually striving for is to obtain the maximum accuracy in the smallest size instrument, having a readability which is suitable for the application.

The table below shows a comparison of the General Electric long-scale instrument with the conventional instruments, on the basis of area versus scale length. This shows a nearly two to one gain in scale length for the same size instrument, and a scale length nearly 50 per cent longer than the six-inch-size instrument requiring more than twice the switchboard area.

It is interesting to note that full advantage was taken of the newly developed materials in each of the different types of elements. It would have been very difficult to have developed instruments of this type having satisfactory characteristics without

Table I

Type	Switchboard Area Required by Instrument (Square Inches)	Scale Length (Inches)
General Electric long-scale types *AB*-10 and *DB*-10	18.1	6.8
Typical 6-inch rectangular-size instrument	44.5	5.1
Typical 4-inch rectangular-size instrument	18	3.5

the use of these materials. One important point in the use of magnetic materials in the field circuits of instruments is that the mechanical structure be designed so that it is mechanically stable, and where air gaps are necessary, they be sufficiently large so that minute shifts in the structure will not adversely affect the operation or accuracy of the instrument. The writer is familiar with the designs described by the authors and considers this detail to be well taken care of.

It is particularly noteworthy that no sacrifices in the instrument characteristics were made in order to obtain the long-scale feature, in fact, in two important respects, (*a*) in torque to weight ratio, and (*b*) shielding, the figures are better than usually found in switchboard instruments. In only one instrument, the temperature indicator, is the torque to weight ratio less than one. In this instrument it is 0.92 as compared to 0.5 which is frequently found in this class of instrument.

With the higher currents in conductors near the switchboard, the shielding of an instrument becomes of greater importance to the user. In the instruments described by the authors the errors shown in the Table 2 under "Stray Field Influence" do not exceed one-half the permissible error given in American Standards Association Standards, and for the majority of the instruments, it is appreciably below one-half the value given by ASA.

The other characteristics such as response, temperature coefficient, overload performance, and so on, are likewise such as to entirely meet the requirements of the various applications, where a universal instrument of this type may be used.

One further point which is of considerable importance to the user, but which is not covered in any existing specifications, is the stability of the mechanical structure of the instrument element. This is very important since it determines whether or not the instrument will operate satisfactorily maintaining its calibration over long periods of time. To do this the clearances between moving and fixed parts must be correctly and permanently maintained.

This means that the element must not only be so designed that it is structurally stable but the different materials must be carefully selected from the standpoint of temperature coefficient of expansion and aging characteristics so that they will not adversely affect the operation of the instrument even when subjected to severe operating conditions.

Paul MacGahan (Westinghouse Electric and Manufacturing Company, East Orange, N. J.): The paper by Messrs. Corson, Rowell, and Hoare is of special interest as another example of the fact that progress often proceeds in spirals—advancing bit by bit, after turning and returning to almost the same point.

Thus, the writer in his paper presented in June 1912, at the annual convention described a complete and harmonious line of long-scale a-c instruments.[1] A reference to this paper might with advantage be added to the bibliography given in the present paper for the sake of the record and to indicate the progress of the art.

In the discussion of the 1912 paper, Mr. F. P. Cox of the General Electric Company stated as follows: "The long scale which is inherent in the type is a desirable feature, but we must not neglect to take into account that what we want to know is the current in the circuit, that if you can read an instrument beyond its limits of accuracy, or if you have an instrument which has an error greater than its reading capacity, you equally get into trouble. What you want is an instrument which will give you, so far as you can read it, the combination of being readable and possessing an accuracy which will give the closest approximation. . . ."

Mr. Cox was right in 1912 in pointing out that a scale length which gives a readability greater than justified by the accuracy of the movement is unwarranted. In my closure I stated that the long scales were an advantage because instruments had to be read from a distance. But, as time went on, the old-fashioned switchboard gave way to the compact control disk type with instrument panels which brought the instruments close to the operator. For this reason as well as for economic and application reasons, the long-scale induction instruments of 1912 were by 1920 superseded by more modern types having scale lengths well calculated to be normal with respect to the accuracy of the measuring element.

A little analysis of the problem of scale-length factor in over-all accuracy bears upon the fact that with the highest grade of construction a certain amount of side shake in the bearings is inevitable because of the end-play requirements in the ordinary horizontal-shaft instruments. This could be and sometimes is reduced in vertical-shaft portable instruments by reverse-pivoting, with the top pivot supporting the weight. But such structures are obviously impractical in switchboard types, if we except the older forms of horizontal edgewise instruments.

The end play and consequently the side play has approximately the same value in all ordinary sizes of practical instruments. This side play is generally of the order of 0.010 inch and allows this amount of uncertainty in the pointer position. The result may be approximately expressed as amounting to an error equal to $1/L$, where L is the scale length in inches.

This then is that portion of the total error in a well-designed instrument which can be reduced by increasing the scale length.

Compared to the usual and most common

form of rectangular switchboard instruments which are about $5^1/_2$ inches square with scales five inches long, the authors have increased the length of scale to 6.8 inches, by using the circular dial construction instead of the flatter 100-degree dial design. To do this has required the development of entirely new measuring elements, a job, the magnitude of which, is not generally appreciated by the user.

A one per cent accuracy rating amounts to over $^1/_{16}$ inch on a 6.8 inch scale. Switchboard instruments having the usual one per cent accuracy rating are also produced with scale lengths of $3^1/_2$ inches in rectangular cases of the size described by the authors. As one per cent of such scale lengths is about $^1/_{32}$ inch they are quite adequate for the rather less frequent applications for which a four-inch switchboard instrument is preferred to the $5^1/_2$-inch type, and where readings within one per cent may be taken with the instrument not over three or four feet from the observer.

REFERENCE

1. INDUCTION-TYPE INDICATING INSTRUMENTS, Paul MacGahan. AIEE TRANSACTIONS, volume 31, 1912, pages 1565–77; discussion 1599–1608.

A. J. Corson: Mr. MacGahan has directed attention to his early interest in long-scale indicating instruments, and specific reference is made to his paper "Induction-Type Indicating Instruments" presented in 1912. In our examination of prior art, this reference was overlooked, but it will be promptly added as he suggests.

The remainder of his discussion originates the interesting question—how shall a development of this character be evaluated? Firstly, the design methods and mechanisms disclosed in the paper are perfectly general in character, and their application to instruments of a $4^1/_4$-inch rectangular dimension is, in a sense, incidental. Opinions as to the importance of this particular size of instrument may differ. We believe it to be of considerable moment as a contribution to more compact switchgear and better instrument grouping on panels. From the designer's point of view, however, the essential point is the extension of the scale length from 90 to 240 angular degrees, resulting in an approximate two to one gain in terms of linear measure, in any instrument of given size.

The question then resolves itself into a determination of the added value of this long scale. Firstly, both general considerations and test results show that long scales are observed more accurately than short ones. This gain in visual accuracy occurs twice, once in calibration and once in the observer's reading. Secondly, errors due to side motion of the moving system are reduced, as has been pointed out. In addition, the moving system is balanced with greater precision in terms of scale length. These and similar considerations have led to the almost universal adoption of long angular scales in such nonelectrical instruments as temperature indicators, mechanical tachometers, pressure indicators, and liquid-level gauges. While the application of long-range indication to electrical measuring instruments is admittedly more difficult, this would hardly appear to constitute valid grounds for attacking the desirability of the long scale as such, particularly when it is demonstrated that the design problems can be adequately solved.

The foregoing discussion assumes long-range indication to be obtainable without loss in factors which determine accuracy. An examination of the performance data shows this assumption to be generally true. Mr. Wilson's discussion is directed principally to these performance characteristics and brings out interesting points relative to torque to weight ratios, shielding, and damping. The various instruments have been designed to meet, and do meet, existing standards of performance, an accomplishment which was made possible by adhering to the fundamental types of mechanisms for which these standards were established.

The Fundamentals of Industrial Distribution Systems

Discussion and author's closure of paper 42-21 by D. L. Beeman and R. H. Kaufmann, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, May section, pages 272–9.

H. G. Barnett (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): As a part of the discussion of the basic factors involved in distributing power in an industrial plant, Mr. Beeman and Mr. Kaufmann have made a very interesting cost analysis of a particular industrial plant. This analysis is specially interesting to me because of a large number of similar studies which I have helped to make both before and after Mr. Powel and I proposed the industrial-plant network idea before the Institute at the last winter convention (AIEE TRANSACTIONS, volume 60, 1941, April section, pages 154–6).

These studies covered a wide variety of plants. The load densities ranged from about 5 to 25 volt-amperes per square foot. All commonly used utilization voltages (120/208, 220, and 440 volts) were involved. Total loads ranged from 1,000 to 10,000 kva.

The results of these studies do not justify the conclusion that any one type of system can be expected to adequately meet the requirements in a large percentage of cases, although the authors have claimed that as the purpose of their analysis of a particular case. The wide variations, among actual plants, of voltage and arrangement of the incoming supply circuits, plant layout, utilization voltage, type of loads, and other factors make it impossible to use any one system in more than a minority of cases.

These studies do not confirm the wide difference of cost between the secondary network and the secondary selective and simple radial systems that is shown by Mr. Beeman and Mr. Kaufmann. Therefore, we have made a study of the plant described in the paper using the same loads, voltages, and requirements set forth in the paper. Cost estimates were based on using drawout circuit breakers in the 440-volt switchgear units. The relative costs shown by this analysis are shown in Table A along with the corresponding costs found by Mr. Beeman and Mr. Kaufmann. We have been able to check the authors very closely in the case of the secondary-selective system when the simple radial system is assumed to cost 100 per cent. However, our analysis shows a cost of 168 per cent for the secondary network system used by Mr. Beeman and Mr. Kaufmann which, according to their analysis, costs 175 to 200 per cent of the cost of the simple radial system. By using four transformer and switchgear units instead of six and using the same type of equipment used in the six unit network, the cost of the network is reduced to 156 per cent instead of 168 per cent of the cost of the simple radial system. By making use of cascading, which is sometimes advocated, the cost is further reduced to 150 per cent.

If it is assumed that the plant studied by the authors, because of reliability, flexibility, or other factors, requires a better system than the simple radial, the network becomes economically comparable to the other systems that can be used. For example, if the cost of the secondary-selective

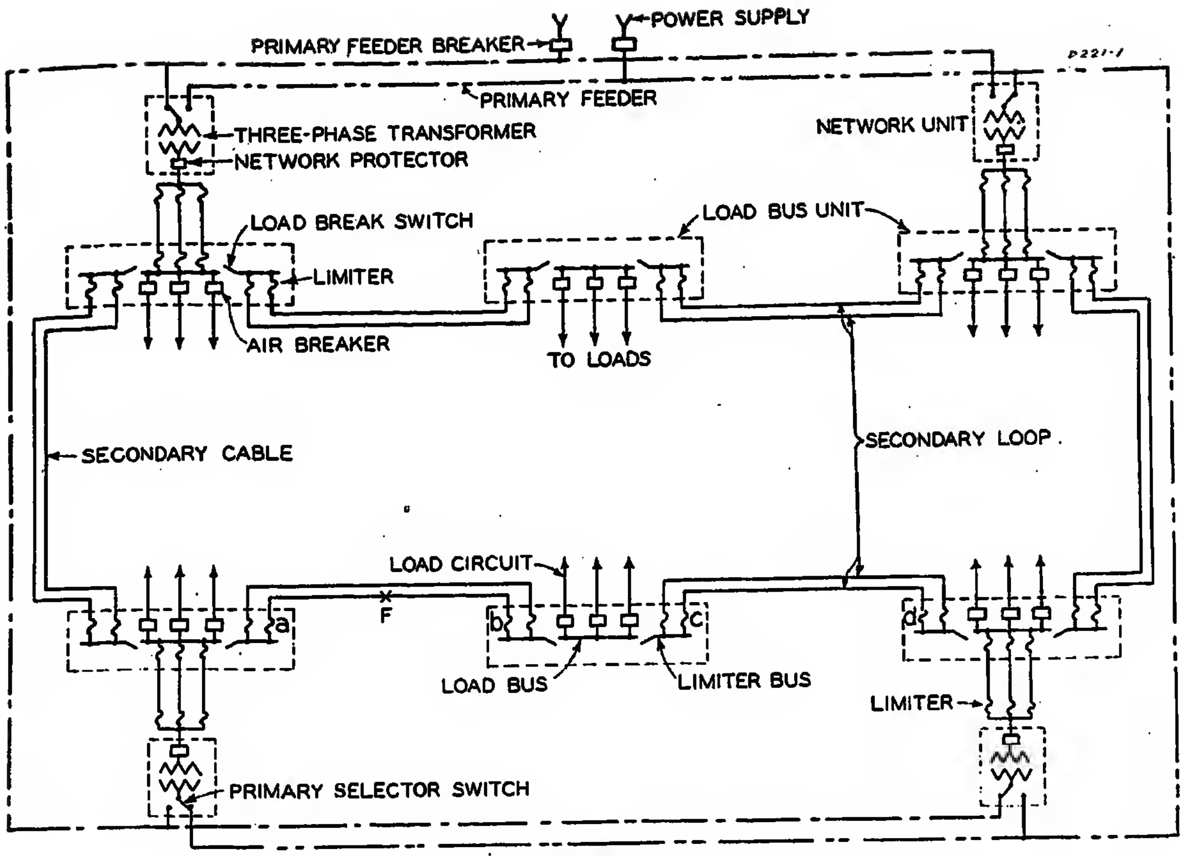

Figure 1

system is taken as the basis of comparison, the cost of the secondary network system ranges from 105 to 118 per cent as shown in Table *A*. The cost of 118 per cent is for the network system used by the authors for their comparisons. Ten other arrangements of the network system using limiters, primary selector switches, cascading, as well as full interrupting capacity breakers in various combinations, prove to be less expensive than the network chosen by the authors. The difference in cost between a network and the secondary-selective system is so small that the two can be compared, for practical purposes, on the basis of their respective operating characteristics.

All the comparative costs shown in Table *A* are based on using drawout breakers in the switchgear assemblies. If fixed breakers are used, the total cost is reduced in all cases but the relative costs are essentially the same as shown by the per cent figures shown in Table *A*.

The authors of the paper have expressed some doubt as to the limiter being a first-rate protective device. A thorough understanding of the characteristics of the limiter and its application should remove this doubt. The secondary loop in the industrial-plant network system is, in effect, a distributed bus extending throughout the load area. This extension of the bus and the consequent increase of the probability of faults on this bus make it necessary to provide means for isolating a faulted section of the loop. The device to do this should be as simple and reliable as possible, because it probably will operate only very infrequently, possibly once every several years.

Since the loop protective equipment is likely to operate very infrequently, maintenance and inspection are apt to be neglected. Lack of maintenance is no hazard to the operation of the limiter. Since the protective device operates only for a fault in the loop circuit, replacing a blown limiter does not materially increase the time required to restore the faulted circuit to operation, because the damaged conductors must be repaired at the same time. Immediate reclosure of the circuit is not even desirable. Therefore, the limiter presents no disadvantage and is actually somewhat more reliable than a breaker. The reason for using limiters in the loop is not a matter of cost but a question of basic system operation.

The correct operation of the loop protective devices depends on the use of parallel conductors in the loop as shown in Figure 1. When parallel circuits are used, a fault such as at *F* in Figure 1 causes only the limiters *a* and *b* to blow. If a single conductor per phase were used, limiters *c* or *d* or both would blow instead of *b* with the result that service from one load bus would be interrupted. If a load bus is established only at transformer locations, the load interruption would be less likely to happen. However, if a transformer should be disconnected from the loop for some reason, the same undesirable situation would exist as described in connection with Figure 1.

Three points will summarize this discussion.

1. **Experience shows that no one system can be expected to adequately meet all the requirements in more than a small part of actual cases.**

2. **Whenever reliability, flexibility, or other operating factors require a better system than a simple radial scheme, the network frequently will be comparable in cost to other systems that can be used.**

3. **Limiters in the secondary loop have a basic operating advantage over the use of breakers; reduction of cost is not the fundamental reason for using limiters.**

John S. Parsons (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors state that their purpose in writing this paper is to obtain the adoption of one system of distribution for industrial plants. Because of the large number of types of industrial plants and the many requirements and conditions peculiar to the various types, the use of any one type of distribution system in all of them is fundamentally unsound and impractical. We might just as well say that one type of distribution system should be used in the commercial areas and the residential areas of all cities and towns, and in all rural areas. As a result of the large amount of work we have done in connection with distributing power in industrial plants, one general conclusion can be definitely drawn. There is no one type of distribution system which should be used in all plants.

Also, as a result of our work on this subject, we have come to the conclusion that the simple radial is the cheapest system which can be used, and the secondary network is the best system, but it is by no means universally applicable. During the last year we have made distribution studies for more than 60 specific plants. As a result of these studies we recommended the secondary network system for about 60 per cent of these plants and some form of radial system for the others. Network systems are now in operation or being installed in about 25 per cent of the plants studied.

A paper dealing with the fundamentals of industrial distribution systems should cover all of the major forms of systems which are in use. The authors, however, in a fundamental paper on the subject have completely ignored the primary-selective network and spot network systems. These two forms of the secondary network system have been used more extensively in industrial plants than has the simple network system covered in the paper. The primary-selective and spot network systems offer practically all of the advantages of the simple network system, and usually at lower cost.

In comparing those forms of distribution systems covered by the paper, the authors place much emphasis on initial installed cost. We have found that for those plants where the simple radial system does not provide sufficiently reliable service, and there are very many such plants, we are in almost all cases talking about an initial cost difference of from 5 to 20 per cent between those systems which might satisfactorily be used. The cost of a plant distribution system will generally represent 10 per cent or less of the total investment in the plant. We are, therefore, talking about a difference in plant investment of approximately 0.5 to 2 per cent. Initial installed cost certainly should be considered when comparing plant distribution systems; however, it should not be over emphasized.

There are many factors which have a bearing on the installed cost of a distribution system. One such important factor is the matter of diversity. Yet diversity has not been discussed in this fundamental paper. When compared with a plant where no diversity between load centers is assumed, that is, a diversity factor of one is assumed, a plant having an appreciable diversity between load centers, such as a shipbuilding plant for example, will result in a higher installed cost for the radial systems and spot network and a lower installed cost for the simple network and primary-selective network systems. Even in those plants where the diversity is small or unknown at the time the distribution system is designed and is not considered in the design of the system, diversity will be reflected in better regulation and lower losses plus ability to carry more load if a simple or primary-selective network system is used. We have found that diversity and other factors peculiar to specific plants may cause the relative costs given in the paper to vary to the point where

a secondary network system is less costly than the secondary-selective radial system.

When considering the cost of different forms of distribution systems, initial installed cost is not the whole story. The cost of meeting growing and changing load conditions over a period of years should be considered. This is of particular importance today, because the plants being built and revamped to turn out defense material will, when the war is over, require considerable modification to fit them for peacetime production. The flexibility of the simple and primary-selective network systems enables them to meet growing and changing load conditions at considerable less cost than do the radial systems and particularly the secondary-selective radial system.

The operating and maintenance difficulties with the secondary network system as discussed in the paper are, in our opinion, greatly exaggerated. This opinion is based on experience with network systems both in industrial plants and in a large number of small cities throughout the country. The great majority of operators we have talked to would rather operate a network system than a radial system. It certainly does not require a crew of supermen to operate and maintain a network system.

Our years of experience with all forms of distribution systems have taught us the danger of drawing general conclusions from one or even a number of distribution studies. Any industrial plant of appreciable size should be specifically studied and the form of distribution system which best meets its individual requirements should be used, whether it be network or radial or a combination of the two. The decision as to the proper system to use should not be made on the basis of generalizations based on the study of one or several specific plants, unless they are practically duplicates of the one under consideration.

Charles P. West (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors have analyzed all the commonly used distribution systems for low-voltage power in industrial plants. Comparisons are made on the basis of cost, performance, reliability, and other factors. They recommend the secondary-selective circuit arrangement (Figure 7 in their paper) above all others and summarize their findings under five headings. The following comments are offered on their conclusions.

1. Installed costs are compared on the basis of the secondary-selective system being 150 per cent of the simple radial system base and the network system 200 per cent. Cascaded breakers are used to justify 25,000-ampere interrupting-capacity breakers for the former while 50,000-ampere breakers are specified for the latter. Cascading also can often be used here to reduce the size of the breakers. The network system is also subject to modification in a similar manner to that discussed for the secondary selective system, if parts of the areas supplied can sacrifice power for short intervals. This would tend to equalize the cost of the two systems.

2. The network system circuits shown by the authors do not show loop load-break isolating switches. These should be recommended, and when used, the loop circuits can be isolated for maintenance. A network system with these switches is as safe as the selective arrangement which is advocated, because there is no more necessity for working on live apparatus. In all cases it should be assumed that first-grade equipment will be applied, not "second-rate."

3. The authors concede "the highest order of service reliability" to the network system. It surpassed their recommended system in this respect. The fundamental network arrangement in the power supply and tie circuits unquestionably permits clearing faults with less disturbance to the continuous operation of a plant than any other system.

4. A network system engineered so that current distributes properly is no more difficult to operate than a selective circuit arrangement. This problem exists in any electrical network, and no difficulties have been experienced in the systems which are operating.

5. Voltage regulation is conceded to be good in both systems.

On the whole, the network system has the advantage in the important third point, reliability, and does not suffer by comparison in the others.

H. L. Rawlins and **P. O. Langguth** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. The authors have presented an interesting analysis of industrial distribution systems wherein four types of distributed load-center arrangements are described. As a result of this comparison, they have recommended a secondary-selective scheme of distribution.

2. To clarify this situation, we are adding a form of distributed load-center system, which consists of the secondary network with limiters. This arrangement will have costs comparable to the secondary-selective circuit arrangement with a service reliability rating of *A*. Safety requirements are completely fulfilled by the use of a knife switch or load-break switch between the cable limiters and the load bus. The particular section of faulted cable and limiters can be serviced dead with no interruption of service by simply opening the switch at each end of the involved cable section. Similar results can also be obtained by the use of disconnecting-type limiters.

3. The necessity for an indicator on limiters has not yet become apparent. There are several convenient means of determining if an open circuit exists in a cable run. Occasional check with a clip-on ammeter has been employed satisfactorily on network systems. No problem, however, is presented if an indicator should be required, because suitable indicators in various forms have been available over a period of years.

4. We note that Messrs. Beeman and Kaufmann describe the limiter as "second-rate apparatus." We might mention that a fusible element which functions directly by heat generated within itself is recognized as the most reliable of all over-current devices. This principle is fundamental and has been used over a long period of years in various forms with complete success.

5. There is a new development in this picture which has not yet been disclosed to the Institute. It consists of a new high-current interrupting device which simplifies the use of a network distribution system. This is a noteworthy development and places an entirely different complexion on the situation.

6. Briefly, this limiter is totally enclosed to prevent external demonstration of the device when clearing a fault. It has repeatedly interrupted currents in excess of 50,000 amperes at 600 volts with no perceptible noise or visible demonstration. A typical oscillogram is illustrated here of an interruption of 52,000 amperes with a restored voltage of 614 volts. The extremely short arcing time should be noted. Numerous tests in the high-power laboratory over a large range of currents have demonstrated the dependability of this limiter both in respect to time-current characteristics and its ability to interrupt any current within its rating.

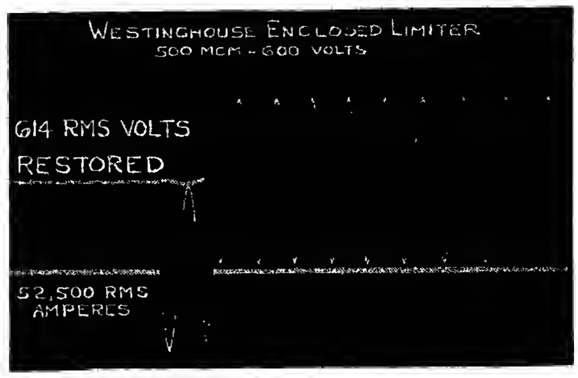

Figure 2

7. The authors of this paper have stated by implication that the secondary network systems utilizing limiters lack reliability and are unsafe. We who have worked with this new form of 600-volt totally enclosed limiter, and who have seen it work repeatedly under exhaustive tests, are confident that the secondary network system utilizing such devices will normally be favored in industrial distribution systems.

E. M. Hunter and **J. C. Page** (General Electric Company, Schenectady, N. Y.): In laying out low-voltage a-c systems, frequently the two most difficult points to be settled are:

1. The basic type of system.
2. The general class of equipment to be used in the step-down substations.

Once these two important general points have been decided upon, the remaining details can usually be worked out easily. It is with respect to these two items that this paper by Messrs. Beeman and Kaufmann should prove valuable to persons engaged in laying out low-voltage a-c systems for industrial plants.

It is interesting to note that a system cannot be judged fairly unless both the basic circuit arrangement and the general class of equipment used in the circuit are judged simultaneously. For example, a low-voltage network, with open-type bus work or wiring, circuit breakers of inadequate interrupting rating, or fused knife switches, is probably considerably less reliable than a simple radial system incorporating properly insulated wiring, metal-enclosed load-center unit substations, and with circuit breakers of adequate interrupting rating.

Attention is called to Table I of the paper. The simple radial system in the tabulation is given a triple-*A* rating, and is marked down only on "service reliability." It will be of interest to see how this service reliability rating can be improved. The basic principle of load-center distribution is to divide the entire factory load area into small areas, each with its own substation. In some of the defense plants that have been installed, as many as 30 load-center unit substations have been used. Each of these units have been made alike in kilovolt-ampere rating, and so on, so that one spare load-center unit kept in the store room provides the means of restoring service to any

area and without additional investment in spare capacity in each of the units. Sometimes these spare units are made portable. From this it is apparent that the simple radial type of system need not be condemned too severely for poor service reliability if the proper precautions are taken.

The network type of system is the highest in cost and has an *A* rating which is the highest in service reliability. It is the opinion of the discussers that the network type of system can be justified only when the ultimate in service reliability is required. The high cost of a network results, at least in part, in the fact that the secondary circuit breakers must have higher interrupting capacities than those used on the other three types of systems. Cost reductions obtained by the use of devices of inadequate interrupting capacities on the secondary of the network have been proposed in some applications. These methods, of course, lower the service reliability rating of the network, and it appears that they have no place in the network system.

A. E. Anderson (General Electric Company, Philadelphia, Pa.): The items of safety to operating personnel and continuity of service have been referred to in the paper. These, with other factors, are of considerable importance, particularly under present conditions, when such great importance is being placed on the nation's manufacturing facilities.

The use of circuit breakers in the high-voltage sides of the transformers in place of disconnecting switches as shown in the various schemes, Figures 2, 4, 5, 7, and 8 of the paper, would make possible a safer switching scheme and one more desirable from an operating standpoint. Along with protective relays it would provide additional protective and operating advantages.

At one time the value of short-circuit current obtainable from a low-voltage a-c system was generally considered as limited, regardless of system capacity. Fairly recent investigations have shown that these currents can be readily calculated, and that the calculated and measured values agree within usual engineering tolerances. Thus, the procedure has changed from something rather vague and mysterious to something that is rational, straightforward, and easy to apply.

The authors have recognized the latter procedure and have provided air circuit breakers of adequate interrupting rating for the various low-voltage circuits. It is further recognized that heavy short-circuit currents are to be expected if the voltage regulation is to be held to low values. While the above consideration points to circuit breakers of higher interrupting rating, there are two major factors that tend to counteract this tendency, without a sacrifice of other desirable operating features. One is the smaller distributed load center, with its saving in I^2R losses and flexibility, as compared with a single large substation. The second factor is the use of circuit breakers in cascade, which permits the use of a breaker, of interrupting rating less than that corresponding to the current obtainable at the particular location, provided it is backed up by a properly co-ordinated breaker, whose interrupting rating is equal to or greater than the available short-circuit current. No longer is it necessary to make a haphazard selection of circuit breakers for these low-voltage systems, with the possibility of running considerable risk of damage to the breaker and associated equipment, in the event of a short circuit near the outgoing terminals of the circuit breaker. It is quite important that breakers of adequate interrupting capacity be used. This means feeder breakers capable of interrupting the maximum short-circuit currents of the circuits in which they are connected, or feeder breakers of somewhat less interrupting rating in cascade with backup breakers of full interrupting rating.

The authors have included a number of pertinent items relating to the use of limiters, or limiters and isolating switches. In many applications the introduction of limiters will raise the short-circuit requirements of the feeder breakers, since they do not permit the cascade connection to be employed. In other words, the time of operation of the limiters with which the discusser is familiar is so great in relation to that of the modern feeder breaker, that it cannot give the desired degree of backup protection. Accordingly, the interrupting rating of the feeder breakers must be increased from some smaller value, permitted by the cascade connection, to a rating at least equal to the available short-circuit current. Consequently the introduction of limiters will, for most applications, increase the size and cost of the feeder breakers.

W. J. McLachlan (General Electric Company, Schenectady, N. Y.): The one most important conclusion drawn from the Beeman-Kaufmann paper is that, while some form of load-center distribution system usually will be found superior for plant supply, no one form of system is universally applicable. The best form for a given case depends principally on *cost* versus the value of *service continuity*, and the selection of the best form requires a rational evaluation of these items. It is to be hoped that the availability of this paper will encourage such rational evaluations, evidence of which has been lacking in an unfortunately large number of cases in the immediate past.

In evaluating the relative *costs*, it is obviously desirable that the forms of systems be costed on a comparable basis. The one item of greatest discrepancy in past comparisons has been the selection of low-voltage breaker interrupting capacities. Systems of one type, with breakers selected with interrupting capacities at least equal to calculated short-circuit currents, have been compared with another with the interrupting capacities grossly below calculated short-circuit values. Investigations, which have shown that calculated currents can be obtained in low-voltage circuits, point to the desirability of selecting interrupting capacities which are not below calculated values. However, if one elects to take the risk of applying lower rated breakers in one system, all logic requires that the same degree of risk be accepted in selecting the breakers for all forms of systems, if the cost comparison is to be equitable and fair.

When evaluating *service continuity*, it is essential that the over-all continuity of the system be considered. The form of load-center system selected can affect only part of the possible service outages. The total power outages result from failures in the following portions of the system:

1. Transmission supply to the plant.
2. Plant-supply stepdown substation.
3. Plant-distribution primary feeders.
4. Load-center unit transformers.
5. Low-voltage feeders from load-center units to individual load areas.
6. Laterals to individual loads and individual load and control equipment.

In general, only those outages due to failures in the plant-distribution primary feeders and load-center unit transformers are influenced by the form of load-center system selected. If the majority of the outages are expected to be due to failures in the other parts of the system, the total outages can be influenced by but a small degree by the form selected and differences in reliability of the types of systems described are of proportionately small significance. As an example, several applications of the more expensive secondary-network system have come to attention in plants supplied by only one long high-voltage transmission circuit. In such cases, the probability of failures of the entire plant supply is several times that of failures in the plant-distribution primary feeders, making it appear that little effective benefit will be derived from the added cost and operating complication of the network system.

On the other hand, if the expected interruptions in the primary supply system are rare, which presupposes at least duplicate transmission sources, and probably dual supply substations, the service reliability of the distribution system takes on increased significance. Even then, it should be remembered that, regardless of the form of load-center system selected, the outages due to failures in the low-voltage feeders and laterals and in the individual load and control equipment will be unaffected by the selection made.

These comments are made to encourage rational evaluation in the selection of the system to be employed in specific instances. It is believed that this desirable condition will be considerably enhanced by the availability of the comparative data in the Beeman-Kaufmann paper.

R. H. Kaufmann: It is indeed gratifying to note the interest which is displayed in the subject of industrial power distribution. It is indicative of an increasing consciousness of the importance of this phase of the industrial electrical problem which is the first step leading toward a more general recognition of the important part which the distribution system plays in the performance of electrified industry.

The debatable issues which have been raised in the several interesting and valuable discussions center largely on the selection of the particular form of load-center distribution to be used, and more specifically a consideration of the secondary-selective system versus the secondary network.

The secondary-selective system has a distinct advantage in respect to electrical simplicity and safety of operation. Each main low-voltage bus section has access to two independent power-supply channels which insures reliability of service. The secondary-selective system obviously will not be

used to the complete exclusion of all others. A very considerable number of present industrial systems are adopting the straight radial form. The primary-selective system will find application in some instances, particularly for load areas involving scattered independent buildings each requiring only a small amount of power which will hardly justify more than a single load-center unit. The secondary network system will likewise find fields of application, particularly for continuous process operations in which even a momentary loss of voltage would result in large consequential losses either in the form of damage to productive machinery or spoilage of large quantities of material.

Variation in System Form

It has been intimated that the form of secondary-network system illustrated in Figure 8 of the basic paper fails to realize as good an over-all economy as can be obtained with other variations.

Mr. Barnett, for instance, suggests the incorporation of the primary selective feature as illustrated in Figure 1 of his discussion. The fundamental difference lies in the use of two primary feeders instead of three and the addition of primary transfer switching equipment at each load-center unit. Relative to the straight radial system as in Table I of the basic paper, the primary selective-secondary network system shows a first cost level of 185 per cent as compared with 175 per cent for the system illustrated in Figure 8 with no improvement in other characteristics. In fact, some definite disadvantages must be accepted:

1. Both primary feeders must come in close proximity at each load center, which provides a number of vulnerable spots at which a disturbance could result in a complete power outage for the entire area.
2. Operating hazards as described in the primary-selective system would likewise be accepted.
3. This system depends for its merit on the prompt transfer of units to the healthy feeder following a feeder outage.
4. It is important that the primary-selective switches be alternately positioned under normal service conditions to avoid the connection of two or more adjacent stations to the same primary feeder. If this precaution is neglected, loss of power on that primary feeder would impose a very heavy transfer load in the tie circuit and in the next adjacent energized load-center unit.

The use of four rather than six substations, as suggested by Mr. Barnett, in either of these secondary network systems would fail to improve the over-all economy. The size of each station would be increased to 1,125 kva (6/4 of 750 kva) and short-circuit current levels on the low-voltage bus sections would exceed 50,000 amperes. A substantial increase in low-voltage switching-equipment cost would thus be incurred. The interconnecting low-voltage tie circuits would be of substantially the same total length but would require 50 per cent increased current-carrying capacity due to the greater load fed from one station.

The spot network represents a variation which closely resembles the secondary-selective system. It differs in that the spot network permanently parallels the two transformers on a common bus using network protectors in the low-voltage circuit from each transformer. The absence of interconnecting low-voltage tie circuits with remotely located stations (as in the secondary-selective system) considerably simplifies the problem for the operating department. The chief question to be considered in deciding between these two system forms is: Is there justification for the additional initial investment resulting from increased switching-equipment cost to obtain uninterrupted voltage in those few instances that power flow on one primary feeder is interrupted; or will service reliability requirements be adequately met by maintaining an alternate low-voltage power supply which can be tapped at a moment's notice merely by closing the low-voltage tie breaker between the complementary bus sections?

Cascade operation of low-voltage air circuit breakers in the secondary network system is regarded as contrary to the fundamental objective. The secondary network system distinguished itself by affording service continuity (uninterrupted service) as contrasted with service reliability (available service). A compromise in this respect would strip the secondary network of its chief advantage.

Diversity Factor

Mr. Parsons in his discussion stresses diversity factor as an important influence on over-all cost of the secondary network system. Although it may have significant influence, yet to be able to take advantage of diversity factor between load-center substations, it is important that, at the time of heavy load on one particular station, the immediately adjacent stations be operating at subnormal load. It is of little benefit to have lightly loaded stations on the opposite side of the loop as they will contribute only slight support to the remotely located, heavily loaded section. The installation of cross tie circuits to improve this situation will likely defeat its own purpose as a result of increased tie-circuit cost and switching-equipment interrupting capacity and cost. Furthermore, the small advantage obtained affects only the transformer capacity. Primary feeder circuits together with switching equipment, low-voltage feeders together with switching equipment, and interconnecting tie circuits together with switching equipment are not benefited. Inasmuch as the transformers account for approximately 10 to 15 per cent of the cost of the over-all system under investigation, based on unity diversity factor, it must certainly be concluded that no substantial reduction in system cost could be realized as a result of diversity factor.

Limiters

For all comparisons reported in the paper, standard air circuit breakers have been used in all low-voltage circuits, including feeders and tie circuits. The standard air circuit breaker constitutes a recognized power-switching device with ratings and performance thoroughly covered by industry standards. The application of standard air circuit breakers within the limits defined by ratings provides the advantages:

1. Ability to repeatedly switch the circuit at will with assured safety.
2. Ability to safely and positively interrupt the maximum fault current.
3. Ability to quickly restore service following an interruption.
4. Reliable indication of operation and position. (Remote indication of circuit-breaker position is easily possible.)
5. Availability of electrical operation.

Messrs. Barnett, Rawlins, and Langguth have commented on the possible application of limiters located in the tie circuit of the secondary network system, in combination with a suitable switching device to provide the necessary degree of circuit control. In the discussion by Messrs. Rawlins and Langguth, reference is made to the limiter as a new development not yet publicly disclosed. This, of course, implies that it is still in the developmental stage and that the ultimate stabilized product will likely incorporate any improvements that installation and use indicate are needed.

In addition to the ability to interrupt fault currents safely, positively, and consistently, there are a number of other considerations. Thermal overload protection of circuit runs within the building should be provided. The thermal effect from heat normally liberated in the fusible unit must be recognized and cared for. Provision should be made for dissipating the heat so generated without subjecting the terminal section of the cable or low-voltage bus to elevated temperatures. The use of tie-circuit switching equipment which duplicates that used in the balance of the structure would be desirable.

Operation

In respect to operating problems of the several typical system forms, there can be no question that the secondary network system is excelled by the other three forms. Beyond that, the ratings in Table I have been assigned no quantitative significance.

That the secondary network system permits growing loads to be met with greater ease and less cost is a controversial contention. In addition to installation of the new substation with associated high-voltage supply and low-voltage feeder circuits, the secondary network system involves incorporation of the new station in the existing tie-circuit system. Unless tie circuits are properly designed, short-circuit current levels on existing stations may be elevated. The primary feeder arrangement must be reviewed to insure that power supply to two or more adjacent stations will not be simultaneously interrupted as a result of a single primary feeder outage.

A New Voltage-Regulating Relay Plus Line-Drop Compensator

Discussion of paper 42-32 by H. J. Carlin, presented at the AIEE winter convention, New York, N. Y., January 26–30, 1942, and published in AIEE TRANSACTIONS, 1942, February section, pages 63–6.

H. L. Prescott (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): The new relay described in Mr. Carlin's paper has several features differing from previous voltage-regulating relays which affect

the application of the relay to a step voltage regulator and it may be well to look at it from an application viewpoint.

This relay has a damping characteristic of importance on many circuits on which there are, almost continuously, small voltage changes which are not large enough to close the voltage-regulating relay contacts. The conventional type of relay follows these changes as they occur. The relay described in this paper, due to its inherent time delay, damps out these continual changes and operates smoothly, following the mean voltage. Many circuits also are subject to relatively large momentary voltage changes due, for example, to switching surges. The conventional relay will also follow these changes while the new relay will to a large extent damp them out. This damping characteristic, therefore, reduces the mechanical duty on the relay, reduces wear on the bearings, and increases the length of life of the mechanical parts.

A second feature of importance in applying this relay is its integrating or cumulative characteristic. In general, the older types of voltage-regulating relays are used to operate a time delay relay and in order to cause an operation of the step regulator, the voltage applied to the voltage-regulating relay must hold the relays contacts closed for the full timing period of the time delay relay. With the new voltage-regulating relay, the relay response depends not upon the voltage remaining outside the range of the relay setting continuously for a definite time but upon the difference in the time it is outside the range from the time it is within the range. Therefore, if the voltage is outside the range more of the time than it is inside the range, this voltage-regulating relay will close its contacts and cause the regulator to operate to bring the mean voltage inside the relay settings. This relay will hold the voltage closer to the desired value than will the older types of voltage-regulating relays.

A third feature of the new voltage-regulating relay is its differential or inverse time characteristic. When conditions on the power system cause relatively large voltage changes, it is desirable to have the voltage regulators operate more quickly than when the voltage changes are small. Figure 1 of the paper shows that the greater the voltage variation from the neutral value from which the relay is set, the shorter will be the time until the contacts close. The new relay, then, instead of having a constant time delay regardless of the magnitude of the voltage change as is the case with separate voltage-regulating and time delay relays, has a shorter time delay when large voltage corrections are required than it has when the voltage variation from normal is small.

The characteristics just described result in reducing contact maintenance. Since momentary voltage variations do not cause the voltage regulating relay to close its contacts, this relay closes its contacts after the time delay period rather than before the time delay period, and, therefore, the contacts close only when an operation of the regulator is actually to be made. The number of contact operations, therefore, is reduced to equal the number of tap-changer operations, resulting in less burning of the contacts than on the older type voltage-regulating relays whose contacts closed to initiate operation of the time delay relay. This feature also eliminates the necessity for separate compounding coils.

The line-drop compensator which is built into the relay described in this paper is different in both construction and principle of operation from the line-drop compensators which have previously been built into voltage-regulating relays. In the older relays, the line-drop compensator operation was based only on the magnitude of the current. In the new relay, the compensator operation is based not only on the magnitude of the current, but also upon its power factor and the impedance angle of the line. The new device, therefore, gives a closer approximation to the theoretically correct value than the older type. It will, therefore, be applicable in some cases where in the past separate voltage-regulating relay and line-drop compensator were used.

Thermal Co-ordination of Motors, Control, and Their Branch Circuits on Power Supplies of 600 Volts and Less

B. W. JONES
ASSOCIATE AIEE

THE protection of a motor against an overload or the protection of a motor and its branch circuit against a short circuit are basically the same problem. The entire circuit is heated at a rate which is a function of the amount of current flowing, and this current must be interrupted before the winding or any part of the circuit exceeds a prescribed temperature. The means used to protect against these two magnitudes of power may be the same, or it may be entirely different as will be brought out later. It is the purpose of this article to show what the heating characteristics are of the motors, the control, and the branch circuit wiring, and what the characteristics of the protective devices should be in order that the power will be disconnected from the main feeders under all conditions of excess current before excess temperatures are attained.

The points which this article will discuss and some of the conclusions reached are:

1. That the short-time heating characteristic of three-phase induction motors stators can be shown in a simple graphical method when we know the current density in the stator windings at rated current. These data should then be used as the basis for determining the tripping characteristic of overload and short-circuit protective devices.

Paper 42-79, recommended by the AIEE committee on industrial power applications for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted February 16, 1942; made available for printing March 30, 1942.

B. W. JONES is consulting engineer, industrial control department, General Electric Company, Schenectady, N. Y.

2. If the cross section of the reduced section of a zinc fuse link is not greater than any part of the copper conductors nor greater than 45 per cent of any Nichrome conductor (the heaters of overload relays), then the fuse will give good short-circuit protection to the copper and to the Nichrome conductors.

3. Small horsepower starters, which are within the range of from 1 to 50 horsepower at 440 or 550 volts, or of 1 to 25 horsepower at 220 volts (classified as National Electrical Manufacturers' Association size 3 or smaller), require a short-circuit protective device that will interrupt the circuit during a heavy short circuit in less time than one-half cycle. Tests have shown that a suitable size nonrenewable cartridge-type fuse of good design is capable of doing this.

4. Because of this fast interrupting ability, this type of fuse is current-limiting (see Figures 6 and 7). Therefore, it gives two-way protection, in that it both limits the amount of current which reaches the starters, and it is exceptionally fast when the currents are high.

5. Because of the inductance in a d-c generator, its current will build up at a slower rate during a short circuit than will the current in an a-c circuit, and therefore a fuse will be more current-limiting on a d-c system when supplied from a d-c generator than on an a-c system. Unlike the a-c power, the peak voltage and the average voltage is the same on d-c systems. Because of these two factors it is easier for a fuse to interrupt a short circuit on a d-c system than on an a-c system of the same rated voltage since the entire interrupting period takes place in a fraction of a half cycle.

6. A NEMA size 3 starter (50 horsepower at 440 volts or 550 volts, three phase) or smaller can be fully protected against any major damage from short circuits on a system having available currents up to 100,000 amperes, provided a correct current and voltage nonrenewable cartridge-type fuse of good design is placed in each branch circuit line, and provided the fuses are positively held in their clips so as to prevent magnetic forces from throwing them out.

7. A circuit breaker provided with a fast instantaneous magnetic trip, as used on our tests, demonstrated its ability to protect NEMA size 4 and larger starters, when on a system having an available current equal to or less than the interrupting rating of the breaker.

8. The maximum size fuse that should be used is $3^1/_2$ times the current rating of the overload relay, or four times the current rating of the motor, and if this does not result into the same current, then the smaller of the two should be selected. See Figure 3.

Permissible Temperatures

Let us first decide what are excess temperatures. Much has been written on this subject,[1] but it is quite generally agreed that 90 to 100 degrees centigrade is a satisfactory temperature (approximately 50 degrees rise), where it is maintained for long intervals, but where the temperatures are transient and last for only a few seconds or minutes and occur infrequently, then this 50 degrees rise can be materially increased. For conditions like a stalled squirrel-cage induction motor which lasts for only a few seconds the 50 degrees rise can be doubled. A rise of 100 degrees is satisfactory for a stalled motor because it will seldom be called upon to withstand this condition and then for only a few seconds.

Current-Time Heating Characteristics

Let us now ascertain the heating characteristic of a three-phase squirrel-cage type of induction motor. When a representative type of induction motor is running at rated load, approximately one third of its total heat loss will be produced by the iron, and the remaining two thirds will be produced by the copper. But if the motor is stalled and taking five times rated current, then the iron loss will re-

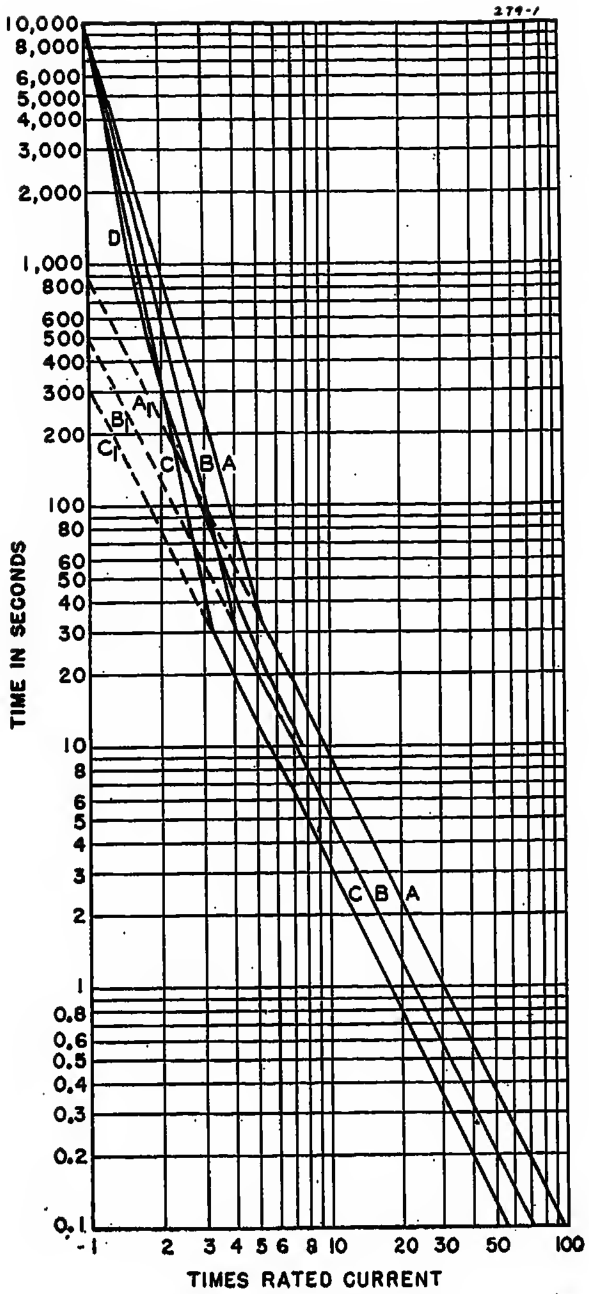

Figure 1. Heating characteristics of three-phase induction motors. Also tripping characteristics of a representative temperature overload relay

Curve *D*—Current-time tripping curve of a high-grade temperature overload relay

Because of heat conduction into the insulation and into the iron of the motor, and because of convection from the motor, the temperature rise for times of 30 seconds and longer will range between 50 degrees centigrade minimum and something under 100 degrees centigrade maximum

main the same, but the copper loss will be 25 times larger. Under either a running or a stalled condition, the copper will lead the iron in temperature, but in the stalled condition will be leading so far that we can assume the iron temperature

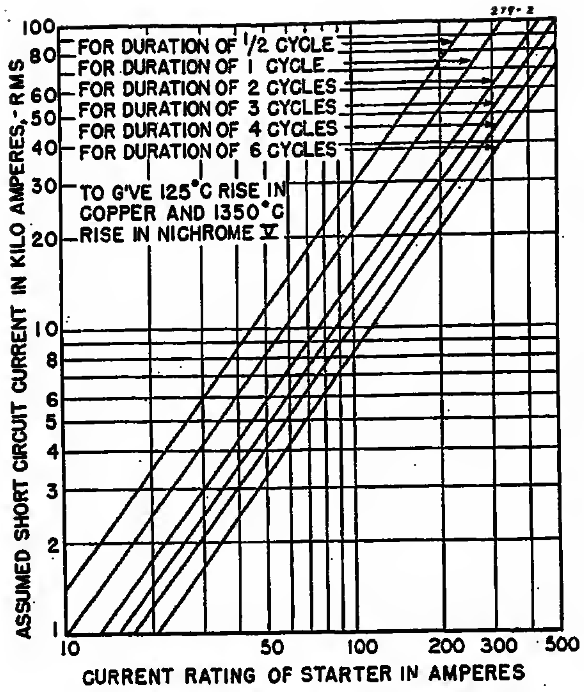

Figure 2. Required interrupting speeds fully to protect starters having heater-type overload relays against specified short-circuit currents

will be stationary in temperature, while the copper is going its limit. The length of time required for the copper to go its limit of 100 degrees centigrade rise will depend upon the current density in the copper. Let us assume that the current densities in the stator copper of the standard lines of three-phase induction motors fall within 3,000 to 5,000 amperes per square inch when carrying their rated currents, then curves *A*, *B*, and *C* of Figure 1 show the time required for these three copper densities to reach 100 degrees rise for any current from 1 to 100 times their ratings. This is based on the assumption that all the heat remains in the copper, and none is conducted out into the insulation or iron, or carried off by convection or by radiation. For short circuits where the considered time is one second or less, this assumption is sufficiently correct, but for stalled conditions of the motor, or for heavy running overloads where the no-loss time required to reach 100 degrees rise is 30 seconds or more, there will be sufficient loss from the copper due to heat transfer that recognition should be made. Referring to Figure 1, it will be noted that at the 30-second position of the *A*, *B*, and *C* curves they have changed their current-time rate in order that this heat transfer can be approximately indicated in a simple diagrammatic manner. At the 30-second position, where the two curves diverge, we know that if no heat had escaped from the copper, it would have a 100 degrees rise, but we know that some heat has escaped during this 30 seconds, so the temperature will be below the 100 degrees rise (perhaps 85 or 90 degrees rise or less). Likewise, at the 10,000-second position, where the motor is carrying its rated load, the heat transfer has reached an equilib-

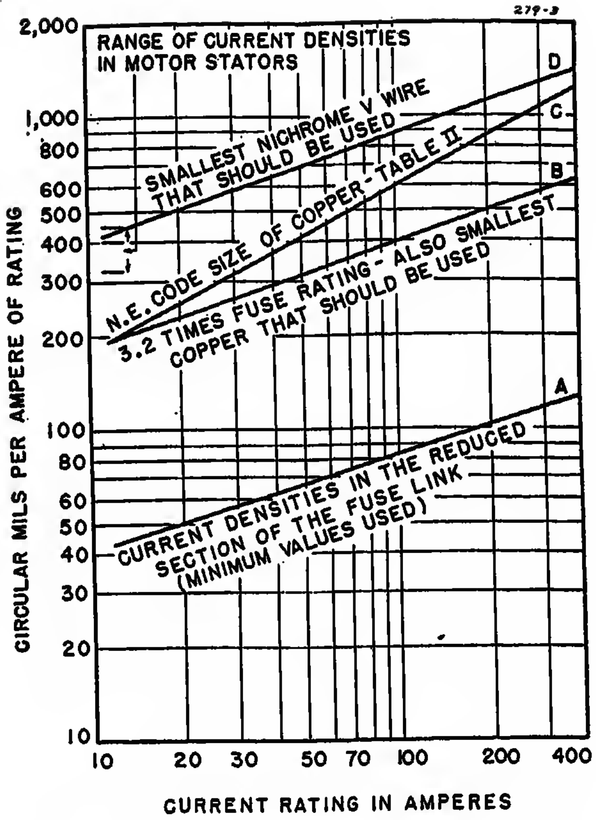

Figure 3. Current densities in copper and in Nichrome V wires, in stator windings of squirrel-cage three-phase induction motors, and in the restricted section of General Electric low-voltage cartridge-type fuses when carrying their respective rated currents

rium whereby the temperature rise on the copper is 50 degrees—the rated rise of the motor—therefore, along various positions of the *A*, *B*, and *C* curves between 30 and 10,000 seconds, the temperature rise gradually increases as the load increases, reaching something less than 100 degrees rise at a stalled condition.

Thus, by the use of log-log-paper a very simple graphical method can be used, wherein the well-known thermal capacity of copper and the assumed current density used in the motor design can be used as the basic factors in this graphical method. The resultant temperatures obtained in this simple manner will be sufficiently close for all practical purposes, and the temperatures will be on the conservative side. Therefore, the three straight lines in Figure 1 between 30 and 10,000 seconds, which are labeled *A*, *B*, and *C* can be used to closely represent the transient heating time-current characteristics of the stator of the three designs of motors which have the 3,000-, 4,000-, and 5,000-amperes per square inch densities in the copper when carrying their rated currents.

Required Temperature-Overload-Relay Characteristics

Thus, if these three time-current characteristic curves are used as the basis for designing three temperature overload relays such that the relay-tripping times never exceed those shown on these curves and yet keep fairly close to them, then these relays should be capable of protect-

ing the three designs of motors against all magnitudes of overloads and yet permit them to do their full quota of work. However, the heater type of temperature overload relay, which develops its source of heat in one element—its heater—and transfers this heat to the bimetal or temperature sensitive element, tends to slow down on the high-current end such that the relay-tripping characteristic curve would normally cross the motor-heating curve at the high-current end. This type of relay must, therefore, be sufficiently fast at the stalled current value—approximately six times current—to give the required protection, and then at the lower current values of overload it will overprotect the motor. But since this is the characteristic of the relay most commonly built for the smaller motors, it follows that if this design is so made that it is correct for the stalled condition of the motor, it will be somewhat faster than necessary for all the lower degrees of overloads. This degree of overprotection is not generally sufficient to interfere with the motor's doing its required work.

The total thermal capacity of a motor is a function of its copper, its insulation, and its iron, but under a stalled condition the *effective* thermal capacity of this same motor is primarily a function of only its copper. Thus the effective thermal capacity of a motor under all degrees of overloads is a variable, having about a four-to-one range. Therefore, if a relay is designed which has a duplicate heating characteristic to that of the motor, then it must also have an effective thermal capacity which is a variable. This of course complicates the problem and results in a larger and a more complicated relay. Such a design is available and has been supplied since 1924, but it is not a large production unit because of its size and cost. Unless this desired characteristic can be designed into a relay which is both inexpensive and small, I doubt whether the trade will need this variable thermal-capacity characteristic sufficiently to demand it. Large motors will always require the best designs available, but the control for small motors will be determined largely by cost. Therefore, the small and inexpensive heater type of thermal overload relays will very likely be continued for some time.

The above discussion regarding how we can protect the insulation of a motor by protecting it against excess temperatures should not lead us to conclude that, if we do a good job in this respect, no insulation troubles will occur. These troubles may develop as a result of transient voltages, faulty work, mechanical injury, or from many other causes. Therefore means should be provided which will give adequate fault protection to the branch circuit, the control devices, the motor, and to the operating personnel.

Short-Circuit Protection

The devices which provide the degree of overload protection just discussed will not, in general, provide the necessary protection to the branch circuit and to the control against short circuits. In our discussion we have assumed that ten times rated current is the dividing line between overload and short-circuit conditions. Above ten times current the effective thermal capacity will be proportional to the copper in the stator winding of the motor and in the branch circuit and the control. Also we have assumed that 100 degrees centigrade rise will be the upper limit of temperature for the stator copper under overload conditions, but for short-circuit conditions 100 degrees rise is somewhat low. We will, therefore, assume that the temperature rise may be 125 degrees—a very, very conservative value—and that the Figure 2 curves will show the necessary speed of interruption required to keep the copper within these limits. The 125 degrees rise (165 or 175 degrees total) is not the limit to which it is permissible to carry copper with its insulation, but, when wire is selected for its continuous current-carrying ability, its resultant temperature under short-circuit condition will be in accordance with the above assumptions.

Since the path of the current which reaches the motor must travel by way of the conductor cable and the devices on the control panel, it will be necessary to also consider the heating characteristic of these current-carrying parts during this short-circuit condition. The conductor cables and contactor parts, we will assume, are made of copper and the heater of the temperature overload relays, which are in most motor circuits, is made of Nichrome. Therefore, we can assume that the path of the short-circuit current will be through copper and through Nichrome of known cross sections.

To protect the conductors adequately in the branch circuit, the control devices, and the motor winding, we must use a device that is both fast in opening the circuit and also has the necessary interrupting ability. The temperature overload relay, which is generally used to protect a motor against overloads, is far too slow to assist in protecting against short circuits. Also the line contactor, connecting and disconnecting the motor to and from the line, does not generally have the necessary interrupting capacity, even if the temperature overload relay could assist it in opening sufficiently fast—as it cannot do—and so we must look for other means which can function sufficiently fast and have adequate interrupting ability.

The most common form of short-circuit protective means used on low-voltage lines is cartridge-type nonrenewable fuses and air-break circuit breakers. If we consider first the fuse then a third material, namely zinc of the fuse link, will be added in the path of the short circuit. We must, therefore, consider the correct relationship between the cross sections of the zinc fuse link, the copper, and the Nichrome heater so that neither the copper nor the Nichrome will exceed certain prescribed temperature rises. To do this we will assume that when the fuse melts, the copper will have reached 70 degrees centigrade rise, the Nichrome 800 degrees rise, this fuse-melting period being one unit of time. Following the melting of the fuse, the current will be reduced to zero in an additional time which we will assume to be two units of time (this has been shown by tests to be a conservative assumption), and the rms current value, during this fuse-arcing period, we will assume to be 58 per cent of the value existing at the instant of melting. During the fuse-arcing period the copper is assumed to have an additional rise of 55 degrees and the Nichrome a rise of 550 degrees, making a total rise of 125 degrees for copper and 1,350 degrees for Nichrome.

Co-ordination of Fuse Size With Copper and Nichrome Wires

In setting up the basis for our problem as shown in Figure 3, we have selected the largest cross sections on the fuses and the smallest cross sections on the copper wire sizes, which means that there is some margin in our basic figures. Let us assume that a copper, a zinc, and a Nichrome wire are connected in series and that a given value of current is put through them. Also let us assume that the cross sections of the copper and of the zinc wires are the same, but the cross section of the Nichrome wire is larger by 2.2 times. The average resistance of

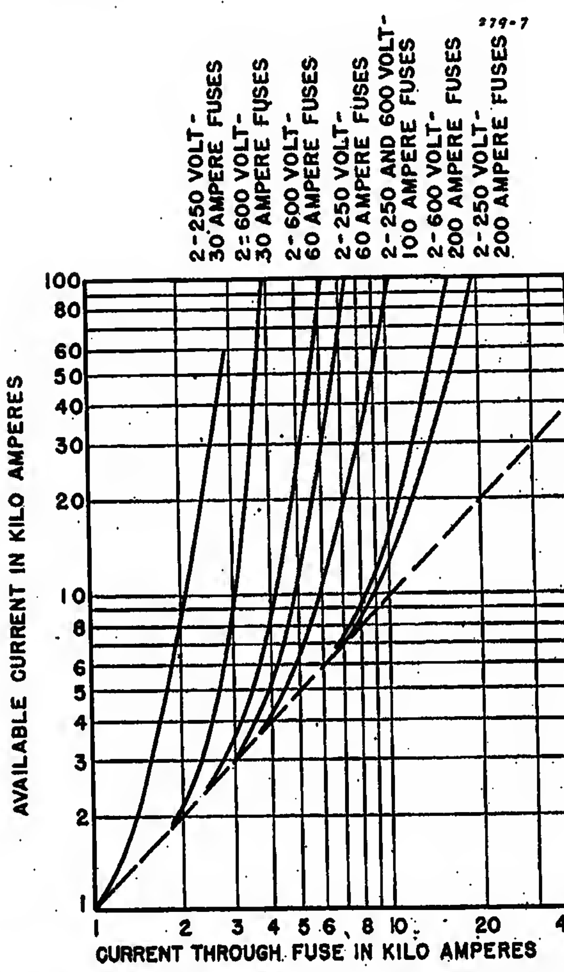

Figure 7. Current-limiting characteristics of standard nonrenewable cartridge fuse on 250-volt d-c power

zinc per circular mil foot between 20 and 419 degrees centigrade (melting) is 69 ohms, while the average resistance of copper per circular mil foot between 20 and 70 degrees is 12 ohms. This makes the average resistance of zinc 5.75 times larger than copper. Therefore, when the copper reaches 70 degrees rise the zinc should be $70\times5.75=400$ degrees centigrade rise assuming no loss of heat. Since the Nichrome wire, which is 2.2 times larger in cross section, is carrying the same current, and since its average resistance is 670 ohms per circular mil foot, the Nichrome wire should have a rise of $70\times670/12\times(1/2.2)^2=800$ degrees centigrade.

Now, the above time is just sufficient to melt the fuse material; to raise the copper to 70 degrees centigrade rise; and the Nichrome to 800 degrees rise. At this time the current is a maximum, and a sufficient additional time must be allowed to reduce this current from this maximum value to zero. We will assume that this current reduces along a straight line so that the rms current is 58 per cent of the maximum.

Tests have shown that for very high currents, twice as much additional time should be allowed for interruption as was required to melt the zinc fuse. Then during this arcing period the rms value of current will be equal to 58 per cent of the value which melted it.

Therefore, if we initially allow a sufficient current to flow through the copper to cause it to reach a 70 degrees centigrade rise (from 20 degrees base) in a unit of time and then allow 58 per cent of this current to continue to flow for two units of time, the copper will have a 125 degrees total rise, because if a given current value flowing for one unit of time results in a 70 degrees rise, then 58 per cent of this current for two units of time will give $70\times(0.58)^2\times2\times1.17=55$ degrees centigrade rise. This rise of $55+70=125$ degrees centigrade. (The 1.17 represents the average increase of the copper resistance due to the higher temperature.)

And if this same 58 per cent value also went through the 220 per cent cross section of Nichrome, it would have an additional rise over its 800 degrees centigrade value of $(125-70)680/14\times(1/2.2)^2=550$ degrees centigrade or a total of $800+550=1{,}350$ degrees centigrade. (The 680/14 also represents the increased resistance due to the higher temperature.)

Therefore, from this line of reasoning, which has been checked by test, we can expect satisfactory results if we have a given cross section of the zinc fuse link—the reduced part of the fuse link—and then see that no part of the copper cross section is smaller than this fuse cross section, and also see that the Nichrome cross section is not smaller than 2.2 times the fuse cross section.

To obtain the above cross-sectional relationships, let us call the current rating of the motor as 100 per cent; then the current rating of the overload relay will be 115 per cent; the current rating of the branch circuit wiring as given in the 1940 National Electrical Code, Table II, chapter 10 will be 125 per cent; and the current rating of the fuse will be 400 per cent. Figure 3 shows graphically the current densities in these three materials. For example a 25-ampere control should have copper cross sections of $250\times25=$ 6,250 circular mils and Nichrome cross

sections of $550 \times 25 = 13,750$ circular mils as minimum cross sections while the maximum size fuse that should be used is $25 \times 3.2 = 80$ amperes, which should have the same cross section as the copper—6,250 circular mils. If the motor has a service factor of 1.15, then the motor rating would be 25 divided by $1.15 = 21.7$ amperes.

Estimated Magnitude of Short-Circuit Current

It is frequently desirable to estimate the magnitude of short-circuit current that will pass through a given size starter, and then determine how long this current can be permitted to flow without exceeding the temperatures prescribed above. Figure 4 was developed on the basis of 20 volt-amperes per phase for the total impedance of the circuit when carrying rated current (this is an approximate minimum impedance generally found). This will hold fairly well for the smaller sizes of control (25 horsepower and less) where the impedance of the supply circuit is a small part, but for larger sizes of starters this method will show too large a value of current. But if an expected value of current is determined by this or other means, then Figure 2 will show how long this value of current can be permitted to flow and still keep the temperatures within the bounds set above, namely 125 degrees centigrade rise on the copper and 1,350 degrees rise on the Nichrome. For example, Figure 4 shows that for a 25-ampere starter at 600 volts the expected short-circuit current would be 10,000 amperes, while Figure 2 shows that a 25-ampere starter can withstand only 4,700 amperes for one one-half cycle or 3,300 amperes for one cycle of time duration. Therefore, since the heating varies as the square of the current this size of starter could carry 10,000 amperes for only $(0.47)^2$ (half cycle) or 0.00184 second. This is obviously faster speed than that of a circuit-breaker operation—which is in the order of 0.008 to 0.015 second—but as shown in Figure 3, a correctly selected fuse can do the job for any current because its time of operation will vary with the magnitude for the current.

Interrupting Speed of Fuses

Another pair of questions that are frequently asked is how fast will a fuse interrupt the circuit, and how much available energy can it interrupt? The first question must be divided into two parts in order that we might segregate the important factors, namely the length of time required to melt the link, and then the time required to interrupt the circuit. The time required to melt the link of General Electric nonrenewable fuses is shown in Figure 5, which gives the time in half cycles (60 cycles assumed). For a fuse to be current-limiting, it must melt in the early stages of a half cycle—such as one fourth of the half cycle—Figure 5 shows that a 100-ampere fuse of this type will melt in this time when approximately 10,000 amperes are put through, and Figure 6, which is a test record, shows that the available current may be around 10,000 amperes value. This means that the fuse stops the current from materially exceeding the value reached at melting. And of course, this effect becomes more pronounced on the smaller size fuses.

It is, therefore, obvious from Figures 5 and 6 that the degree of current-limiting becomes less and less as the size of fuses increases, and that for ordinary powered circuits the fuses larger than 200 amperes size do not give much current-limiting effects. It is also obvious that the 200-ampere fuse and smaller interrupt in one half cycle or less when subjected to currents of 10,000 to 20,000 amperes. This means that fuses do an exceptionally fast interrupting job in protecting motors and controllers of 100 horsepower (size 4 starters) and less.

Interrupting Ability of Fuses

The second half of the question dealing with the amount of available energy which these fuses can interrupt was determined by providing a 250-volt d-c source which was capable of delivering 96,000 amperes, and also a three-phase source which was capable of delivering an rms symmetrical current of 84,000 amperes at 440 volts and 114,000 amperes at 600 volts. In the d-c circuit was placed two standard nonrenewable General Electric 250-volt fuses in series to simulate the usual two fuses that are in a circuit. Two 600-volt fuses were also tested in this circuit, wherein the available currents were varied from 10,000 to 96,000 amperes in several steps, and the results were perfect. The build-up of the current in this circuit was much slower than in an a-c circuit so that the current-limiting effects were much more pronounced as shown in Figure 7.

In the three-phase 440-volt a-c circuit one 250-volt fuse of the above type was connected in each supply line, and the available currents ranged from 18,000 to 84,000 symmetrical rms amperes. The resulting currents are shown in Figure 6, and the performance was perfect. When the supply power was 600 volts, then one 600-volt fuse was connected in each supply line, and the available current ranged from 24,000 to 114,000 amperes. The results, which were perfect in operation, are also shown in Figure 6. It can therefore be said that with this arrangement of connections, these fuses are capable of interrupting a circuit, either a-c or d-c, which has an available short-circuit current of 100,000 amperes.

Conclusions

The following recommendations are made:

1. Correctly designed overload relays should be used to protect all sizes of motors against overloads. To do this, relays having three degrees of tripping speeds should be available—fast, medium, and slow tripping.

2. Every motor should be listed in one of three groups to show whether it is a fast-, medium-, or slow-heating unit. The correct overload relay could then be selected for each motor.

3. Full short-circuit protection for NEMA size 3 and smaller starters can be obtained by the use of correct-size nonrenewable cartridge-type fuses of a good design. Interrupting devices which are slower than these fuses may not give full protection.

4. NEMA size 4 and larger starters will be protected by fast-tripping air circuit breakers which have an instantaneous type of tripping device.

5. The copper cross section of the branch circuit, the control, and the motor should be equal to or larger than the reduced cross section of the zinc fuse link, and the cross section of the Nichrome of the overload relays should be 2.2 times larger than the zinc fuse link.

6. Since safety first laws are becoming more stringent, since available short-circuit energy is rapidly increasing, and since starters are frequently mounted near workmen, it is quite essential that adequate short-circuit protection be provided for all branch-line circuits. Since it has been demonstrated that this protection can be provided for standard existing starters by means of standard fuses, even on large power systems, it was considered of sufficient importance to bring it to your attention at this time so that this needed protection can be obtained and especially during this critical war period.

Selenium Rectifiers and Their Design

JOHN E. YARMACK
ASSOCIATE AIEE

Synopsis: Selenium rectifiers are dry-plate rectifiers of the electronic type. The history of dry rectifiers began some 30 years ago with the advent of the copper-sulphide rectifier. In the early 20's, the copper-oxide type came into common use, and during the past three years, selenium rectifiers have found wide application in American industry. Fundamentally, this third and latest type of rectifier is a continental development and has been manufactured in Europe within the International Telephone and Telegraph group of companies during most of the 1930's. Sufficient experience was gained in the technique of manufacture, as well as in methods of design and in selection of applications, to warrant engineering statements as to their general usefulness and importance to industry.

The purpose of this paper is to outline general principles of design of stacks, one or more of which make a rectifying unit. Starting with the availability of selenium plates or discs of various types, the engineer is confronted with the problem of

1. Selecting the proper size of plate to provide the required d-c output.
2. Computing the required a-c voltage to be impressed on the rectifier stacks to give the necessary d-c output.
3. Analyzing various factors such as type of load, nature of service, and cost of selected rectifier.

The paper includes dynamic and other characteristics of the principal sizes of selenium rectifier plates as applied to the design of single-phase, three-phase, full-wave, and half-wave rectifier units, and all variety of loading. Typical circuits are analyzed and novel representative computations of rectifier units are included.

Selenium Plates

THE rectification of alternating currents by means of the selenium rectifier takes place wholly within the constituent plate or plates, seven sizes of which are shown in Figure 1. The rectifying medium of this electronic device consists of selenium; the principle of operation is similar to that of other dry plate rectifiers, that is, low resistance in the forward direction, and high resistance in the reverse direction. A metal plate serves as back electrode; over it a layer of selenium is deposited, thin enough to give minimum internal losses, but sufficiently thick to withstand high inverse voltage. A soft metal of low-melting temperature is then applied over the selenium layer to form a front electrode. Finally, by means of controlled processes, a barrier layer is formed between the selenium and the front electrode.

Paper 42-86, recommended by the AIEE committee on industrial power applications for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted February 9, 1942; made available for printing March 25, 1942.

JOHN E. YARMACK is commercial engineer with International Telephone and Radio Manufacturing Corporation, New York, N. Y.

Selenium Rectifier Stacks

Rectifier stacks are produced by assembling selenium rectifier plates (40 plates are usually maximum) on a center stud with contact discs or washers interspersed between plates. Series and parallel arrangement can readily be provided as required, by inserting insulators between plates and introducing terminal lugs into the stack.

A stack consisting of 40 plates may be connected in several different ways: for example, as a bridge-circuit unit having ten plates in a series and one plate in parallel (4-10-1), or one plate in series and ten in parallel (4-1-10). The same stack may also be connected as a half-wave rectifier having all 40 plates in series to take care of voltage and one plate in parallel to take care of current (1-40-1). Further, the 40-plate stack may also be assembled as a doubler (2-10-2), two of which make a bridge-circuit rectifier with ten series and two parallel plates in each arm of the bridge.

For the three-phase half-wave circuit the total number of plates must be a multiple of three to allow a total connection such as 3-6-2 for a 36-plate single-stack unit. Similarly, this latter stack, if connected as 6-6-1, becomes either a bridge or center-tap three-phase rectifier.

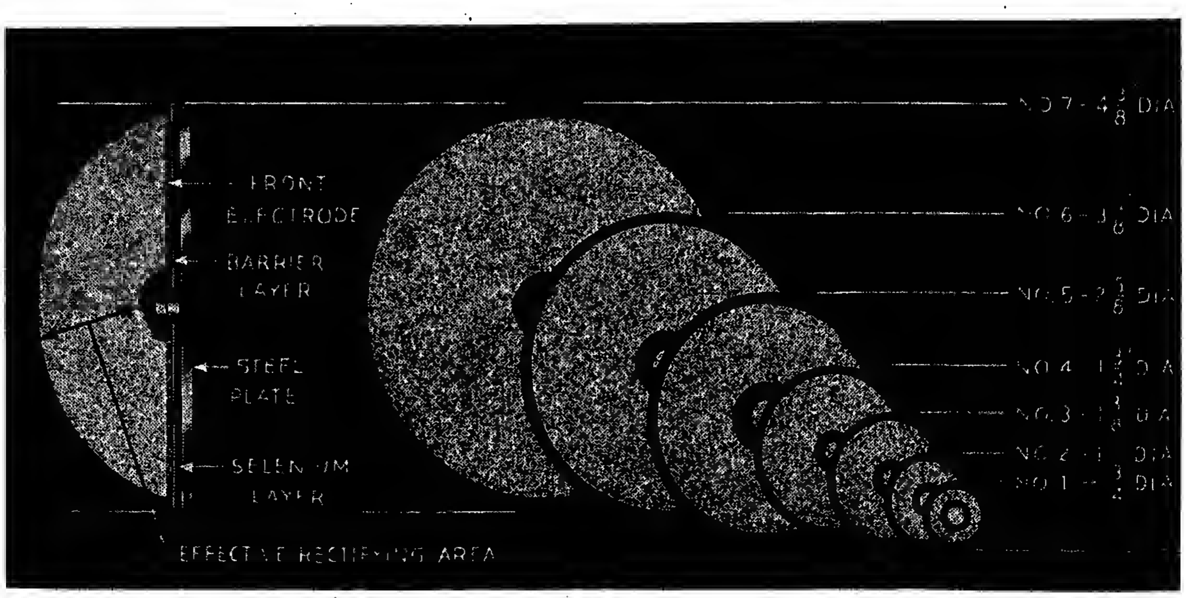

Figure 1 (Below left). Cross section of a selenium rectifier plate showing the sequence of various layers
(Right) Seven basic sizes of selenium rectifier plates

Rating of Plates

Current ratings of selenium plates are a function of their effective rectifying areas and heat-dissipating capacities. Table I lists seven basic plates, ranging from $^3/_4$ to $4^3/_8$ inches in diameter; it also shows ratings of the basic plates in various rectifier circuits. The ampere capacities shown in this table are based on an ambient temperature of 35 degrees centigrade and were determined experimentally. The requirements of a selenium rectifier in respect to current are always met by selecting the proper size of plates and their number in parallel, if the total rating of the rectifier exceeds the rating of an individual plate.

The ratings of the plates shown in Table I can be increased by providing additional cooling. Doubling the spacing between plates assembled in a single stack increases the heat-dissipating ability of the stack; the rating of plates is some 25 to 50 per cent higher than those shown in Table I. Table II lists six selenium plates having the same effective rectifying areas as those listed in Table I, but their current ratings are higher because of wider spacing.

By providing cooling fins, the forward current-carrying capacity of the plates can be raised still further. Table III contains eight additional plates with fins, the current ratings of which are from 2 to $2^1/_2$ times greater than the plates of the same rectifying areas listed in Table I. With extended ratings of the plates, whether by means of wide spacings or cooling fins, the internal losses of selenium rectifiers are greater; consequently, their efficiency is slightly reduced, and the voltage regulation is adversely affected.

Tables I, II, and III also give the maximum permissible reverse rms voltages per plate. The voltages thus indicated have ample safety margin. If, however, the reverse voltage be increased beyond safe limits, the rectifying layer between the selenium and the front electrode alloy breaks down. The maximum specified voltage must not, therefore, be exceeded. Tables I, II, and III include ratings of selenium plates in d-c circuits.

Rectifier stacks with narrow or wide spacing, as well as those with fins, are ordinarily cooled by convection. Large-size selenium rectifiers, however, often utilize forced draft ventilation in order to save space and to economize in rectifying elements. The normal plate rating can thereby be increased twofold and sometimes threefold. If, however, extended loading of plates with the aid of forced ventilation is not desired, substantially greater current output, as compared with free air conditions, can be obtained by mounting the stacks in a chimneylike enclosure (Figure 2). As will be noted from the figure, the least favorable condition is that of mounting the stacks in a cabinet provided with perforated covers.

The current rating of selenium rectifiers is limited only by the final plate temperature resulting from heating. The stacks can be heavily overloaded, provided the maximum safe operating temperature of 75 degrees centigrade is not exceeded. When this temperature is reached, either the load must be reduced to normal, or provision must be made for cutting the rectifying elements out of service as in the two half-wave rectifiers illustrated in Figure 3, widely used in business machines. Each element in these machines is equipped with a pair of bimetal strips connected by means of an adjustable screw. If, by chance, the key punch or the duplicator happens to be jammed and causes the temperature of the stacks to reach a range of 70 or 80 degrees centigrade, the bimetal

strips separate, thus breaking the circuit. The plates then cool off and the bimetal strips again close (Figure 4).

Intermittent Service

Considerable gain in the current capacity of selenium rectifiers can be obtained when they are used in intermittent service, in which case, the duty cycles must be definitely established. The variety of these intermittent applications is great, and their complete discussion here would be too lengthy. One formula, however, is frequently used for periodic loadings:

$$I_m = I_{\max}\sqrt{\frac{A}{A+P}} \tag{1}$$

where I_m is the continuous current rating, $I_{\max}$ the maximum current drawn periodically, A the operating period, and P the inoperative interval; both A and P should be in the same units. Experience has shown that this formula can be used only if A is less than the selenium plate time constant T, which may be defined by:

$$t_1 = t_2(1-e^{-\frac{A}{T}}) \tag{2}$$

and which varies from five to eight minutes, depending on the plate size (t_1 and t_2 are instantaneous and final plate temperatures, respectively). When operating periods are separated by inoperative intervals of such length that the rectifier again cools practically to normal ambient temperature, much greater plate overloads are practicable.

Design of Stacks by Direct Values

After choosing the size of plate with proper current-carrying capacity, the internal voltage drop of the plate is considered. Figure 5 illustrates the average experimentally determined internal voltage drop for seven plates in either bridge or center-tap single-phase circuits. The

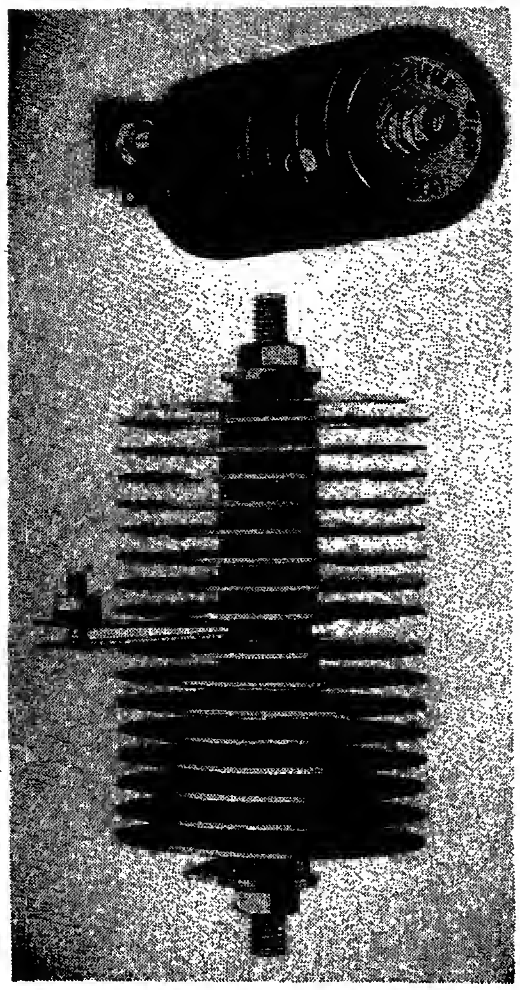

Figure 3. Two half-wave selenium rectifiers for operation of magnets in business machines

Both stacks are equipped with bimetal strips to open the circuit when the plate temperature exceeds a specified value

voltage drop per plate, designated as dv, is one half of the difference between the rms values of voltages read on the input and output side of the rectifier. These quantities are plotted as ordinates against the arithmetical values of output current in amperes plotted as abscissa.

The output voltage of a selenium rectifier is determined by the input voltage V_{ac} less the total voltage drop within the rectifier. The computation of the necessary a-c voltage to be impressed on the selenium rectifier involves consideration of the voltage drop per plate and the number of plates through which the current flows.

Using the data given in Tables I, II,

Table IV. Selenium-Rectifier Design Constants: k_1 = Form Factor; n = Number of Plates in Series; k_2 = Circuit Factor; V_p = Maximum Voltage Per Plate; V_{ac} = Phase Voltage, Except Three-Phase Bridge Where It Is Line Voltage

Number of Phases	Circuit Type	k_1	n	k_2
1	Half-wave	2.8	$\frac{V_{ac}}{V_p}$	1
1	Bridge	1.15	$\frac{V_{ac}}{V_p}$	2
1	Center-tap	1.15	$\frac{2V_{ac}}{V_p}$	1
3	Half-wave	0.855	$\frac{\sqrt{3}V_{ac}}{V_p}$	1
3	Bridge	0.74	$\frac{V_{ac}}{V_p}$	2
3	Center-tap	0.74	$\frac{2V_{ac}}{V_p}$	1

and III, and the internal voltage drop per plate illustrated in Figure 5, any single-phase selenium rectifier can be designed and the necessary a-c voltage computed by the following formula:

$$V_{ac} = k_1 V_{dc} + k_2 n \text{ dv} \tag{3}$$

where V_{ac} is the input voltage, k_1 the form factor to convert the arithmetical value to the rms voltage value (Table IV), V_{dc} the required d-c output voltage, k_2 the number of arms through which the current must pass in the circuit for each half-cycle, n the number of plates in series per arm, and dv the voltage drop per plate for the circuit employed. The constants k_1 and k_2 vary depending upon whether a bridge or center-tap connection, a single or three-phase circuit is employed.

As an example, let us design a bridge-type unit required to deliver four amperes at 16 volts continuously under the maximum ambient temperature of 35 degrees centigrade in a single-phase circuit. Selenium plate 7, 4$^3/_8$ inches in diameter

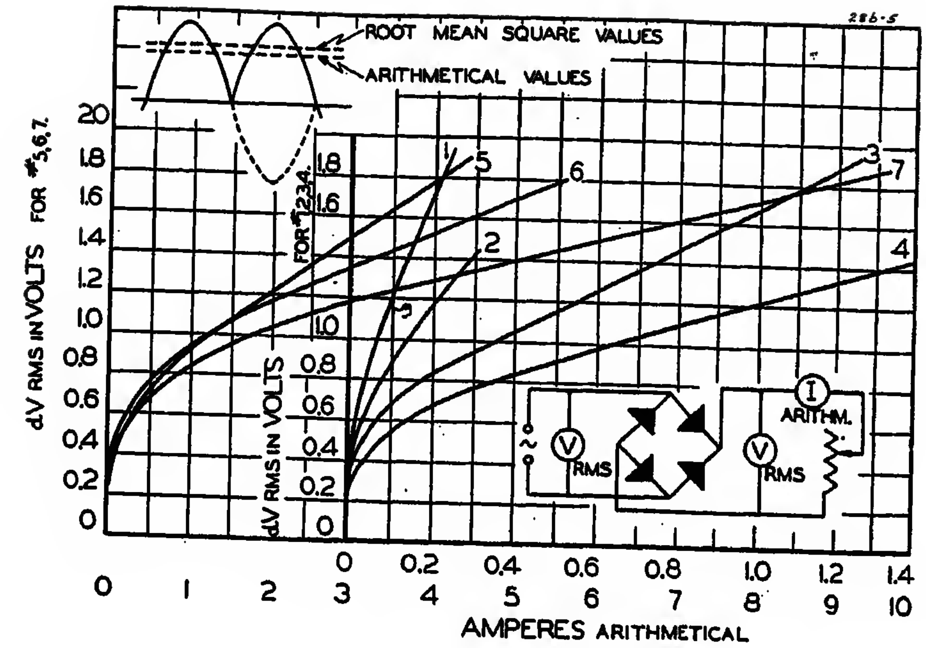

Figure 5. Rectification characteristics of seven basic plates ($^3/_4$, 1, 1$^3/_8$, 1$^3/_4$, 2$^5/_8$, 3$^3/_8$, and 4$^3/_8$ inches in diameter) used in the design of single-phase bridge and center-tap rectifiers for inductive and resistive loads

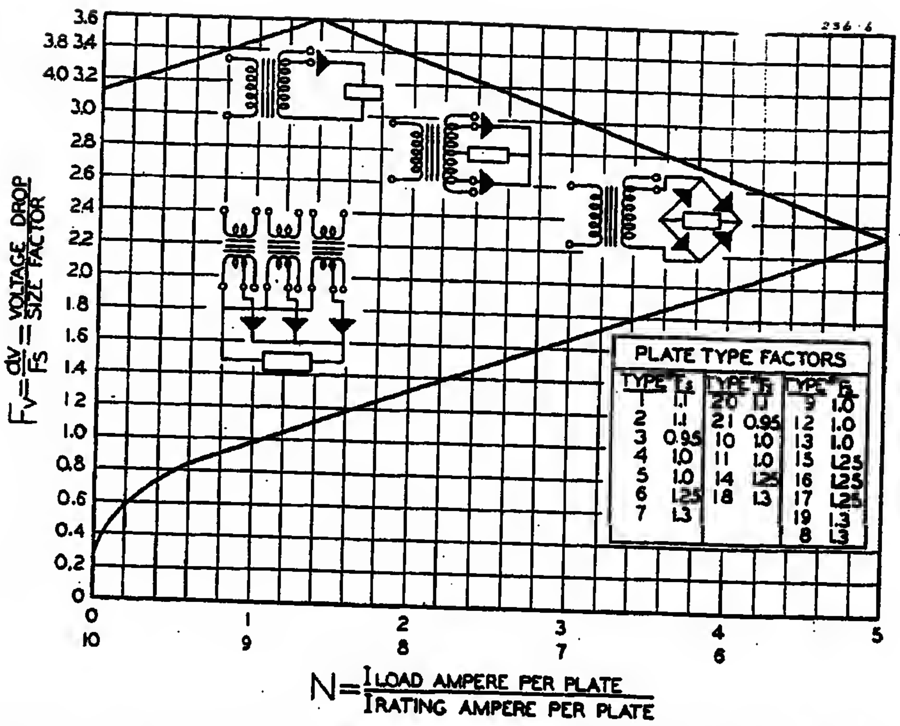

Figure 6. Characteristic illustrating the relation of F_v and N for single-phase half-wave, center-tap, and bridge rectifier circuits with resistive or inductive load; also for three-phase half-wave rectifier circuit with all types of load

(listed in Table I and rated at four amperes) will serve the purpose. Using equation 3 and corresponding constants from Table IV:

$$V_{ac}=1.15\times 16+2n\,\text{dv}$$

The number of plates in series, that is, quantity n, necessary at this stage, can be computed by the following formula:

$$n=\frac{k_1V_{dc}}{V_p-2\,\text{dv}} \qquad (4)$$

V_p for plate 7 is 14, and dv, as read off characteristic 7 in Figure 5, is 1.29; hence

$$n=\frac{1.15\times 16}{14-2\times 1.29}=1.6 \text{ or 2 of number 7 plates in series}$$

V_{ac}, therefore, at the start of service, is equal to 23.6 volts. With the aging of the selenium rectifier, the forward resistance increases, and the inverse resistance also slightly increases. Based on lengthy experience in the design and application of these rectifiers, it can be stated that the only variable quantity of equation 3 is dv, which may increase as much as 50 per cent under most adverse conditions. An additional tap, therefore, should be provided in the transformer winding to give the V_{ac} required for the aged condition:

$$V_{ac}=1.15\times 16+2\times 2\times 1.29\times 1.5=26 \text{ volts}$$

Designs by Relative Values

The foregoing example and reference to Figure 5 characteristic apply only to the single-phase bridge and center-tap designs with either inductive or resistive loads. With capacitive and battery-charging loads, even in the above-mentioned circuits, intermittent loading on the selenium plates occurs with periodic values of the forward current greater than the periodic values for the same d-c output feeding resistive or inductive load; voltage drops per plate are, therefore, greater in the former case. Applications occur, however, where the voltage drop per plate is smaller than the values shown in Figure 5. An example is the three-phase circuit where the rectified current is practically at the peak value of the applied alternating current. The output current density per plate in these circuits is considerably higher than in the case of a single-phase bridge circuit; furthermore, the type of load, whether it be resistive, inductive, capacitive, or battery charging, has practically no effect on the voltage drop per plate.

Inasmuch as a wide variety of circuits and types of loading is encountered, a

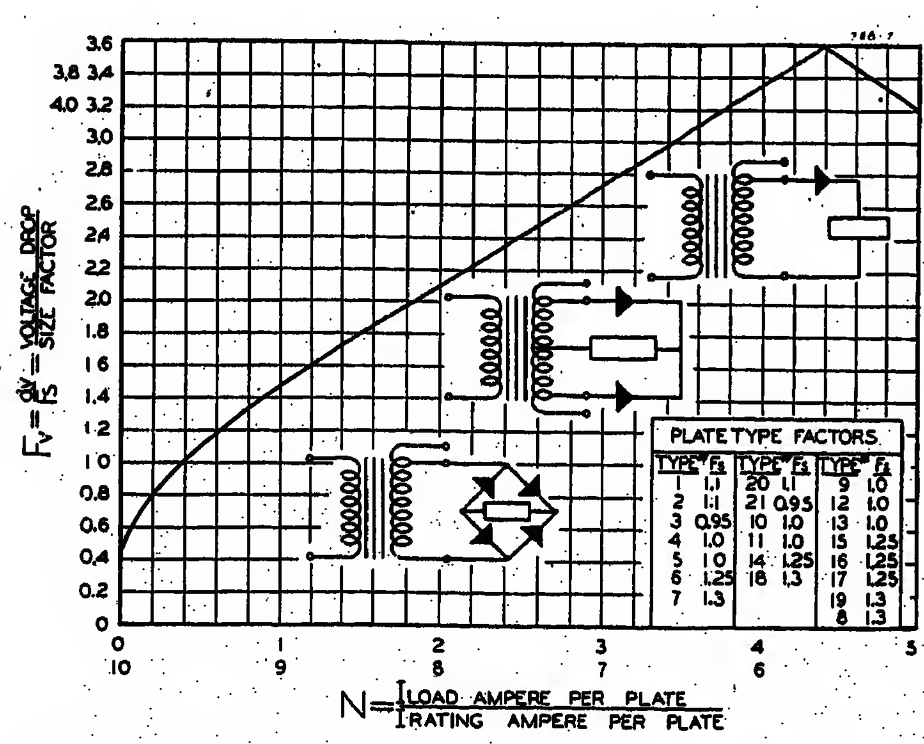

Figure 7. Characteristic illustrating the relation of F_v and N for single-phase half-wave, center-tap, and bridge rectifier circuits for battery-charging application or capacitive loads

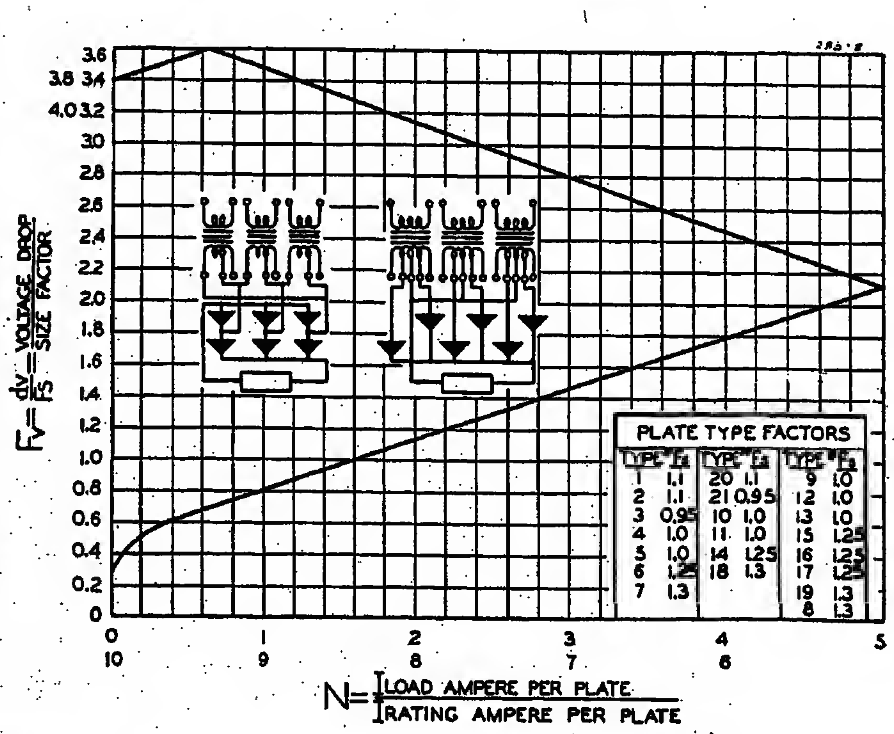

Figure 8. Characteristic illustrating the relation of F_v and N for three-phase center-tap and bridge rectifier circuits for all types of loads

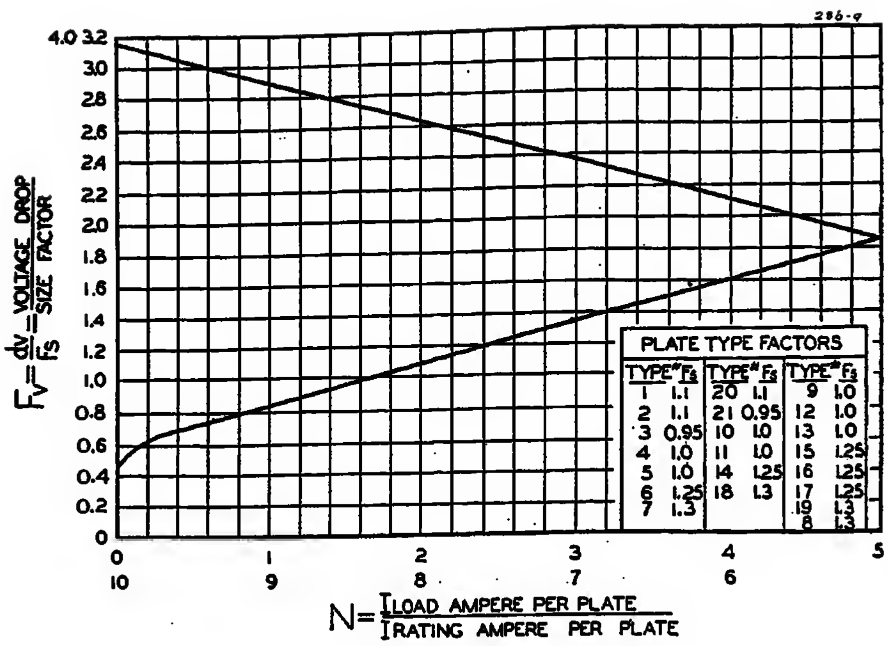

Figure 9. Characteristic illustrating the relation of F_v and N for d-c and blocking circuits

method for rating the 21 rectifier types according to relative values of output current and voltage drop per plate has been developed. Figures 6, 7, 8, and 9 illustrate the relationships N and F_v for various types of circuits and loads.

The use of these characteristics involves first, determination of the value N, which is obtained by dividing the actual ampere load per plate by the ampere rating of the basic plate employed. With this value determined, the value of F_v is read from one of the characteristics and then multiplied by the plate size factor F_s to obtain the actual voltage drop per plate, dv for the plate selected.

Figure 6 illustrates the relationship of F_v to the value N for half-wave, center-tap, and bridge single-phase circuits when loaded with either resistive or inductive load; also for half-wave three-phase circuits for all types of loads. Figure 7 gives a similar relationship for F_v to the value N for half-wave, center-tap, and bridge circuits, all single-phase for capacitive or battery-charging applications. Figure 8 shows the relationship of F_v to N for three-phase bridge and center-tap circuits for all types of loads. Finally, Figure 9 shows the relationship of F_v to N for d-c and blocking circuit applications.

To illustrate this method of design, let us compute a three-phase selenium rectifier capable of delivering 325 amperes at 13 volts for the filament supply of a television transmitter tube. An additional requirement is that the rectifier deliver not more than 488 amperes at approximately two volts into tube when cold.

Several plates in Tables I, II, and III should be tried; however, plate 13, rated at 3.3 amperes, will be most economical; the total current of 325 amperes can be safely handled by 100 plates connected in parallel.

$$I_{dc}=\frac{325}{100}=3.25 \text{ amperes per plate}$$

This plate loading with 1.8 ampere rating for basic plate 5 used in type 13 will give

$$N=\frac{3.25}{1.8}=1.8$$

From Figure 8, $F_v=1.07$ and $dv=1.07\times 1=1.07$.

In aging, the dv value may increase 50 per cent, and thus becomes 1.6. Substituting the known quantity in formula 4:

$$n=\frac{0.74\times 13}{18-2\times 1.6}=0.65; \text{ or 1 plate in series}$$

The foregoing proves that the entire rectifier should consist of a total connection of (6-1-100), where the first number (6) designates the number of arms of the three-phase circuit, the second number (1) indicates the number of plates in series, and the third number (100) gives the number of plates in parallel. The total of 600 plates of type 13 may be conveniently assembled into 24 stacks, each having 25 plates in parallel.

Using formula 3 and the design constants of Table IV:

$$V_{ac}=0.74\times 13+2\times 1\times 1.07=11.8 \text{ volts}$$

when rectifying elements are new;

$$V_{ac}=0.74\times 13+2\times 1\times 1.6=12.8 \text{ volts}$$

when they are fully aged.

In order to meet the requirements of approximately two volts with the current output of 488 amperes:

$$I_{dc}=\frac{488}{100}=4.88 \text{ amperes per plate}$$

$$N=\frac{4.88}{1.8}=2.7$$

From the characteristic of Figure 8

$$F_v=1.37$$

For the new stacks, therefore, $dv=1.37\times 1=1.37$, and for fully aged stacks

$$dv=1.37\times 1.5=2.06$$

Using formula 3 and these two values of dv, the new and aged V_{ac} will be found to be 4.2 and 5.6 volts, respectively. The 50 per cent limit for the current requirement is actually met by the external limiting reactances in each phase of the three-phase circuit. The complete assembly of this rectifier is shown in Figure 10.

The ordinary single-phase bridge-type rectifier for resistive loading can also be designed through the use of relative values. Figure 11 illustrates a two-ampere, 120-volt telautograph unit.

With two number 9 plates in parallel, or one ampere per plate:

$$N=\frac{1}{0.6}=1.67$$

From the characteristic of Figure 6

$$F_v=1.2 \qquad dv=1.2\times 1.0=1.2$$

Hence

$$n=\frac{1.15\times 120}{18-2\times 1.2\times 1.5}=9.6, \text{ or 10 plates in series}$$

The total connection of the rectifier is then 4-10-2. Practical considerations suggest four stacks, two of which make one bridge with ten plates in each arm of the bridge. Again, from formula 3, corresponding constants of Table IV and the above dv value, V_{ac} is found to be 162 volts when new and 174 volts when aged.

Ratings (Tables I, II, and III) of selenium rectifier plates, functioning as blocking valves in d-c circuits, are higher in current and lower in voltage value than they are in half-wave alternating circuits. The higher current rating is acceptable, inasmuch as the forward resistance ordinarily decreases when only forward current passes through the selenium rectifier plates. The reverse current of the blocking unit, on the other hand, is higher, and the safe voltage limit is, therefore, more conservatively established than for a-c circuits. As an example, a 30-volt, 4.5-ampere blocking unit consists of a total connection of 1-2-5 number 5 plates. The value N for this unit is equal to one, and dv is 0.84 (Figure 9).

Experience has shown that for constant-current battery-charging and capacitive loading, the current rating should be only

Table V. Relation of Factor k_s by Which Normal Rating of Number 7 (That Is, $4^3/_8$-Inch-Diameter) Selenium Plates Can Be Increased, and the Speed and Amount of Air Necessary

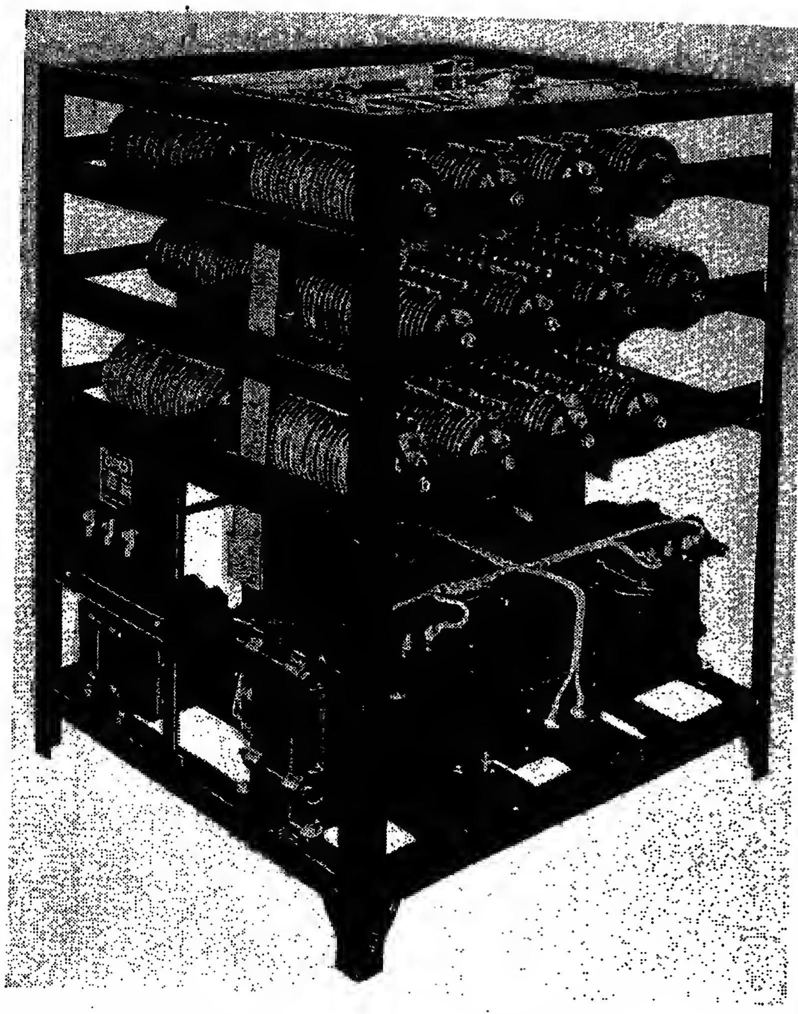

Figure 10 (left). Rectifier unit of 325-ampere 13-volt rating with reactances limiting output current to 488 amperes at two volts

A-c input: 220 volts, three phases, 60 cycles. Rectifying element consists of 600 plates arranged in 24 stacks, each stack consisting of 25 plates in parallel

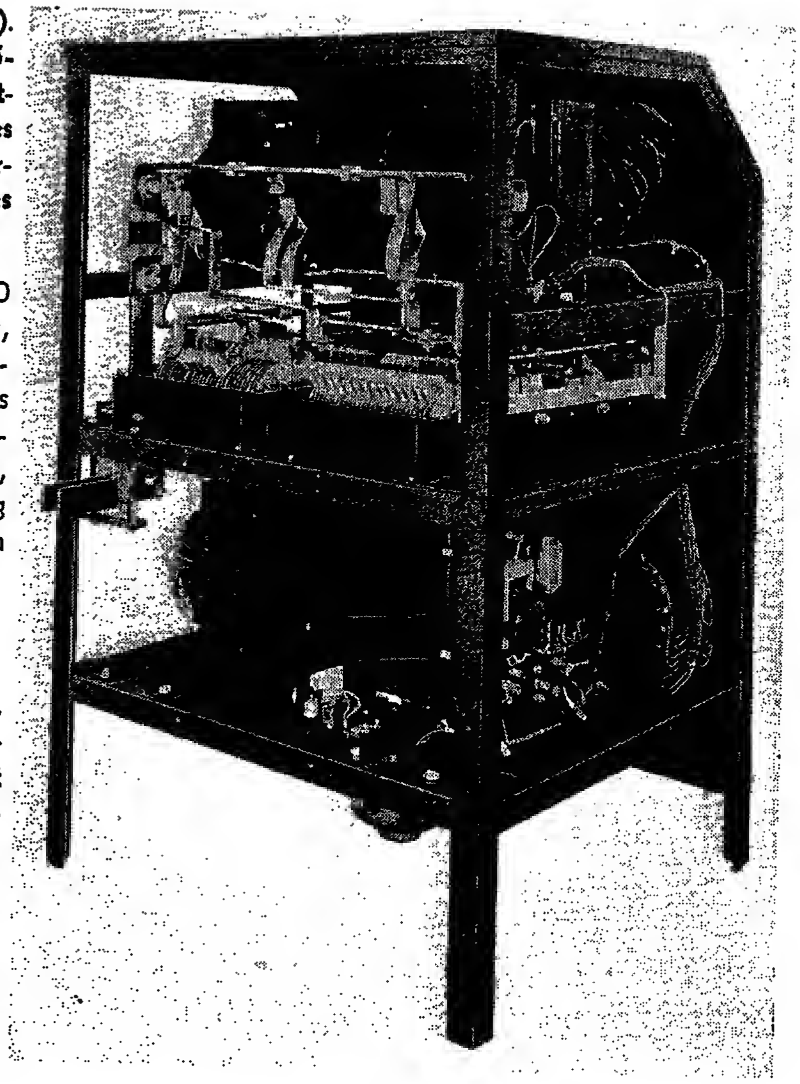

Figure 12 (right). Three-phase selenium rectifier unit employing forced-draft ventilation for output of 600 amperes at six volts

Over-all efficiency: 74 per cent; power factor: 94 per cent

80 per cent of the values tabulated in Tables I, II, and III. In the design of the rectifier for charging a 60-cell battery at the rate of 0.4 ampere, with 2.4 volts per cell, plate 4 may be selected. The value of N is 0.67. The new dv, as read off the characteristic of Figure 7, is 1.25 and, after aging, it becomes 1.87. The number of plates in series is determined either by

$$n=\frac{V_b}{V_p} \tag{5}$$

$$\text{or } n=\frac{V_b/\sqrt{2}}{V_p-2\text{ dv}} \tag{6}$$

depending on which is greater.

Figure 11. Selenium rectifier with output of two amperes at 120 volts for powering telautograph equipment

$$V_{ac}=\frac{V_b}{\sqrt{2}}+k_2n\text{ dv} \tag{7}$$

$$=\frac{60\times2.4}{\sqrt{2}}+2\times8\times1.25=122\text{ volts}$$

An additional tap to give 132 volts for the fully aged condition of the stacks should be provided.

Design of Forced-Draft-Ventilation Unit

The extended current rating of selenium rectifier plates with forced draft or fan cooling and the speed of air constituting the forced ventilation require further consideration. A rather conservative relationship of current rating to air velocity has been established and successfully used for the $4^3/_8$-inch-diameter number 7 plate (Table V).

As an example, let us design a three-phase full-wave rectifier supplying a d-c output of 600 amperes at six volts. Because of the low required output voltage, as compared to the full rms voltage permissible for the number 7 plate, the center-tap circuit is most economical and gives greatest efficiency. With the fan delivering air at a speed of 120 feet per minute, the 7.5-ampere (Table I) loading of this plate can be increased 2.5 times (Table V), thus making it 18.7 amperes per plate. Practical consideration of possible 10 per cent overload suggests that this unit should have 36 plates in parallel for the total current output of the unit. This makes the value N (Figure 8) equal to 2.22, and the initial and aged dv equal to 1.6 and 2.4 respectively. The total connection of the rectifier is, therefore, 6-1-36. The new V_{ac} for half of the transformer secondary voltage is 6.1 volts, and for the fully aged condition 6.9 volts. A view of this equipment is shown in Figure 12.

Voltage Regulation

The inherent voltage regulation of the selenium rectifier is in the neighborhood of 10 to 20 per cent. In computing the regulation, one must determine the no-load

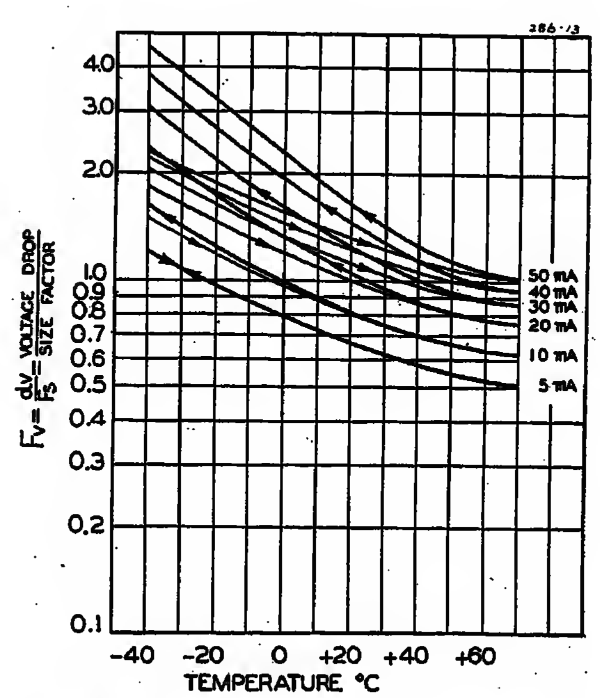

Figure 13. Relation of F_v at varying current densities to the ambient temperatures throughout a heating and cooling cycle

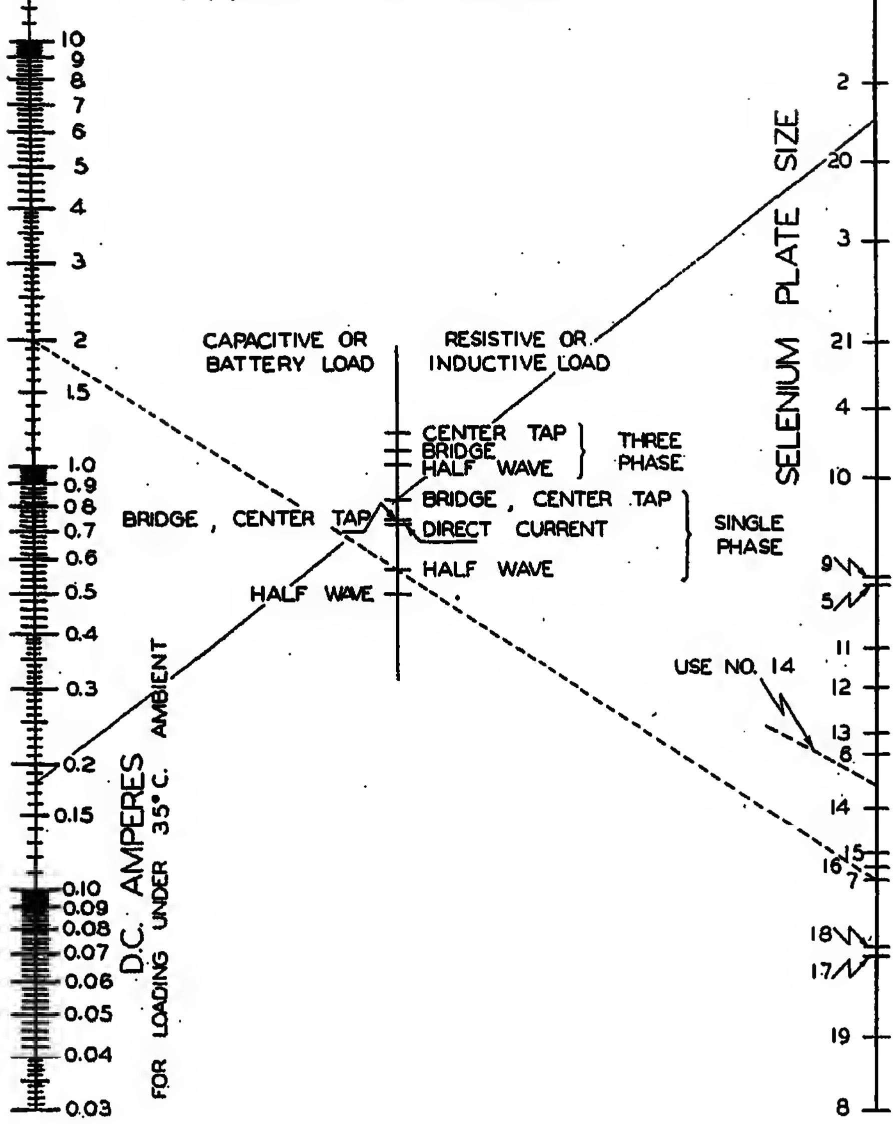

Figure 14. Alignment chart for determining the rectifier type number for (1) output current, (2) nature of load, (3) type of circuit

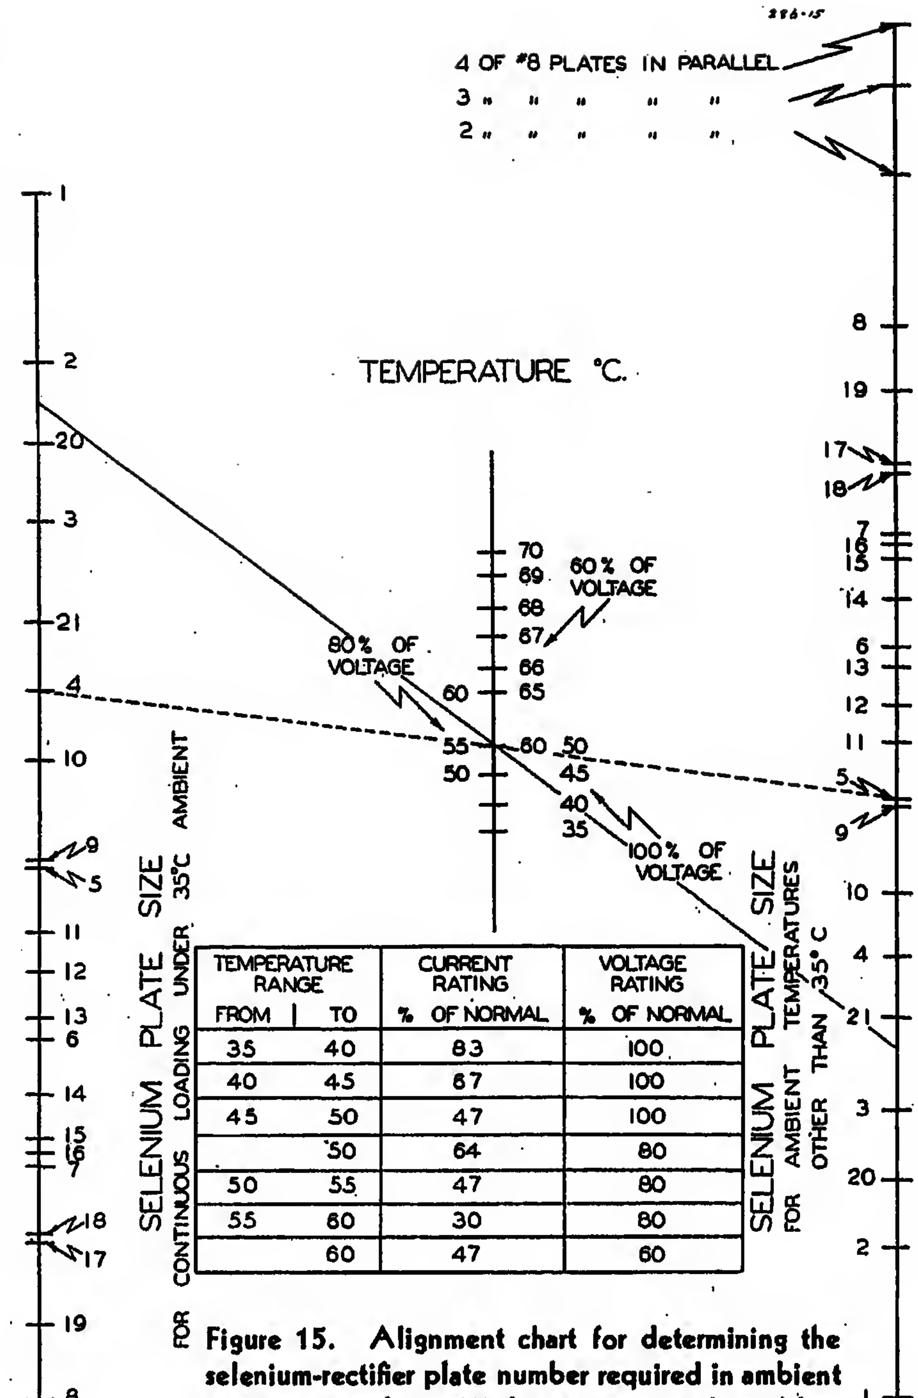

TEMPERATURE RANGE FROM	TO	CURRENT RATING % OF NORMAL	VOLTAGE RATING % OF NORMAL
35	40	83	100
40	45	67	100
45	50	47	100
	50	64	80
50	55	47	80
55	60	30	80
	60	47	60

Figure 15. Alignment chart for determining the selenium-rectifier plate number required in ambient temperatures above 35 degrees centigrade. Also, table of percentage of current and voltage ratings at ambient temperatures above 35 degrees centigrade

value of dv and then the no-load output voltage. In the case of the first example of a four-ampere, 16-volt rectifier, the dv value from Figure 5 is 0.4. The d-c output voltage, therefore, at no load is

$$V_{dc}=\frac{23.6-2\times 2\times 0.4}{1.15}=19.1$$

$$\text{Regulation}=\frac{19.1-16}{16}\times 100=19.4 \text{ per cent}$$

Similarly, the regulation of the three-phase 325-ampere 13-volt unit (Figure 10) is computed by reading F_v for N equal to zero in Figure 8. Substituting 0.3 for the value of dv in formula 3, and taking 11.8 volts for V_{ac}, one finds the no-load voltage to be 15 volts, and the voltage regulation is, therefore, 15.4 per cent.

Efficiency

The efficiency of selenium rectifiers varies with the type of circuit and the nature of the load. The single-phase circuits with fully loaded plates in respect to voltage and current, and when feeding either resistive or inductive loads, give an efficiency of approximately 64 per cent; the same circuits, when used for battery charging give an efficiency some 14 per cent higher due to the greater value of the rectified voltage. The three-phase circuits give efficiency values in the neighborhood of 83 per cent and, for all practical purposes, remain the same irrespective of the type of load. For all circuits and loads, however, the efficiency of selenium rectifiers increases with decrease of load down to approximately 25 per cent of full value, and thereafter falls off rapidly.

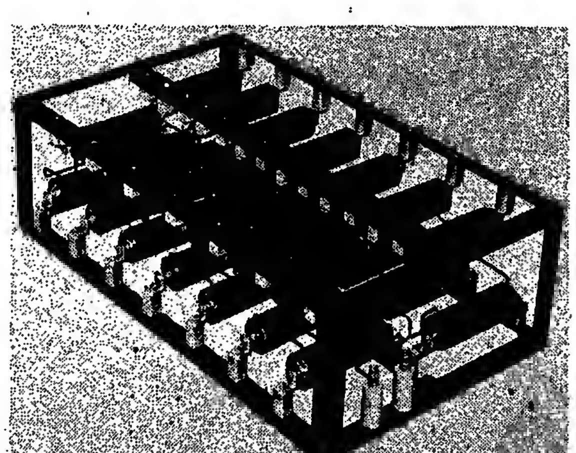

Figure 16. Single-phase bridge-connected rectifier

Output: 180 milliamperes at 2,300 volts under ambient temperatures from −40 to +60 degrees centigrade

The efficiency itself depends on the combined losses in the selenium rectifier from forward and reverse currents, and, in formula form, it is:

$$\frac{V_{dc}I_{dc}}{(V_{dc}I_{dc})+W_f+W_r}\times 100=\%\text{ efficiency} \quad (8)$$

where W_f are losses due to forward current, and W_r are losses due to the reverse current.

The computation of exact efficiency of all sizes of plates and various loads and circuits is rather involved and constitutes an extensive subject in itself.

In order to illustrate the simplified method of efficiency computation and the effect of dv changes on its value, let us compute the efficiency of the 325-ampere 13-volt three-phase unit illustrated in Figure 10.

Forward losses per plate in the three-phase bridge circuit are

$$w_f=\frac{\sqrt{2}I_{dc}\,\text{dv}}{3}$$

where $\sqrt{2}$ is a conversion factor for approximating the peak value of the a-c

wave in terms of effective value of dv. Divisor 3 results from the fact that in three-phase bridge circuit each plate is utilized $2\times{}^1/_6$ times in each cycle.

$$w_f=\frac{325/100\times\sqrt{2}\times1.07}{3}=1.64 \text{ watts per plate}$$

or $W_f=6\times100\times1.64=984$ watts for all 100 plates in six arms.

The reverse losses are approximately one third of forward losses computed for the normal rating of the plate used in this unit

$$W_r=\frac{1}{3}\times\frac{6\times100\times0.8\times\sqrt{2}\times1.8}{3}=136 \text{ watts}$$

The new input wattage W, therefore, is

$$W=(I_{dc}\times V_{dc})+W_f+W_r$$
$$=(325\times13)+984+136=5{,}345 \text{ watts}$$

$$\text{Efficiency}=\frac{4{,}225}{5{,}345}\times100=79.2 \text{ per cent}$$

Similarly, assuming a possible 50 per cent change in dv, the efficiency of this rectifier with stacks fully aged is computed as 72 per cent.

The foregoing designs illustrate the importance of the quantity dv, which is dependent on the forward resistance and current density of the plates, as well as the ambient temperature under operating conditions. Its changing values under varying conditions greatly influence the efficiency, regulation, and aging of selenium rectifiers. The ambient temperature and current density relationships affecting the value of dv are illustrated in Figure 13. The arrows on the curves indicate that the resistance of the plates decreases with increase of temperature. As the plates cool off, the resistance again increases, and dv is greater at the new lower temperatures than during the rising-temperature phase of the heating cycle. This phenomenon diminishes with lower current densities to a point where the resistance is the same at corresponding temperatures of the heating and cooling portions of the cycle.

Selection of Plate Type for 35 Degrees Centigrade and Higher Ambient Temperature

Almost invariably more than one selenium plate type appears suitable for given output requirements. The type of circuit or nature of loading, as well as the cost, however, restricts the choice.

The alignment chart (Figure 14) has been found useful in selecting plate types for specified output currents. If a straight edge is laid connecting the required d-c output with the type of circuit and the nature of load, the intersection of the straight edge on the plate size scale gives the type number of the required rectifier plate. If the intersection falls between two plate type numbers, the plate having the higher current rating should be chosen.

For ambient temperatures higher than 35 degrees centigrade, the plate type number for a 35 degrees centigrade ambient should first be found. Referring to Figure 15, a straight edge connecting the 35 degrees centigrade ambient temperature plate type number with the desired higher ambient value of the temperature scale intersects the right-hand scale, indicating the required higher ambient plate type number. Again, if the intersection is between two plate type numbers, the plate type number with the higher current rating should be used. It will be noted that, by decreasing the voltage rating, a small increase in current rating is allowable.

As an example, let us design a high-voltage low-current rectifier of the type illustrated in Figure 16 for either resistive or inductive load. Referring to Figure 14, the line drawn through the 0.18 reading on the left-hand scale, and the point marked "single-phase bridge" in the middle of the chart, intersects the right-hand scale between "2" and "20." Thus, plate 20 (Table II) would be used if the rectifier is to operate under maximum ambient temperature of 35 degrees centigrade. In order to derate plate 20 for a 60 degrees centigrade ambient, reference is made of Figure 15. The line drawn on this chart through the same point (between "2" and "20") of the left-hand scale (as in Figure 14) and the point marked "60 per cent of voltage" indicates that the number 21 selenium plate (Table II) should be used for the required assembly. Further computations of quantities N, dv, and n result in the design of a rectifier with total connections of 4-224-1, arranged in 28 stacks, each consisting of 32 of $1^3/_8$-inch plates in series.

Rectifier Terminology and Circuit Analysis

C. H. WILLIS
FELLOW AIEE

C. C. HERSKIND
MEMBER AIEE

ANYONE reading several articles on the subject of rectifiers must be impressed by the confusion caused by a lack of exact terminology. This paper presents definitions of a few terms representing the most important concepts arising in the rectifier field. The definitions are presented with the hope that they will be found sufficiently useful to be widely adopted. Constructive criticism of the terms and definitions is invited.

These terms have been defined to conform with the general practice in the power-rectifier field. It is to be hoped, however, that the concepts will be sufficiently broad and accurate to be generally useful in all fields where rectifiers are employed.

In many of the definitions the term "circuit element" is employed. This has not been defined, because it is in general use in electrical literature and has been defined elsewhere.[1] The definitions suggested are given below.

Rectifier Terms

1. *Rectifying Element.* A rectifying element is that circuit element which has the property of conducting current effectively in only one direction.

In arc rectifying devices, the portion of the circuit including an anode, its cathode, and the arc space between the anode and cathode, is the rectifying element.

When a group of rectifying units is connected, in either parallel or series arrangement, to operate as one circuit element, the group of rectifying units should be considered as a rectifying element.

2. *Double-Way Rectifier* (*Double-Direction Rectifier*). A double-way rectifier is a rectifier in which all parts of the alternating-voltage circuit elements, conductively connected to the rectifying elements, conduct current in both directions (that is, in alternate half-cycles).

3. *Single-Way Rectifier* (*Single-Direction Rectifier*). A single-way rectifier is one in which no portion of the alternating-voltage circuit elements, conductively connected to the rectifying elements, conducts current in both directions (that is, in alternate half-cycles) because of the action of the rectifying elements.

4. *Simple Rectifier.* A simple rectifier is a rectifier in which the total direct current at any instant, exclusive of the commutating time, flows through a single rectifying element for a single-way rectifier, or flows through two rectifying elements in series (one on either side of the a-c circuit element) for a double-way rectifier.

5. *The Number of Phases in a Simple Rectifier.* The number of phases in a *simple single-way* rectifier is equal to the number of rectifying elements.

The number of phases in a *simple double-way* rectifier is equal to half the number of rectifying elements.

A double-way rectifier may have a primary-current wave shape and a d-c ripple voltage corresponding to a single-way rectifier having twice the phases of the double-way rectifier.

In describing a *simple rectifier*, three items of information are usually necessary and sufficient:

(*a*). The number of phases of the rectifier.

(*b*). Classification as either single way or double way.

(*c*). The transformer-circuit description if transformers are used.

Example: A three-phase single-way rectifier using delta zigzag wye transformers.

6. *Multiple Rectifier.* A multiple rectifier is one in which two or more similar simple rectifiers are connected in such a way that their direct currents add, but their d-c voltage ripples do not coincide. Interphase transformers are usually required between the component simple rectifiers in a multiple rectifier.

When two or more groups of rectifying elements operate so that their d-c currents add and their d-c voltage ripples coincide, the groups of rectifying elements are in parallel.

Paper 42-83, recommended by the AIEE committee on electrical machinery and joint subcommittee on electronics for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted February 17, 1942; made available for printing April 2, 1942.

C. H. WILLIS is professor of electrical engineering, Princeton University, Princeton, N. J., and C. C. HERSKIND is electrical engineer, power rectifier department, General Electric Company, Schenectady, N. Y.

In describing a multiple rectifier, four items of information are usually given, and a fifth, the classification as single-way, is usually assumed. The information expressly stated is:

(*a*). The primary wave shape, or the number of phases in a simple single-way rectifier to give the same primary wave shape.

(*b*). The number of component simple rectifiers in the multiple rectifier.

(*c*). The number of phases in a component simple rectifier.

(*d*). The transformer-circuit description if transformers are used.

Example: a 12-phase quadruple wye (single-way) rectifier, using delta zigzag wye transformers.

7. *Cascade Rectifier.* A cascade rectifier is a rectifier in which two or more similar simple rectifiers are connected in such a way that their d-c voltages add.

8. *Commutating Reactance.* The commutating reactance is the reactance which effectively opposes normal currens transfer between rectifying elements which conduct consecutively.

In the actual rectifier circuit this reactance is usually distributed in various parts of the circuit; for example, the anode leads, the transformer windings, and the a-c supply system. In many cases these reactances may be considered as lumped in the transformer secondary.

9. *Reactance Factor* (*Commutating-Reactance Factor*). The commutating-reactance factor is the per-unit commutating reactance calculated on the arbitrary base of the rms value of the secondary line-to-neutral voltage divided by the direct current commutated.

Particular attention is called to the terms "double-way" rectifier and "single-way" rectifier. These terms are suggested to replace the terms "half-wave" and "full-wave" as frequently employed. There are two arguments against the old terms. In the first place, they have been used by two groups in different ways. For example, the circuit shown in Figure 1 is sometimes described as a "full-wave" circuit. It is also described as a "half-wave" circuit by a substantial group.

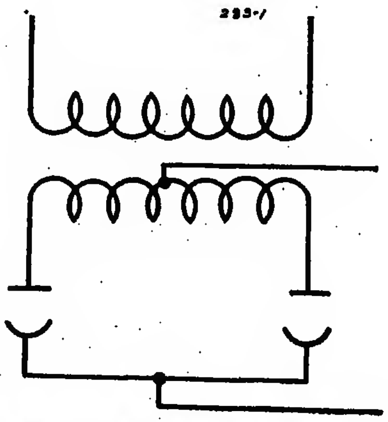

Figure 1. Single-way rectifier circuit

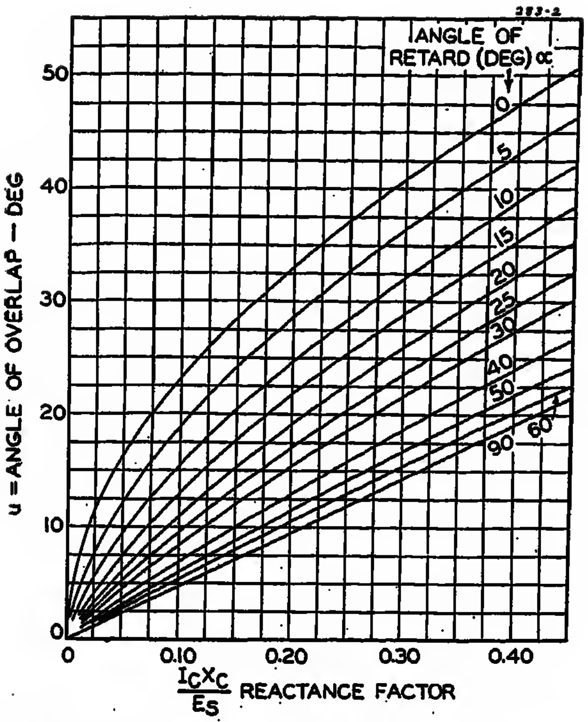

Figure 2. Angle of overlap—characteristic curves. $P=3$

$$\cos(u+\alpha)=\cos\alpha-\frac{I_C X_C}{\sqrt{2}E_S \sin\frac{\pi}{P}}$$

when $\alpha=0$

$$\cos u=1-\frac{I_C X_C}{\sqrt{2}E_S \sin\frac{\pi}{P}}$$

With this background of confusion a new term seems the only solution. A further objection to the terms "full-wave" and "half-wave" is the fact that they are accurately descriptive only in the case of 180-degree conduction, which is not widely used in power rectifiers. The terms "double-way" and "single-way" describe accurately the physical difference which separates the two classes of rectifiers and results in different general relations for several current and voltage ratios.

The "simple rectifier" is an essential step in the development of the more complicated rectifier circuits, and it seems necessary to employ this term.

The definition of the number of phases as given is required if a general relation for the d-c voltage is to be employed. This definition is logical and consistent. Unfortunately the biphase rectifier as here defined has frequently been classed as a single-phase rectifier.

The "multiple rectifier" is here restricted to the case of several simple rectifiers operating in parallel in such a way that their d-c voltage ripples do not coincide. This is a unique arrangement in rectifier practice which improves the operation on both the a-c and d-c sides. Some name for this type of rectifier is needed.

The effect of commutating reactance in causing d-c voltage regulation is a source of much confusion. It is to be hoped that an exact definition of commutating reactance may help to dispel some of this confusion.

Reactance Factor

The methods employed in analyzing rectifier circuits and the formulas for rectifier-circuit characteristics have been quite thoroughly covered in the literature and are now well understood. However, no standard procedure has been devised for making the circuit calculations or presenting the calculated data, and as a result

Per-unit base amplitude of fundamental with no overlap

the routine calculation of rectifier characteristics has been more laborious than necessary. Furthermore, with the lack of a standard method for presenting the calculated results, it is difficult to make comparisons between the different types of circuits.

Some attempts have been made to express the rectifier characteristics as a function of a single-circuit factor.[2–5] This work has indicated the usefulness of a factor which combines the current, reactance, and voltage constants of the circuit in a single quantity, although the use of such a quantity has been limited largely to the determination of the harmonic content of the d-c voltage and the a-c line current waves.

This paper proposes the definition and advocates the general use of a single factor of this kind for the purpose of simplifying the description and calculation of the operating conditions of any rectifier circuit. It is further proposed that this factor be known as the "reactance factor" and that it be the product of the direct current commutated I_C and the line-to-neutral commutating reactance X_C divided by the rms value of the transformer secondary line-to-neutral voltage E_S, that is, I_CX_C/E_S.

Circuit Analysis

The rectifier-circuit characteristics depend to a large degree upon the effect of reactance in causing an overlapping of the anode current waves The amount of overlapping is given by the well-known equation for the angle of overlap, which follows:

$$\cos u = 1 - \frac{I_CX_C}{\sqrt{2}E_S \sin \frac{\pi}{P}}$$

With phase control, the overlap equation is

$$\cos (u+\alpha) = \cos \alpha - \frac{I_CX_C}{\sqrt{2}E_S \sin \frac{\pi}{P}}$$

It will be noted that the angle of overlap is a function of the "reactance factor," I_CX_C/E_S. Therefore, for any given value of the reactance factor, the angle of overlap will always be the same, regardless of the particular current, voltage, or reactance constants of the circuit. From this, it follows that if the magnitudes of the current and voltage waves in the rectifier circuit are expressed in per-unit quantities upon a suitable base, the configuration of the current and voltage waves will be the same for any given value of the reactance factor, regardless of the voltage, current, and reactance constants of the circuit. Inasmuch as the reactance factor enters directly in the determination of the overlap, and may be calculated readily from the circuit constants, it provides a convenient quantity for indicating the functional relations between the rectifier characteristics and the circuit constants.

The use of per-unit quantities greatly facilitates the calculation of rectifier circuits. One set of characteristic curves may be prepared for each type of rectifier circuit, if the circuit constants are represented by the reactance factor I_CX_C/E_S and the rectifier characteristics, such as voltage drop, harmonic voltages, and currents, interphase voltages, power factor, and so forth are expressed in per unit. Using such a procedure, it is possible to reduce rectifier calculation to a minimum, calculating the characteristic curves only once. For example, to obtain information regarding any specific circuit, its reactance factor is first calculated from the circuit constants. Reference is then made to the characteristic curves, and the corresponding per-unit value of the desired characteristic determined. The actual numerical value may be calculated by multiplying this per-unit value by the base value. The theoretical d-c voltage E_{do} and the rms value of the transformer secondary line-to-neutral voltage E_S are convenient bases for calculation of per-unit voltages, while the direct current commutated I_C and the theoretical a-c line current I_L are convenient bases for per-unit currents.

The list of rectifier formulas and the accompanying curves show a few of the more commonly used rectifier characteristics, with their equations reduced to their simplest form in terms of reactance factor and the calculated values given on a per-unit basis. These curves illustrate the application of the reactance factor to one type of circuit. Characteristic curves for other types of circuits may readily be prepared from the equations.

Rectifier Formulas

1. Angle of overlap u (Figure 2)

$$\cos (u+\alpha) = \cos \alpha - \frac{1}{\left(\sqrt{2}\sin\frac{\pi}{P}\right)} \cdot \frac{I_CX_C}{E_S}$$

(with no phase control)

$$\cos u = 1 - \frac{1}{\left(\sqrt{2}\sin\frac{\pi}{P}\right)} \cdot \frac{I_CX_C}{E_S}$$

2. Overlap factor $\sqrt{1-cf(u,\alpha)}$ (Figure 3)
where

$$f(u,\alpha) = \frac{1}{2\pi}\left[\frac{\sin u(2+\cos(u+2\alpha)) - u(1+2\cos\alpha\cos(u+\alpha))}{(\cos\alpha - \cos(u+\alpha))^2}\right]$$

3. D-c voltage drop E_X

$$E_X = \frac{I_CX_CP}{2\pi}$$

(in per unit on base E_{do})

$$\frac{E_X}{E_{do}} = \frac{1}{2\sqrt{2}\sin\frac{\pi}{P}} \cdot \frac{I_CX_C}{E_S}$$

4. Power factor PF (Figure 4)

$$PF = K \cdot \frac{\left(\cos\alpha - \frac{E_X}{E_{do}}\right)}{\sqrt{1-cf(u,\alpha)}}$$

5. Harmonics in d-c voltage (Figure 5)
Amplitude of sine components

$$a_m = \frac{E_{do}}{2}\cos m\pi \times \left[\frac{\sin(mq+1)(u+\alpha)+\sin(mq+1)\alpha}{mq+1} \quad \frac{\sin(mq-1)(u+\alpha)+\sin(mq-1)\alpha}{mq-1}\right]$$

Amplitude of cosine components

$$b_m = \frac{E_{do}}{2}\cos m\pi \times \left[\frac{\cos(mq+1)(u+\alpha)+\cos(mq+1)\alpha}{mq+1} - \frac{\cos(mq-1)(u+\alpha)+\cos(mq-1)\alpha}{mq-1}\right]$$

Amplitude of resultant

$$h_m = \sqrt{a_m^2+b_m^2}$$

All amplitudes may be expressed in per-unit values by dividing the above equations by E_{do}.

6. Harmonics in a-c line current (Figures 6 and 7)
Amplitude of sine component of fundamental

$$a_1 = \frac{\sqrt{3}I}{\pi}[\cos\alpha + \cos(u+\alpha)]$$

Amplitude of cosine component of fundamental

$$b_1 = \frac{\sqrt{3}I}{\pi}\left[\frac{{}^1/_2\sin(2u+2\alpha) - {}^1/_2\sin 2\alpha - u}{\cos\alpha - \cos(u+\alpha)}\right]$$

Amplitude of the resultant of the fundamental components

$$h_1 = \sqrt{a_1^2+b_1^2}$$

Temperature-Aging Tests on Class-A-Insulated Fractional-Horsepower Motor Stators

J. A. SCOTT
MEMBER AIEE

B. H. THOMPSON
NONMEMBER AIEE

Synopsis: Temperature-aging data are presented on class-*A*-insulated fractional-horsepower motor stators, determined at 200, 160, and 135 degrees centigrade. Of particular interest is the relative aging time to failure at the different temperatures and the resultant temperature-aging curve. This curve shows a slope of 10 to 15 degrees centigrade increase in temperature to halve the aging time to failure in the temperature range covered, 135 to 200 degrees centigrade.

THE question of the rate at which motor insulation ages due to the temperature to which it is exposed was brought actively to the fore several years ago[1–7] by discussion concerning methods of rating machines whose normal load cycle was intermittent. Many such are encountered in air conditioning, welding, and other applications governed by automatic controls. In such intermittent operation the temperature of the motor varies, depending upon the load cycle to which it is subjected. It is desired that the effect of such temperature variation be not greater, as regards aging of the insulation, than the continuous temperature for which the motor was designed. In order to know this, it is necessary to have a knowledge of the rate of aging at different temperatures. This is really a demand for a knowledge of the aging temperature characteristic of insulation such as is shown in Figure 6.

To obtain such a temperature-aging characteristic, we must carry out our tests at more elevated temperatures, starting perhaps much higher than those in which we are interested, and, through simultaneously started tests at a number of temperatures between this and our operating range, gradually accumulate the data from which our life-temperature curve may be drawn as far down toward the operating range as the results lead us to continue.

Method of Test

The question of type of test must next be answered. The actual operation of motors of even moderate size, under load in numbers sufficient to yield statistically reliable results, becomes costly and subject to a number of causes of motor failure, such as bearings, starting switches, and so forth.

If we wish to study the influence of temperature on the insulation alone, it is desirable that the tests be conducted so that they are not complicated by these additional sources of failure which arise in an actual running test.

In the past[1] this has been attempted by constructing samples of a variety of kinds, aging them at a number of selected test temperatures, and periodically making a number of tests and measurements of properties, usually destructive. The study of these results enabled one to plot the deterioration of these arbitrarily selected properties in terms of time and temperature, and, with some approximation, to arrive at a temperature-aging relation. One of the present authors gave the results of such a study several years ago.[1] Such tests involve doing things to the sample of insulation such as breaking it, bending it, or otherwise maltreating it. Since service does not involve these factors in similar kind or degree, one usually finished his labors with a curiosity as to

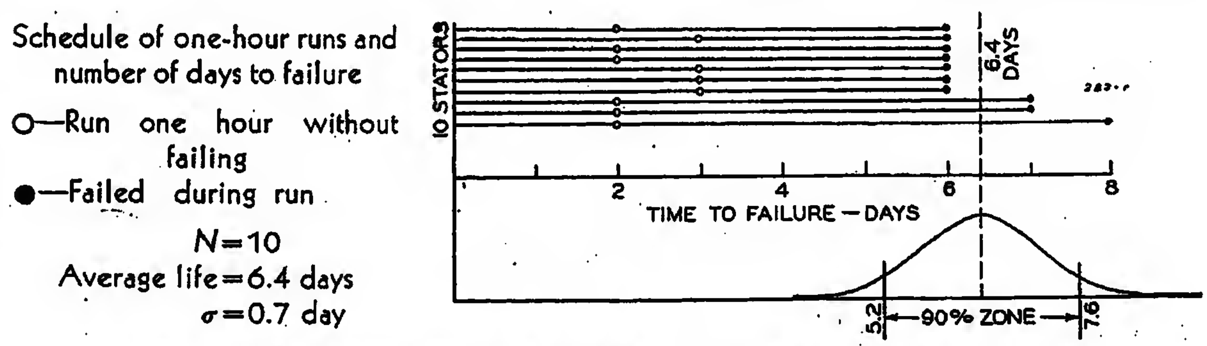

Figure 1. 200 degrees centigrade aging tests on class-*A*-insulated stators, type *N*

Paper 42-82, recommended by the AIEE committee on electrical machinery and standards co-ordinating committee 4 for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted March 4, 1942; made available for printing April 2, 1942.

J. A. SCOTT and B. H. THOMPSON are with the general engineering laboratory, General Electric Company, Schenectady, N. Y.

Amplitude of sine component of higher harmonics

$$a_m=\frac{4I}{\pi}\cdot\frac{\sin(m\pi/3)}{m(m^2-1)(\cos\alpha-\cos(u+\alpha))}\times$$
$$[\cos\alpha\cos m\alpha-\cos(u+\alpha)\cos m(u+\alpha)+m\sin\alpha\sin m\alpha-m\sin(u+\alpha)\sin m(u+\alpha)]$$

Amplitude of cosine component of higher harmonics

$$b_m=\frac{4I}{\pi}\cdot\frac{\sin(m\pi/3)}{m(m^2-1)(\cos\alpha-\cos(u+\alpha))}\times$$
$$[\cos\alpha\sin m\alpha-\cos(u+\alpha)\sin m(u+\alpha)-m\sin\alpha\cos m\alpha+m\sin(u+\alpha)\cos m(u+\alpha)]$$

Amplitude of the resultant for each of the higher harmonics

$$h_m=\sqrt{a_m^2+b_m^2}$$

The amplitude of the fundamental of the theoretical line current wave, that is, with no phase control ($\alpha=0$) and no overlap ($u=0$) is

$$a_1=\frac{2\sqrt{3}I}{\pi}\qquad b_1=0$$

All amplitudes may be expressed in per-unit values using the amplitude of the fundamental with no phase control and no overlap as a base by dividing the above equations by $\frac{2\sqrt{3}I}{\pi}$.

what the actual service life at the test temperature might have been.

The present tests followed a course intermediate between the two alternatives outlined above, with the full recognition that the results could not be directly used to predict motor life in service, but hopeful that some light might be thrown on the temperature-aging relationship, even though only in a proportional manner. Recognizing that the completely wound and insulated stators of fractional-horsepower induction motors are both low cost and convenient specimens, and ones which represent a very widely used kind of class-*A* insulation, it was decided to use these for the test specimens. Exploratory tests and previous experience led us to choose aging temperatures of 200, 160, 135, and 115 degrees centigrade. To determine when these stators had temperature-aged to a nonserviceable condition, selected groups were removed from the aging ovens periodically and in turn assembled with the other parts of the motor (squirrel-cage rotor, end shields, bearings, and suitable switch arrangement), and subjected to an actual and severe operating test. This test consisted of a one-hour period of operation at no load, and approximately full-load heating, with a sudden and complete reversal in rotation from full speed every two minutes. On successful completion of this operation test the stators were restored to the aging oven for a continuation of the aging test. When the aging had proceeded to the point at which failures began to be experienced, tests were made more often. Proceeding in this way, an aging time was determined which reduced the insulation to such a state of embrittlement and crumbliness that physical separation was no longer afforded the conductors, and short circuits, or grounds, resulted. This aging time we call the time to failure of the insulation at that temperature for the specific conditions of the test.

Results

Figures 1, 2, and 3 show the results which have been obtained to date at 200, 160, and 135 degrees centigrade for one type of class-*A*-insulated stator, which we will, for purposes of identification, call *N*. Figures 4 and 5 show the results at 200 and 160 degrees centigrade on another type of class-*A*-insulated stator, which we will designate *M*1. Figures 8 and 9 show the results at 200 and 160 degrees centigrade on another type of class-*A*-insulated stator, designated *M*2. Stators *M*1 and *M*2 are similar except for winding differences.

These figures are similarly drawn and show:

1. The time for each stator at which test runs were made.

2. The time of the test run at which failure occurred; this is called the "time to failure" at that stator.

3. The average time to failure of the group of stators tested at each temperature.

4. The root-mean-square deviation, σ, of the time to failure of the individual stators from that of the group average. This is the customary statistical measure of the dispersion of test results.

5. A normal distribution curve calculated from the root-mean-square deviation, σ.

6. The width of the 90 per cent zone or the time interval during which approximately 90 per cent of all the motors fail. This total width is 3.29 σ.

We have purposely placed emphasis in this presentation on the normal variation in the life span, here at least 2 to 1. Life is inherently a variable thing, and engineers must accept this in their motors as they do in their own lives.

Having determined the "time to failure" of these three types of stators at several temperatures, the data can now be plotted in the form of the temperature-aging characteristic listed at the start as the object of our investigation. The average times to failure at the several test temperatures are plotted opposite each temperature. Figure 6 is such a curve for the type *N* stators from 200 down to 135 degrees centigrade (with another point at 115 degrees centigrade due to come at some time in the future). Figure 7 is for the type *M*1 stators, covering only the two temperatures—200 and 160 degrees

centigrade, and similarly Figure 10 for the type *M*2 stator.

At the present time after 660 days elapsed time since starting, the tests on the *M*1 stators at 135 degrees centigrade have yielded five failures in 30 stators, 17 per cent. The 135 degrees centigrade point may thus be seen as lining up fairly well with the trend outlined by the two higher temperatures.

Conclusions

A method of studying the temperature-aging characteristics of class-*A*-insulated fractional-horsepower motor stators has been presented. The results available to date cover the tests made at 200 and 160 degrees centigrade and some results at 135 degrees centigrade. The tests are being continued at lower temperatures so that this paper is in the nature of a progress report. The following general statements can be made as to the comparative effects of various temperatures.

1. Below 200 degrees centigrade there is no temperature which, if exceeded, causes an abrupt failure of the insulation; that is, the temperature-aging curve of the insulation of these motors is uniform and continuous.

2. Operation at higher temperatures than normal results in a shortening of the time to failure of the insulation. Figures 6 and 7 agree that a temperature increment of 10 or 11 degrees centigrade is required to cut the time to failure of the stators in half. This agrees nicely (without the implications of accuracy) with the eight-degree value widely used for transformer insulations.[8,9] Figure 8 gives a corresponding temperature increment of 15 degrees centigrade. The value has not yet been established below the 135 degrees centigrade range in these tests.

3. The width of the "90 per cent zone" (or zone containing 90 per cent of the values) is shown to emphasize the normal spread of results. Its width is obtained from Figures 1 through 5.

4. The normal time to failure of the insulation of duplicate specimens has a spread of 2 to 1.

It will be noted that no conclusion as to the probable actual operating life of the insulation for any given temperature has been drawn from these tests. This is for the reason that, as pointed out previously, the tests have been made in such a manner as to single out the effects due to temperature and to exclude other effects which would be met with in actual operation of the motor in service. This might include the effect of moisture, the effect of dirt, oil, or various gases in the atmosphere, the effect of vibration which might

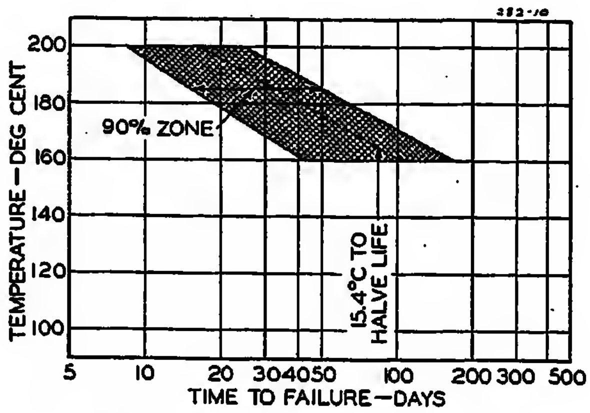

Figure 10. Temperature-aging characteristic, class-*A*-insulated stators, type *M*2

be encountered with various types of loads, changes in ambient temperature, intermittent loading, and other factors, some of which may tend to increase and others to decrease the life in actual operation.

F. ZWEIG
ENROLLED STUDENT AIEE

J. G. CLARKE
ASSOCIATE AIEE

Synopsis: In the preceding papers[1] of this series a method was described for determining the circle diagram and predicting the characteristics for the brush-shifting motor as it is used when the brushes are shifted to control speed. This paper extends the earlier work to show how the motor can be used to correct power factor. The range and limitations for this condition of operation are revealed from the circle diagram of the motor which has been developed and verified experimentally. Characteristics of the motor when used in this manner are presented.

Brush Settings for Power-Factor Correction

UNDER normal operation of the brush-shifting a-c motor, the two sets of brushes which carry the secondary current of the stator coils are coupled mechanically so that one set of brushes cannot be moved without a corresponding motion of the other in the opposite direction. Thus, the voltage introduced in the secondary circuit from the commutator, while it may vary in magnitude with speed adjustment, does not vary in phase relative to the voltage induced in the stator winding. Figure 1a is a schematic diagram of a two-pole, three-phase brush-shifting motor. The horizontal projections of the vectors represent the instantaneous voltages induced in the adjacent coils. The flux, ϕ, rotates at slip speed, say clockwise, relative to the stator. Brushes A_1, A_2, and A_3 are mounted rigidly on an adjustable frame so that a motion of the frame will move them all through the same angle; brushes B_1, B_2, and B_3 are mounted similarly and also move in unison. These two frames are coupled mechanically so that when making speed adjustments, the brushes are always equal distances from the center lines drawn between them. The points of maximum and minimum potential about the commutator rotate with the field relative to the stator so that the voltages at the brush pairs are at slip frequency. If the center lines drawn midway between the brushes A_1 and B_1, A_2 and B_2, and so on, remain fixed relative to the stator, the voltages collected from the commutator are fixed in phase relative to the induced voltage in the stator. The magnitude of this voltage, E_{11}, will vary with the degree of separation of the brushes but is approximately independent of speed for a given primary voltage. Interchanging the positions of the brushes A_1 to B_1, B_1 to A_1, and so on, will change the phase by 180 degrees, that is, reverse the polarity of the commutator voltage, E_{11}.

If the coupling between the frames supporting each set of brushes is removed, either set can be moved in either direction independently of the other. The various possible brush settings provide the motor with an extremely wide range of characteristics. If the flux, ϕ, is rotating clockwise relative to the stator, and the two frames are moved opposite to the direction of rotation of the flux with respect to the stator by 90 degrees from the position shown in Figure 1a (see Figure 1b), the voltage, E_{11}, will be advanced by 90 degrees inphase with respect to the voltage, E_2, induced in the stator. This procedure will advance the center lines designating the brush positions by 90 degrees relative to the stator. The phase of the voltage, E_{11}, collected from the commutator can be varied only by altering the mean position of the brushes as indicated by these center lines.

Figure 2a shows the voltage, E_2, induced in one phase of the secondary when brushes are set as in Figure 1a, that is, when E_2 is in opposition to E_{11}. Figure 2b shows what occurs when both sets of brushes are rotated in a direction so as to advance E_{11} by 90 degrees as illustrated in Figure 1b. Since both voltages, E_2 and E_{11}, are in series, and force currents through the same impedance, I_2 and I_{11} of Figure 2b must lag their voltages by the same angle. I_2 and I_{11} are the currents flowing in the secondary resulting from the voltages E_2 and E_{11} respectively. The two currents and their circle loci are shown. If the center lines are allowed to remain in their new positions of Figure 1b, and the two sets of brushes are moved across the center lines, that is, brushes A and B interchange positions, the voltage, E_{11}, from the adjusting winding will be shifted in phase by 180 degrees from the direction shown in Figure 2b, and E_{11} will lead E_2 by 90 degrees as shown in Figure 2c. The current I_2 lags the voltage E_2 by the same angle that the current I_{11} lags the voltage E_{11}.

If the motor is designed so that the effective number of series turns in the adjusting winding is half the effective number of stator turns, the largest value of the voltage, E_{11}, is half the stator voltage, E_2 at standstill. If in Figures 2a, 2b, and 2c, the brushes of each phase are spaced 180 electrical degrees apart on the commutator, E_{11} will have its largest

value. The largest value of I_{11} (its value at synchronous speed) and the largest value of I_2 are as determined in part I of this series. The resultant secondary current is the vector sum of I_2 and I_{11}, and, as is shown in Figures 2b and 2c, this current is never zero whenever E_{11} has a quadrature component relative to E_2. The locus of the extremity of the vector representing the sum of I_2 and I_{11} is derived in appendix A, and is found to be another circle shown in wide lines in Figures 2b and 2c.

In Figure 2b it is evident that the total current flowing in the secondary lags the voltage, E_2, induced in the secondary by a relatively large angle at all times. In Figure 2c the total secondary current leads the voltage, E_2, over a considerable portion of the circle. These features enable the machine to generate power at a lagging power factor when used as a generator excited from a synchronous source. Furthermore it can supply these lagging loads over a wide range of speeds. This paper is primarily concerned with power-factor correction, and, therefore, will deal only with conditions illustrated in Figure 2c, rather than those of Figure 2b.

Primary Currents With Power-Factor Correction

The phase current in the primary of this motor can be determined from a knowledge of the magnetomotive forces in the adjusting winding and the stator winding for different values of slip. For each current I_2 and I_{11}, shown in Figure 2c, there is a corresponding magnetomotive force produced in each of these windings. The magnetomotive force produced by the current I_{11}, of Figure 2c, in the stator is represented by the vector oa of Figure 3. Likewise, the magnetomotive force produced by the current I_2 of Figure 2c in the stator is represented by the vector ob of Figure 3. The total magnetomotive force produced in the stator by the currents I_2 and I_{11} is therefore the vector oc of Figure 3, which is the sum of oa and ob. The locus of this stator magnetomotive force, oc, is defined by the circle dce. With this particular brush setting on a three-phase motor, there is a magnetomotive force produced by these same currents, I_2 and I_{11}, flowing in the adjusting windings. This magnetomotive force is 90 degrees behind the magnetomotive force that these currents produce by flowing in the stator. The vector oc' therefore represents the adjusting winding magnetomotive force when the stator magnetomotive force is oc. The locus of the vector oc' is the circle $d'c'e'$. The proportions of this circle are such that

$$\frac{oc'}{oc} = \frac{od'}{od} = \frac{oe'}{oe} = \frac{N_{AW}}{N_2}$$

With the brushes set as described here, motor action results only at speeds below synchronism. For such speeds, magnetomotive forces in the stator and adjusting windings are cancelled by equal and opposite magnetomotive forces in the primary. In Figure 3, the stator magnetomotive force co is counteracted by the component primary magnetomotive force oc'', and the adjusting winding magnetomotive force oc' is counteracted by the component primary magnetomotive force oc'''. The total magnetomotive force of the primary that is necessary to counteract the magnetomotive forces of the adjusting winding and the stator is the sum of oc'' and oc''', which is oc''''. The locus of the extremity of this vector oc'''' is defined by the circle $d''''c''''e''''$. The primary magnetomotive force must be produced by a current which is proportional to and in phase with oc''''. In Figure 3 this current is shown as the vector I_{1L}. The locus of I_{1L} is another circle having a center coincident with the center of the circle $d''''c''''e''''$. The locus of the primary current can be obtained by adding to this current I_{1L}, the current po. The current po is the no-load current taken by the motor when the brushes are set to make

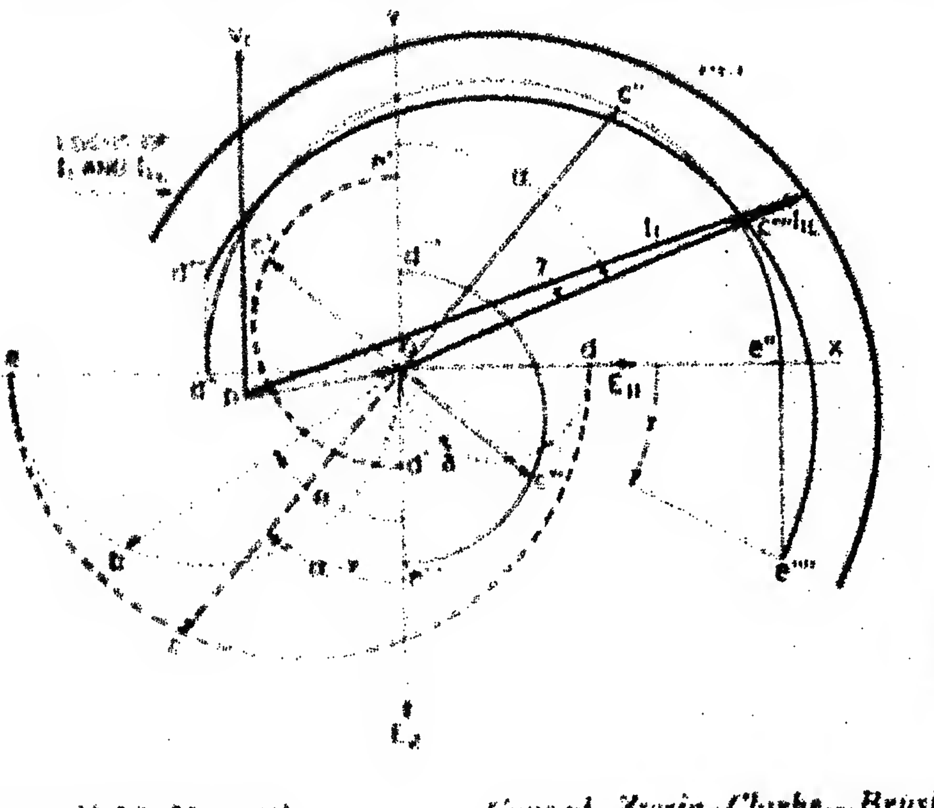

Figure 3. Vector diagram of motor when used to correct power factor

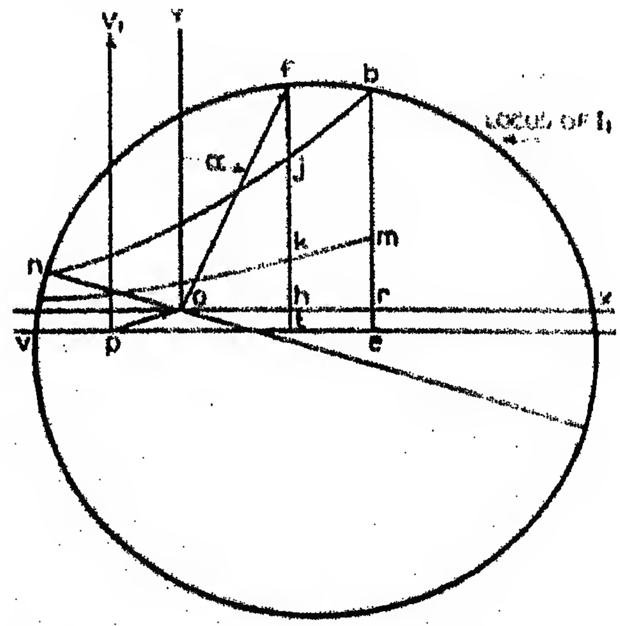

Figure 4. Characteristic vector diagram of motor (primary), E_{11} 90 degrees ahead of E_2

E_{11} zero. The total current taken by the primary, shown on this diagram, is the vector I_1, and the locus of its extremity with respect to the point p is defined by the same circle that defines I_{1L}. This circle has a diameter passing through the point o at an angle γ, the tangent of which is equal to the ratio of the effective number of turns in the adjusting winding between brushes to the effective number of stator turns, N_{AW}/N_2.

A change in the brush setting will change the total resistance and reactance of the total secondary circuit and, consequently, change the diameters of both the circle loci of I_{11} and I_2. With the brushes set to obtain the characteristics illustrated in Figure 3, the motor will take a leading current, I_1, with respect to the impressed voltage, V_1 over a considerable range of loads. For such conditions of load, it can be used to correct the power factor of the line supplying the motor.

Determination of Characteristics When Motor Is Used to Correct Power Factor

On the basis of the theory and assumptions of part I of this series, it was shown that the currents I_2 and I_{11} could be expressed thus:

$$I_2=\frac{{}_{ss}E_2S}{\sqrt{(R_2+R_{AW})^2+S^2({}_{ss}X_2+{}_{ss}X_{AW})^2}} \qquad (1)$$

$$I_{11}=\frac{E_{11}}{\sqrt{(R_2+R_{AW})^2+S^2({}_{ss}X_2+{}_{ss}X_{AW})^2}} \qquad (2)$$

Therefore

$$\frac{I_2}{I_{11}}=\frac{{}_{ss}E_2S}{E_{11}} \qquad (3)$$

If the brushes supplying each stator phase are set so that E_{11} equals half ${}_{ss}E_2$, as is illustrated in Figures 2b and 2c, then

$$\frac{{}_{ss}E_2S}{E_{11}}=2S \qquad (4)$$

At standstill S equals one, and

$$\frac{I_2}{I_{11}}=2 \qquad (5)$$

Since the ratio of I_{2max} to I_{11max} is, from equations 1 and 2,

$$\frac{I_{2max}}{I_{11max}}=\frac{{}_{ss}E_2}{E_{11}}\left(\frac{R_2+R_{AW}}{{}_{ss}X_2+{}_{ss}X_{AW}}\right) \qquad (6)$$

a knowledge of the ratio of R_2+R_{AW} to ${}_{ss}X_2+{}_{ss}X_{AW}$ is all that is required to determine the diameters of the two component circles, I_2 and I_{11}, and from them the resultant circle defining the extremity of the primary current vector as described above. At synchronous speed I_2 is zero and I_{11} is maximum. If the primary currents for standstill and for some other speed are known, it is possible to determine the characteristic copper loss curves for the circle diagrams as it is done for the two-element induction motor. At standstill all the energy in excess of the no-load losses is lost in the primary and secondary windings, while for other speeds these losses vary as the square of that component of the primary current which is labelled I_{1L} in Figure 3. This involves the same approximation with regard to losses that is made in plain induction motor theory; namely, that the primary copper loss varies as the square of the load component of primary current rather than as the total primary current. The error introduced by this approximation in the two-element induction motor is negligible. The error due to this approximation is somewhat larger in this motor than in the two-element motor, but not so large as to invalidate the method.

The characteristic copper loss curve, bjn, is shown in Figure 4. The point, m, determined by measurement of primary resistance divides rb into components proportional to the primary and secondary losses. The current pb produces a primary loss which is represented by mr. The loss for any primary current, pf, can be represented by kh which in turn can be determined by the relationship

$$kh=mr\left(\frac{pf}{pb}\right)^2$$

The secondary copper loss represented by jk can be found in similar fashion.

The slip is a function of the angle $(\alpha-\gamma)$ by which I_2+I_{11} lags E_2. This is also the angle between the vector oc in Figure 3, representing the magnetomotive force due to I_2+I_{11} in the stator windings, and the vector labelled E_2, the voltage induced in the stator by the air-gap flux. The angle α is the phase angle between the voltage V_1 and the primary-current component I_{1L}, or the magnetomotive force oc''''. This angle varies with slip. The angle γ is determined by its tangent which equals N_{AW}/N_2; thus, γ is independent of slip. The relation between slip and $(\alpha-\gamma)$ is given by

$$\tan(\alpha-\gamma)=\frac{1-\left(\dfrac{1}{\tan\gamma}\right)^2\left(\dfrac{I_{11max}}{I_{2max}}\right)S^2}{\left(\dfrac{1}{\tan\gamma}\right)\left(\dfrac{I_{11max}}{I_{2max}}+1\right)S} \qquad (7)$$

This equation is developed in appendix B and may be used to determine the slip at any point f (see Figure 4) on the circle defining the extremity of I_1. The speed may be obtained, since speed equals synchronous speed times the quantity, $(1-S)$. If the motor is loaded so that the primary draws a phase current pf in Figure 4, the slip will have some value,

———— Characteristics predicted from the circle diagram

S, corresponding to the point, f, and can be determined from measurements of α and equation 7.

If the impressed voltage per phase is represented by V_1, then for the input current, pf:

(1) Input $=(tf)\,V_1$ watts per phase
(2) Output $=(jf)\,V_1$ watts per phase
(3) Iron loss, friction, and windage $=(th)\,V_1$ watts per phase
(4) Primary copper loss $=(hk)\,V_1$ watts per phase
(5) Copper loss of stator and adjusting winding $=(kj)\,V_1$ watts per phase
(6) Efficiency $=\frac{jf}{tf}$ times 100 per cent
(7) The slip is determined by the angle between of and V_1 (or between of and oy) using the equation (7)
(8) Speed $=(1-\text{slip})$ (synchronous speed in rpm) in rpm
(9) Torque $=$

$$\frac{(jf)\,V_1\,(\text{number of phases})\,33{,}000}{2\pi\,(\text{speed in rpm})\,746}$$

in pound-feet

The output torque is zero at the point n in Figure 4. For slips less than that at n, power must be supplied to the machine through the shaft. At the point v, slightly above synchronous speed, all the power into the machine comes by way of the shaft.

Results of Test With Leading Commutator Voltage

In order to check the validity of the foregoing theory, a test was made on a General Electric BTA, 550–1,650-rpm. 4.17–12.5-horsepower, six-pole, 60-cycle motor. With the brushes set so that the commutator voltage was ahead of the induced voltage of the stator by 90 degrees, the gap between brushes was fixed so that the commutator voltage was 7.8 per cent of the stator voltage at standstill. The results of the load test and the blocked rotor test are indicated by the encircled points on the circle diagram of Figure 5a. The theoretical primary-current circle locus was determined from three no-load readings as described in parts I and II of this series. It is observed that the diameter of the circle lies beneath the horizontal chord by an angle of approximately ten degrees. Only about five degrees of this shift is accounted for by γ (the shift caused by the magnetomotive force of the adjusting winding). The remainder can be attributed directly to the leakage reactance of the primary circuit which, with high current values, causes the induced voltage, E_2, in the secondary to lag the primary voltage. Figure 5 shows the results predicted theoretically in comparison with the experimentally determined results.

Conclusions

The advantages of power-factor correction on a line supplying a motor are well-known. Advantages of power-factor correction to the motor itself result only when these corrections increase the efficiency of the motor or its horsepower capacity. The effect of power-factor correction on the efficiency of this motor is illustrated in Figure 6. Each of the efficiency curves shown here was obtained by a load test with brush settings that provided synchronous speed at no load.

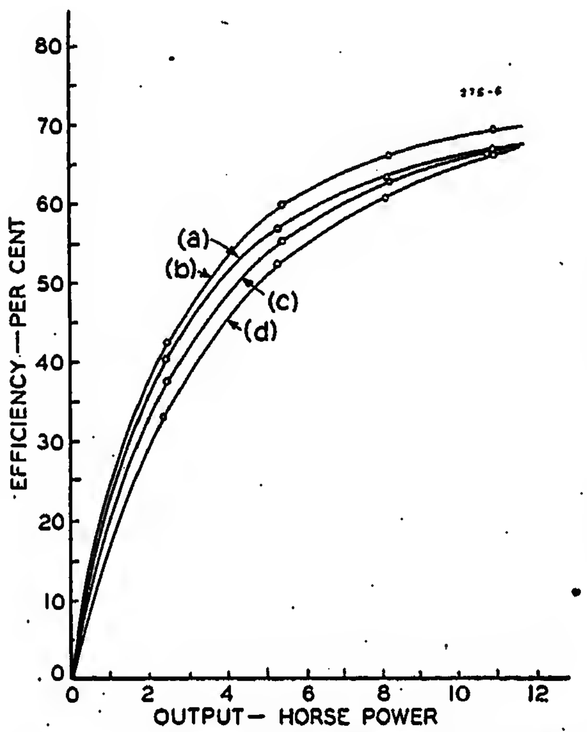

Figure 6. Efficiency as affected by power-factor correction

Brushes separated
(a). 0 electrical degrees
(b). 6 electrical degrees
(c). 12 electrical degrees
(d). 18 electrical degrees

It is evident that the addition of a small value of E_{11} (two per cent of its maximum value, that is, a brush separation of approximately five electrical degrees) to improve power factor will increase the efficiency only slightly. Further increases in E_{11} will cause excessive secondary currents and reduce the efficiency. It is evident from the theory developed here that if the primary exciting current is to be reduced the secondary must carry an additional exciting current to compensate for the reduction in the primary. Maximum efficiency for a given load will occur when the voltage E_{11} is adjusted so as to make the total copper losses in the motor a minimum. Any exciting current flowing in the secondary must be supplied through the commutator. For some conditions of load this additional current will cause poor commutation. Thus there is little to be gained from standpoint of the motor by setting its brushes to improve its power factor beyond the values obtained when E_{11} is made opposite to E_2.

From information revealed in Figure 5 it is quite evident that the motor can be adjusted to draw various amounts of leading current. This feature provides the possibility of improving the regulation and efficiency of the line supplying the motor. These curves of Figure 5 also show the relative high power factor obtainable on the brush-shifting motor as compared with the ordinary well-known two-element induction motor.

Appendix A

It can be shown that the locus of the sum of I_2 and I_{11} is a circle as follows:

The line OP of Figure 2c indicates the current vector representing the sum of I_2 and I_{11}. Let x equal the horizontal component of OP, and y equal the vertical component of OP. Since I_2 and I_{11} are always at right angles

$$OP^2=I_2^2+I_{11}^2$$

or $$OP^2=I_2^2+I_{11}^2I_{2max}I_{11max}-I_{2max}I_{11max}(\sin^2\theta+\cos^2\theta)$$

But $I_2=I_{2max}\sin\theta$

$$I_{11}=I_{11max}\cos\theta$$

$$OP^2=I_2I_{2max}\sin\theta+I_{11}I_{11max}\cos\theta+I_{2max}I_{11max}-I_{2max}I_{11}\cos\theta-I_{11max}I_2\sin\theta$$

$$OP^2=I_{2max}(I_2\sin\theta-I_{11}\cos\theta)-I_{11max}(I_2\sin\theta-I_{11}\cos\theta)+I_{2max}I_{11max}$$

$$OP^2=(I_{11max}-I_{2max})(I_{11}\cos\theta-I_2\sin\theta)+I_{2max}I_{11max}$$

but $x=I_{11}\cos\theta-I_2\sin\theta$

and $OP^2=x^2+y^2$

$$x^2+y^2=(I_{11max}-I_{2max})x+I_{2max}I_{11max}$$

$$y^2+x^2+x(I_{2max}-I_{11max})+\frac{(I_{2max}-I_{11max})^2}{4}=I_{2max}I_{11max}+\frac{(I_{2max}-I_{11max})^2}{4}$$

$$y^2+\left(x+\frac{I_{2max}-I_{11max}}{2}\right)^2=\left(\frac{I_{2max}+I_{11max}}{2}\right)^2$$

This is the equation of a circle of radius $(I_{2max}+I_{11max}/2)$ with its center at $x=-\frac{1}{2}(I_{2max}-I_{11max})$ and $y=0$. A similar method may be used to show that the locus of P in Figure 2b is also a circle.

Appendix B

In order to establish equation 7, it is necessary to refer to Figure 3. In this figure $(\alpha-\gamma)$ is the angle by which oc lags E_2. The vector oc represents the magnetomotive force produced in the stator by I_2+I_{11}. The magnetomotive forces produced in the stator by I_2 and I_{11} separately are ob and oa respectively. The currents I_{11}, I_2, and

I_2+I_{11} with proper change in scale could be represented by oa, ob, and oc. If this is done, and if the point c is determined by the rectangular co-ordinates x and y, then

$$\tan(\alpha-\gamma)=-\frac{x}{y}$$

Since oc now represents I_{2max} and od represents I_{11max}, if θ is the power factor angle of the secondary circuit:

$$I_2=I_{2max}\sin\theta$$
$$I_{11}=I_{11max}\cos\theta$$

In Figure 3

$$x=I_2\sin\theta-I_{11}\cos\theta$$
$$y=I_2\cos\theta+I_{11}\sin\theta$$

so

$$\tan(\alpha-\gamma)=-\frac{x}{y}=\frac{I_{11}\cos\theta-I_2\sin\theta}{I_{11}\sin\theta+I_2\cos\theta}$$

or

$$\tan(\alpha-\gamma)=\frac{1-\dfrac{I_2}{I_{11}}\tan\theta}{\tan\theta+\dfrac{I_2}{I_{11}}}$$

From above

$$\frac{I_2}{I_{11}}=\frac{I_{2max}}{I_{11max}}\tan\theta$$

and from equation 3,

$$\frac{I_2}{I_{11}}=\frac{{}_{ss}E_2S}{E_{11}}$$

therefore

$$\tan\theta=\frac{I_{11max}}{I_{2max}}\left(\frac{{}_{ss}E_2S}{E_{11}}\right)$$

Since $\dfrac{E_{11}}{{}_{ss}E_2}=\dfrac{N_{AW}}{N_2}=\tan\gamma$, it follows that

$$\tan\theta=\frac{I_{11max}}{I_{2max}}\left(\frac{S}{\tan\gamma}\right)$$

$$\tan(\alpha-\gamma)=\frac{1-\left(\dfrac{1}{\tan\gamma}\right)^2\left(\dfrac{I_{11max}}{I_{2max}}\right)S^2}{\left(\dfrac{1}{\tan\gamma}\right)\left(\dfrac{I_{11max}}{I_{2max}}+1\right)S}$$

Appendix C. List of Symbols

E_{11}—Voltage generated in adjusting winding between brushes supplying one phase of stator

E_2—Voltage induced in one phase of stator

${}_{ss}E_2$—Stator voltage at standstill

ϕ—Total flux produced by primary windings

α—Angle between V_1 and I_{1L}

γ—Angle $\tan^{-1}\dfrac{N_{AW}}{N_2}$

$(\alpha-\gamma)$—Phase angle between total secondary phase current and voltage induced in stator

I_{1L}—Load component of primary current

I_1—Total primary phase current

I_{11}—Current flowing in stator and adjusting winding resulting from the voltage E_{11}

I_2—Current flowing in stator and adjusting winding resulting from the voltage E_2

I_{11max}—Maximum value of I_{11} and thus diameter of I_{11} circle

I_{2max}—Maximum value of I_2 and thus diameter of I_2 circle

N_2—Effective number of stator turns per phase

N_{AW}—Effective number of adjusting-winding turns per phase

R_{AW}—Resistance of adjusting winding per phase

R_2—Resistance of stator per phase

S—Per cent slip

θ—Phase angle between I_{11} and E_{11}, or I_2 and E_2

V_1—Voltage impressed upon one phase of primary

${}_{ss}X_{AW}$—Adjusting-winding reactance at standstill

${}_{ss}X_2$—Stator reactance at standstill

Synopsis: The preceding papers of this series presented an analysis of the brush-shifting a-c motor. Parts I and II dealt with the case when the voltage introduced into the stator coils from the commutator was collinear with the voltage induced in the stator coils by slip. Part III dealt with the case when the voltage introduced into the stator coils from the commutator was in quadrature with the induced voltage.

This paper extends the earlier analysis to include all the possible phase positions of the voltage introduced into the stator coils from the commutator. Under these conditions power factor and speed are controlled simultaneously. Methods for constructing the circle diagram for these conditions are given, and the characteristics of the motor predicted from the circle diagram are compared with the characteristics obtained by laboratory tests.

It has been demonstrated[1] that the locus of the extremity of the current vector of the brush-shifting motor is a circle when the brushes are set for speed adjustment, that is, when the voltage, E_{11}, collected from the commutator is collinear with the induced voltage, E_2, in the stator. Further analysis[3] has shown that when the brushes are set to make E_{11} perpendicular to E_2 for the purpose of power-factor correction, that the locus of the extremity of the current vector is also a circle. An analysis of these circles has provided[1,3] a means of explaining the operation of the motor for these special brush settings and of predicting all of its characteristics from no-load measurements.

The developments described above have been made from an analysis of:

(*a*). The secondary currents I_{11} and I_2 produced by the voltages E_{11} and E_2 respectively.

(*b*). The magnetomotive forces produced by these currents flowing in the stator and the adjusting winding.

(*c*). The resultant magnetomotive forces produced in the primary winding as a result of the secondary magnetomotive forces.

(*d*). The primary currents associated with the required primary magnetomotive forces.

This paper, employing the same methods of analysis, extends the theory of the brush-shifting motor and explains its operation when the brushes are shifted to control speed at the same time that the motor is used to correct the power factor of its supply. Specifically, it deals with the operation of the motor when the brushes are set to make E_{11} out of phase with the standstill value of E_2 by any angle β. An understanding of the developments presented here presupposes a knowledge of the material presented in the preceding papers of this series.[1-3]

Figure 1a shows a representative vector diagram of the secondary currents I_{11} and I_2, and their loci when they are produced by the voltages E_{11} and E_2 which are no longer collinear. Appendix A demonstrates that the sum of I_{11} and I_2 for this condition is a vector the locus of which is defined by another circle. This circle, representing the locus of the sum of I_2 and I_{11}, is shown in Figure 1a. For the condition shown, the machine will run above synchronous speed at no load, and the power factor will be leading. The current vectors will follow the circle loci shown when the speed is varied from synchronous speed through higher speeds to infinite speed—infinite negative slip. Since the diameter of the I_{11} circle coincides with E_{11}, swinging E_{11} to various phase positions moves the I_{11} circle along with it. For values of β ranging from 0 to 180 degrees, a current is reflected into the primary which has a leading component over the operating range of the motor. The no-load speed of the machine is above synchronous speed if β is between 0 and 90 degrees, as in Figure 1, and below synchronous speed if β is between 90 and 180 degrees.

When the brushes are set to make E_{11} in the same direction as ${}_{ss}E_2$, ($\beta=0$), the center lines of corresponding stator and adjusting winding coils are collinear, and their magnetomotive forces aid. With this reference position of E_{11}, β is also the angle by which the magnetomotive force of the adjusting winding lags the magnetomotive force of the stator coils. This is the angle in electrical degrees through which it is necessary to rotate the brushes about the commutator in order to shift E_{11} by β degrees (see Figure 2). Only the phase position of E_{11} is changed if the brushes are all rotated about the commutator by the same angle, keeping their relative spacing unchanged. Positive values of β are obtained by moving the brushes in the direction of rotation from the position where $\beta=0$. Values of magnetomotive force and of E_{11} identical to those at any given setting of the brushes can be obtained by rotating all brushes 360 electrical degrees around the commutator, or by interchanging the positions of all brush pairs, and moving them all 180 electrical degrees around the commutator.

Determination of the Primary Currents

The primary current resulting from the secondary currents shown in Figure 1a can be obtained from a consideration of the various magnetomotive forces involved. If the resultant flux crossing the air gap is to remain unchanged (so that the generated voltage will remain approximately equal and opposite to the applied voltage), the magnetomotive forces produced by the secondary currents flowing in the stator and the adjusting winding coils must be cancelled by component magnetomotive forces produced by component currents flowing in the primary coils.

While the polyphase current I_2+I_{11}, which flows in the stator coils also flows in the adjusting winding coils, the magnetomotive forces produced by these two sets of coils in series are not, in general, in the same time phase with respect to the primary. This is because the adjusting winding coils are mechanically displaced from the stator coils by β electrical degrees, as shown in Figure 2. If the brushes have been shifted to retard E_{11} by β degrees (which advances the primary current), the magnetomotive force of the adjusting winding lags the magnetomotive force of the stator by β degrees, so that the primary current cancelling the magnetomotive force of the adjusting winding lags the primary current which cancels the magnetomotive force of the stator by β degrees.

Figure 1b shows a vector diagram of the components of the primary current necessary to cancel the magnetomotive

Paper 42-76, recommended by the AIEE committee on electrical machinery for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted December 19, 1941; made available for printing March 30, 1942.

A. G. Conrad is associate professor, and J. G. Clarke and F. Zweig are instructors in the school of engineering, Yale University, New Haven, Conn.

force produced by the secondary currents of Figure 1a flowing in the *stator*. Figure 2 shows that this component of primary current is obtained by a *mirror reflection* of the secondary current while the motor is running above synchronous speed, and by a *180-degree reflection* of the secondary current when the machine is running below synchronous speed. Figure 1c shows a vector diagram of the components of primary currents which cancel the magnetomotive forces of the secondary currents flowing in the *adjusting winding*. Figure 1d shows the magnetizing component of the primary current. Figure 1e shows the sum of these component currents, or I_1, the total primary current. At a given load, the currents reflected from the adjusting winding and the stator winding are separated by the angle β. Their sum is separated from the component reflected from the stator by the angle

$$\gamma = \tan^{-1}\frac{N_{AW}\sin\beta}{N_2+N_{AW}\cos\beta}$$

The currents reflected into the primary from the stator and the adjusting winding bear the ratio N_2 to N_{AW}.

By adding the reflected currents vectorially, the load component of the primary current is obtained. The ratio of transformation between the secondary and the primary can be obtained from the equation

$$N_1I_{1L} = \sqrt{(N_2+N_{AW}\cos\beta)^2+(N_{AW}\sin\beta)^2}\,(I_2+I_{11})$$

Obtaining the Circle Diagram

For specific cases, two general methods have been considered for obtaining the circle locus of the primary current without loading the machine. One method makes use of the fact that a circle is uniquely determined if two points and the slope of the diameter through one of the points is known. This method is commonly used to obtain the circle diagram for the two-element induction motor. It is also applicable for the brush-shifting a-c motor for any value of E_{11}. The two points commonly used are the extremities of the no-load and blocked-rotor current vectors. In the two-element induction motor, the diameter through the no-load point is 90 degrees behind the impressed voltage, so the circle can be constructed from these two currents. However, the presence of E_{11} in the brush-shifting a-c motor causes a shift of the diameter of the secondary current locus through the no-load point so that it is no longer perpendicular to E_2 (or the applied voltage). As is seen in Figure 1a, the tangent of the angle of slope of this diameter is

$$\frac{\dfrac{E_{11}}{R}\cos\beta}{\dfrac{_{ss}E_2}{X}+\dfrac{E_{11}}{R}\sin\beta} = \frac{\dfrac{E_{11}}{_{ss}E_2}\cos\beta}{\dfrac{R}{X}+\dfrac{E_{11}}{_{ss}E_2}\sin\beta}$$

where R and X are the total resistance and reactance at standstill referred to the secondary. The voltages and β in this equation may be determined by opening the brush leads and measuring E_{11}, $_{ss}E_2$, and $E_{11}+{}_{ss}E_2$. β is determined by forming a triangle of these three voltages. The quantities can also be determined directly if the brush positions and turns ratio are known. The remaining term, R/X, can be evaluated from the blocked rotor current. At standstill, the resultant secondary current, $I_{11}+I_2$, lags the resultant secondary voltage, $E_{11}+E_2$, by an angle the tangent of which is X/R. This is the same angle that I_{1L} lags V_1 at standstill. Hence, X/R is the tangent of the angle between I_{1L} and V_1 at blocked rotor. The corresponding diameter of the primary current locus lags this diameter of the secondary current locus by the angle γ, which was defined earlier.

Erecting a perpendicular bisector to the chord joining the no-load and the blocked rotor current extremities gives another diameter, and the center of the

(d). The magnetizing current

(e). The sum of the component currents in the primary

primary-current circle locus lies at the intersection of these two diameters.

This method for determining the locus of the primary current, from the two points and the direction of the diameter through the no-load current extremity, involves the same approximation that is made in ordinary induction motor theory—that this diameter of the circle passes through the no-load point. Actually, when the machine is running with no output torque, it is loaded with rotational losses. The circle should be constructed with the diameter drawn through the true no-load point, which can be found by supplying these losses mechanically. This refinement produces almost no change in the circle diagram.

The circle can also be located by obtaining three points, rather than by two points and a diameter. This method, which was discussed for specific cases in the earlier papers,[1,2] is valid for all brush positions, since the current locus is always a circle, and three points determine a circle. The necessary data are:

(a). The no-load input current and watts at normal voltage.

(b). The standstill input current and watts at reduced voltage.

(c). The no-load input current and watts at reduced voltage, with the machine running at some speed between the no-load speed and standstill.

This method eliminates the inaccuracies introduced by primary leakage reactance and rotational losses.

Characteristics From the Circle Diagram

When the locus of the extremity of the primary-current vector has been established by the methods discussed above, the characteristics of the motor can be predicted, using methods similar to those used in parts I, II, and III of this series.

In the ordinary induction-motor theory, it is assumed that the total copper loss of the motor is the loss produced by the no-load current plus the loss produced by the load component of current that is reflected from the secondary. The portion of the primary copper loss produced by the no-load current is grouped with the other no-load losses, and the sum of these is assumed to be constant. These assumptions involve two approximations, neither of which seriously affects the accuracy of the method for the two-element induction motor. First, it assumes that the current flowing in the primary is directly proportional to the current in the secondary, so that the division of copper loss between the primary and secondary is the same for all loads. Second, it assumes that the loss for two component currents flowing in a conductor simultaneously is equal to the sum of the losses produced when each component flows separately.

$$(I_{mag}^2+I_{1L}^2)R_1=(I_{mag}+I_{1L})^2R_1$$

This is true only when the component current vectors are in quadrature. Over the operating range of the ordinary induction motor, the magnetizing current is nearly at right angles to the reflected component, I_{1L}, so that the error due to this approximation is small. However, in the brush-shifting motor, the voltage E_{11} may be introduced into the secondary in such a phase position that the phase angle of the reflected current may vary widely with respect to the magnetizing current, introducing quite appreciable errors. The loss curves for the machine can be located without these approximations. Referring to Figure 3, for some general running condition when the input current is *pf*, the current flowing in the secondary is proportional to *of*, where *po* is the magnetizing current. *po* can be determined by running the machine at no load with the brushes set to make E_{11} zero. The primary copper loss is proportional to $(pf)^2$, and the secondary copper loss is proportional to $(of)^2$. When the rotor is blocked, the total input to the motor is used in supplying losses. Assuming that the sum of the iron, friction, and windage losses remains constant from no load to blocked rotor, the total copper loss can be determined for blocked rotor. From the resistances of the two windings, the division of this loss between the primary and the secondary can be determined. Thus, if the point *m* is located so that $rm\times V_1$ is the primary copper loss per phase for a primary current *pb*, and $mb\times V_1$ is the secondary copper loss per phase for a reflected current *ob*, then for a primary current *pf*, the primary copper loss per phase is $hk\times V_1$ where

$$hk=rm\frac{pf^2}{pb^2}$$

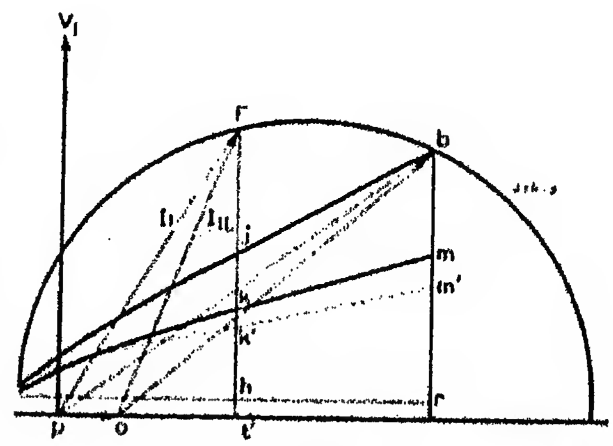

Figure 3. Locus of the primary current, and curves dividing the power component into the parts allocated to the output and the various losses

and the corresponding secondary loss is $kj\times V_1$ where

$$kj=mb\frac{of^2}{ob^2}$$

This method can be used to determine the copper losses at no load. By subtracting these copper losses from the no-load input, the friction, windage, and iron loss is determined.

Using these relations, curves can be constructed that divide the power component of the input current into the portions that are allocated to the output and the various losses. Thus, in Figure 3, for an input current *pf*:

Input $=tf\times V_1$ watts per phase
Output $=jf\times V_1$ watts per phase
Friction, windage, and iron loss $=th\times V_1$ watts per phase
Primary copper loss $=hk\times V_1$ watts per phase
Secondary copper loss $=kj\times V_1$ watts per phase

(a). Schematic diagram of the motor, showing the brushes set to retard E_{11} by β degrees. The magnetomotive force of the adjusting winding is β degrees behind that of the stator

(b). Effective currents, representing the magnetomotive forces of the stator, adjusting winding, and primary windings

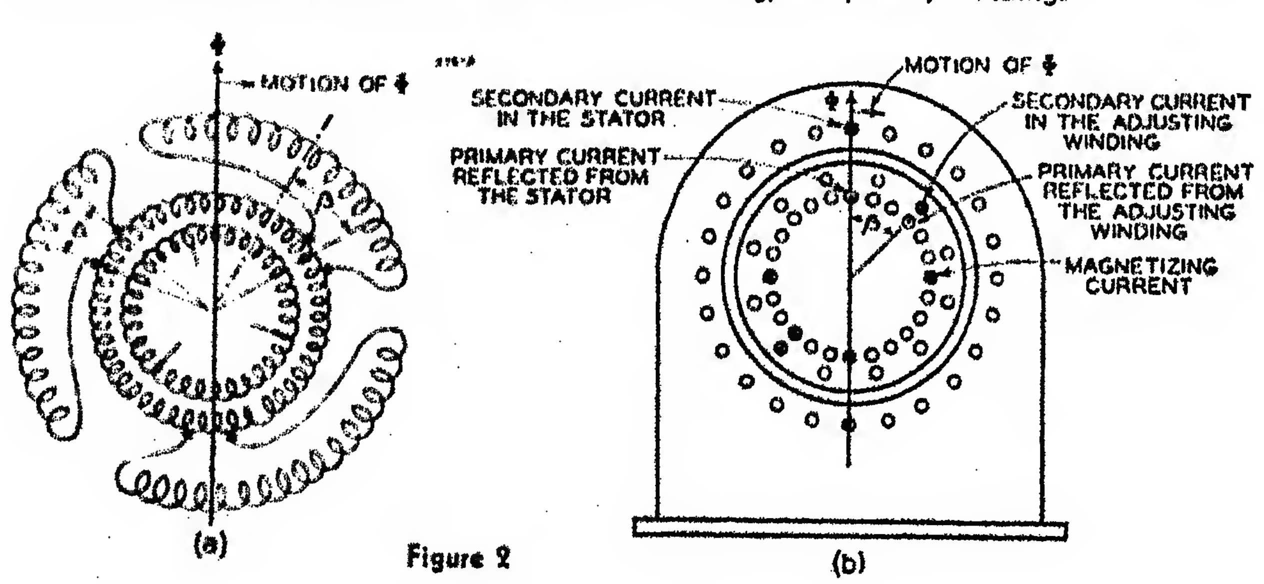

Figure 2

$$\text{Efficiency} = \frac{if}{tf}$$

$$\text{Power-factor} = \frac{tf}{pf}$$

When E_{11} has no quadrature component with respect to ${}_{ss}E_2$, ($E_{11} \sin \beta = 0$), the slip is equal to the secondary loss divided by the total power across the gap, or

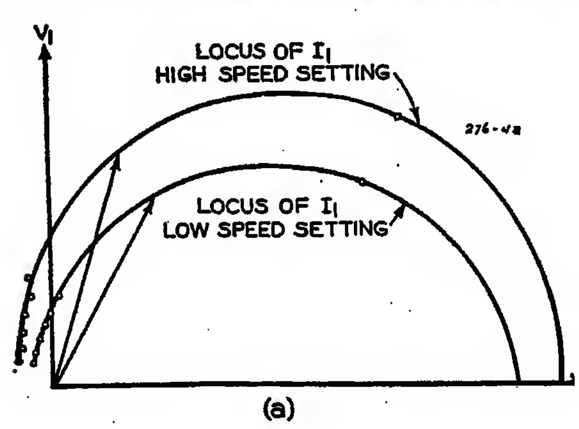
$$S = \frac{{}_{sec}(I^2R)}{\text{developed power} + {}_{sec}(I^2R)} \times 100 \text{ per cent of no-load speed}$$

where I is the total secondary current $(I_2 + I_{11})$. Under this condition, all of the I^2R loss in the secondary is supplied by the *speed* voltage, IZ, which varies directly with slip. Appendix B demonstrates that when E_{11} has any phase position β, the voltage supplying the secondary I^2R loss is a combination of a *speed* voltage $(IZ)_s$, which varies directly with slip, and a *transformer* voltage $(IZ)_t = E_{11} \sin \beta$, which is independent of slip. Under this condition, the slip can be evaluated (see appendix B) in terms of the output and the component of the secondary loss, ${}_{sec}(I^2R)_s$, which is associated with the speed voltage. The expression for the slip is

$$S = \frac{{}_{sec}(I^2R)_s}{\text{developed power} + {}_{sec}(I^2R)_s} \times 100 \text{ per cent of } N_o$$

Figure 4. Comparison of observed and predicted characteristics

Points are observed. Lines are predicted



This slip is expressed in per cent of N_o, the no-load speed at which the motor would operate if the brushes were shifted to eliminate the quadrature component ($E_{11} \sin \beta$) without altering the inphase component ($E_{11} \cos \beta$). Similarly, the torque can be shown to be proportional to the component of the total secondary power which is independent of the transformer voltage.

$$\text{Developed power} + {}_{sec}(I^2R)_s = \frac{2\pi N_o T_{dev}}{33{,}000} \times 746$$

or

$$T_{dev} = \frac{33{,}000}{2\pi N_o 746} (\text{developed power} + {}_{sec}(I^2R)_s)$$

The quantities ${}_{sec}(I^2R)_s$ and (developed power $+ {}_{sec}(I^2R)_s$) may be evaluated by projecting the components of I_{1L} on V_1 as outlined in appendix B. Also, it can be shown that these quantities may be evaluated from the product of the projections of I_{1L} and V_1 on an axis lagging V_1 by γ degrees, and that ${}_{sec}(I^2R)_t$, the component of the loss associated with the transformer voltage, can be evaluated from the product of the projections of I_{1L} and V_1 on an axis perpendicular to this axis. Regardless of the method used to evaluate these quantities, it is convenient to draw the dotted line $m'k'$, and so forth, on the circle diagram of Figure 3, so that

${}_{sec}(I^2R)_t = k'k \times V_1$ watts per phase
${}_{sec}(I^2R)_s = k'j \times V_1$ watts per phase
Output $+ {}_{sec}(I^2R)_s = k'f \times V_1$ watts per phase

From this, the slip and torque can be evaluated in a manner which is almost identical with that used for the ordinary induction motor circle diagram.

$$\text{Slip} = \frac{k'j}{k'f} \times 100 \text{ per cent of } N_o$$

$$\frac{2\pi N_o T}{33{,}000} \times 746 = k'f \times V_1 \text{ watts per phase}$$

This involves the same approximation that is made with the ordinary induction motor—that the effect of rotational losses on the slip is negligible.

Experimental Check on the Circle-Diagram Theory

To check the theory that has been presented here, tests were made on the General Electric *BTA* 550–1,650-rpm 4.17–12.5 horsepower 60-cycle brush-shifting motor that was used in the earlier tests.

The brushes were set for two tests so that β was approximately 45 degrees and 135 degrees. The power factor was improved with each of these settings, and the machine ran above synchronous speed when $\beta = 45$ degrees, and below synchronous speed when $\beta = 135$ degrees.

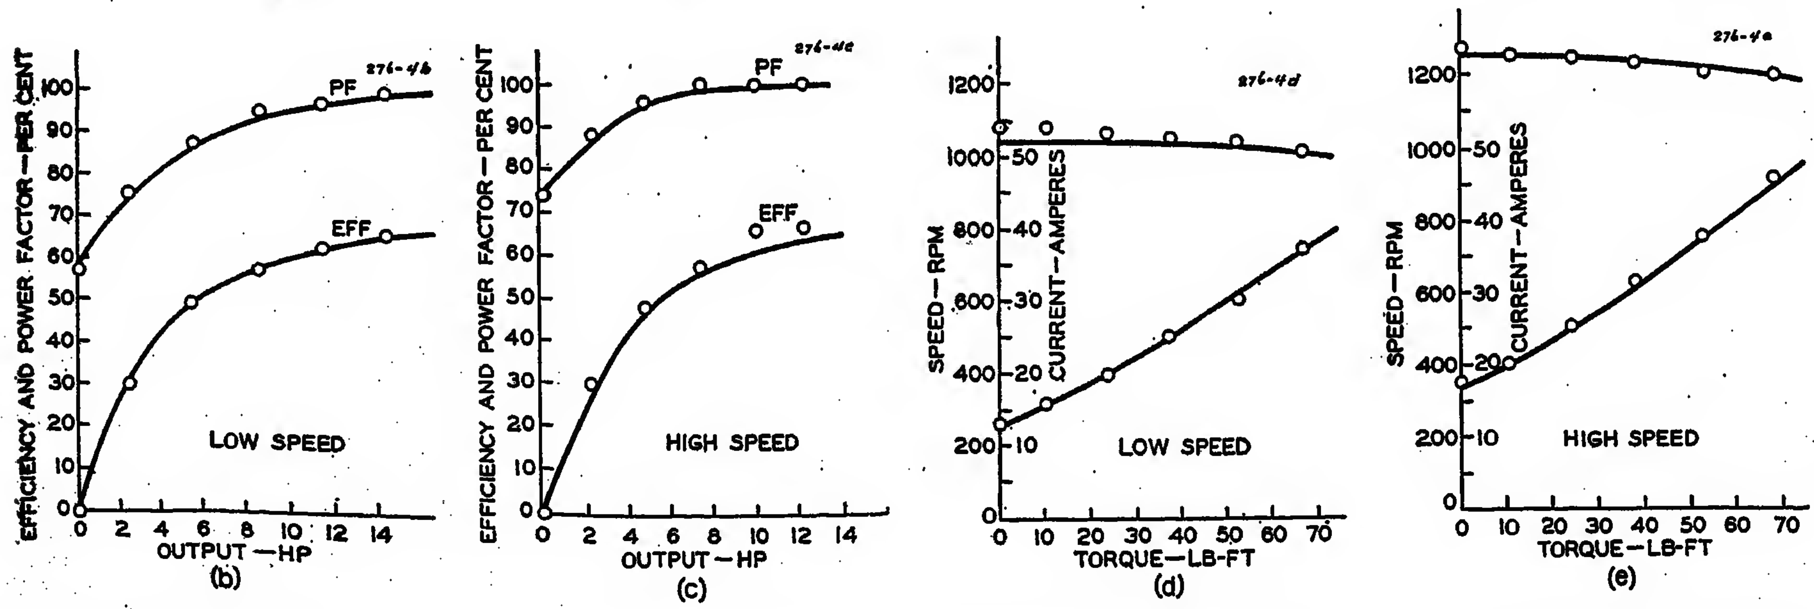
The magnitude and phase position of E_{11} were determined accurately by the voltage measurements described earlier, and from this, from the no-load measurements and from the blocked-rotor measurements, the circles shown in Figure 4a were constructed. It is seen that these predicted circles check the observed points quite closely. Curves of speed and current against torque, and power factor and efficiency against output were constructed from the predicted circle. Figures 4b, c, d, and e show these predicted characteristics compared with those actually observed.

Conclusions

1. Theory and experiments described here have shown that it is possible to adjust the brushes of the brush-shifting a-c motor to correct the power factor of the current supplying it, regardless of the speed to which it is adjusted.

2. The locus of the extremity of the primary current with such adjustments is a circle. The magnitude and location of this circle with respect to the primary-voltage vector can be determined from no-load measurements taken on the motor.

3. Power-factor correction is accomplished



by causing exciting current of the motor to flow in the secondary elements instead of the primary. This causes extra heating in the secondary and reduces the permissible load current that the secondary can carry. In the particular machine used in this investigation values of the quadrature component of E_{11}, ($E_{11}\sin\beta$) in excess of 10 per cent of the standstill value of the induced secondary voltage E_2 cause excessive secondary currents.

4. While the range of $E_{11}\sin\beta$ (power-factor adjustment) is limited, $E_{11}\cos\beta$ (speed adjustment) is not limited except by the design of the motor. The voltage $E_{11}\cos\beta$ is opposed in normal operation by a speed voltage, E_2, which limits the flow of current produced by it. The quadrature component, $E_{11}\sin\beta$, causes a secondary current which is opposed only by the motor impedance and not by the speed voltage. Consequently, a small angle β can cause considerable change in power factor in a low impedance motor.

5. A method of determining the characteristics of the motor when used to perform the double function of speed adjustment and power-factor correction has been presented. This method employs the theory and use of the circle diagram. The accuracy of the predicted characteristics indicates that the theory and description of the operation of the motor as presented here are essentially correct.

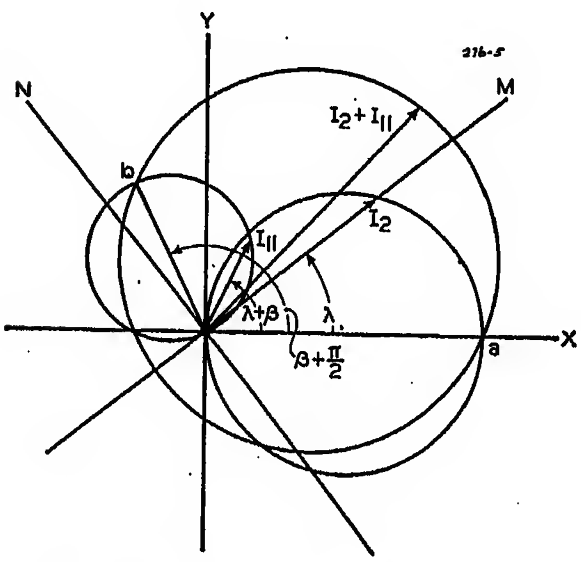


Figure 5. Diagram for appendix A

Appendix A. Proof of the Circle Locus of (I_2+I_{11})

The two small circles of Figure 5 with diameters a and b represent the loci of the currents I_2 and I_{11} respectively. Establish the rectangular co-ordinates, x and y, with the x axis along the diameter a. If angles are measured counterclockwise from the x axis, the angle between b and a is $\beta+\pi/2$. A current I_2 at angle λ from the x axis, when added to the corresponding current I_{11} at angle $\lambda+\beta$ from the x axis, results in (I_2+I_{11}). The locus of the extremity of (I_2+I_{11}) is to be expressed in terms of the x, y co-ordinates. To do this it is convenient to establish another set of rectangular co-ordinates m, n rotated counterclockwise by the angle λ from the x, y axis. It is seen that

$$m=I_2+I_{11}\cos\beta=a\cos\lambda+b\sin\lambda\cos\beta$$
$$n=I_{11}\sin\beta=b\sin\lambda\sin\beta$$

By the Pythagorean theorem

$$(I_2+I_{11})^2=(I_2+I_{11}\cos\beta)^2+(I_{11}\sin\beta)^2$$
$$(I_2+I_{11})^2=I_2^2+I_{11}^2+2I_2I_{11}\cos\beta-ab\times\sin\beta\,(\sin^2\lambda+\cos^2\lambda)+ab\sin\beta$$

Since $I_2=a\cos\lambda$ and $I_{11}=b\sin\lambda$

$$\begin{aligned}(I_2+I_{11})^2&=I_2^2+I_{11}^2+2I_2I_{11}\cos\beta-a\sin\beta\times\sin\lambda I_{11}-b\sin\beta\cos\lambda I_2+ab\sin\beta\\&=I_2^2+I_{11}^2+I_2I_{11}\cos\beta-I_2b\cos\lambda\times\sin\beta+I_2I_{11}\cos\beta-a\sin\beta\times\sin\lambda I_{11}+ab\sin\beta\\&=I_2^2+I_{11}^2+I_2b\sin\lambda\cos\beta-I_2b\times\cos\lambda\sin\beta+I_{11}a\cos\lambda\cos\beta-I_{11}a\sin\lambda\sin\beta+ab\sin\beta\\&=I_2^2+I_{11}^2+I_2b\sin(\lambda-\beta)+I_{11}a\times\cos(\lambda+\beta)+ab\sin\beta\\&=I_2[I_2+b\sin(\lambda-\beta)]+I_{11}[I_{11}+a\times\cos(\lambda+\beta)]+ab\sin\beta\\&=I_2[a\cos\lambda+b\sin(\lambda-\beta)]+I_{11}\times\{b\sin[(\lambda-\beta)+\beta]+a\cos(\lambda+\beta)\}+ab\sin\beta\\&=I_2[a\cos\lambda+b\sin(\lambda-\beta)]+aI_{11}\times\cos\lambda\cos\beta-aI_{11}\sin\lambda\sin\beta+I_{11}b\sin(\lambda-\beta)\cos\beta+I_{11}b\times\cos(\lambda-\beta)\sin\beta+ab\sin\beta\end{aligned}$$
$$(I_2+I_{11})^2=[a\cos\lambda+b\sin(\lambda-\beta)](I_2+I_{11}\times\cos\beta)+I_{11}\sin\beta[b\cos(\lambda-\beta)-a\sin\lambda]+ab\sin\beta$$

Since $m=I_2+I_{11}\cos\beta$ and $n=I_{11}\sin\beta$

$$\begin{aligned}(I_2+I_{11})^2&=[a\cos\lambda+b\sin(\lambda-\beta)]m+n\times[b\cos(\lambda-\beta)-a\sin\lambda]+ab\sin\beta\\&=m[\cos\lambda(a-b\sin\beta)+b\sin\lambda\times\cos\beta]+n[-\sin\lambda(a-b\sin\beta)+b\cos\lambda\cos\beta]+ab\sin\beta\end{aligned}$$
$$(I_2+I_{11})^2=(a-b\sin\beta)(m\cos\lambda-n\sin\lambda)+b\cos\beta(m\sin\lambda+n\cos\lambda)+ab\sin\beta$$

Since the co-ordinates x, y are expressed in the m, n co-ordinate system by the equations

$$x=m\cos\lambda-n\sin\lambda$$
$$y=m\sin\lambda+n\cos\lambda$$
$$(I_2+I_{11})^2=(a-b\sin\beta)x+(b\cos\beta)y+ab\times\sin\beta$$

But

$$(I_2+I_{11})^2=x^2+y^2$$

so

$$x^2-x(a-b\sin\beta)+y^2-yb\cos\beta=ab\sin\beta$$

Completing squares

$$\left[x-\left(\frac{a}{2}-\frac{b}{2}\sin\beta\right)\right]^2+\left[y-\frac{b}{2}\cos\beta\right]^2=ab\times\sin\beta+\frac{a^2}{4}-\frac{ab}{2}\sin\beta+\frac{(b\sin\beta)^2}{4}+\frac{(b\cos\beta)^2}{4}$$

$$\left[x-\left(\frac{a}{2}-\frac{b}{2}\sin\beta\right)\right]^2+\left[y-\frac{b}{2}\cos\beta\right]^2=\left[\frac{a}{2}+\frac{b}{2}\sin\beta\right]^2+\left[\frac{b\cos\beta}{2}\right]^2$$

This is the equation of a circle in x, y co-ordinates with center at

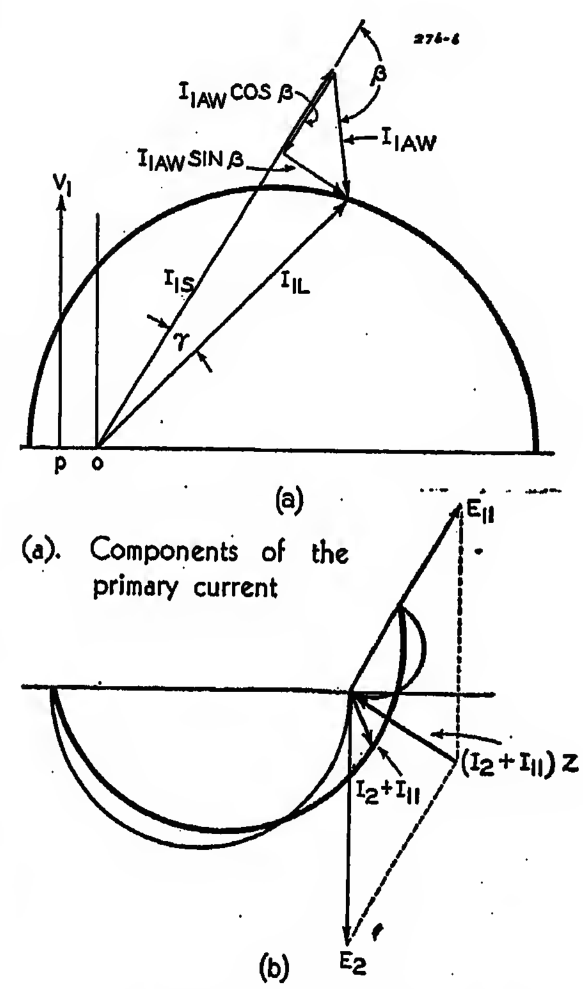
$$x=\frac{a}{2}-\frac{b}{2}\sin\beta$$
$$y=\frac{b}{2}\cos\beta$$

and radius

$$r=\left[\left(\frac{a}{2}+\frac{b}{2}\sin\beta\right)^2+\left(\frac{b\cos\beta}{2}\right)^2\right]^{1/2}$$

Appendix B. Determination of Slip and Torque

As is seen from Figure 1, I_{1L} is made up of two components, one of which, I_{1S}, cancels



(a). Components of the primary current

(b). Secondary voltages and currents

Figure 6. Diagrams for appendix B

the magnetomotive force of (I_2+I_{11}) flowing in the stator coils, and the other, I_{1AW}, cancels the magnetomotive force of (I_2+I_{11}) flowing in the adjusting winding. These component currents bear the ratio

$$\frac{I_{1S}}{I_{1AW}}=\frac{N_2}{N_{AW}}=\frac{{}_{ss}E_2}{E_{11}}$$

and are added together at the angle β to form I_{1L} as shown in Figure 6a. Thus, if I_{1L}, β, and ${}_{ss}E_2/E_{11}$ are known, all the component currents are determined.

By projecting the various current vectors in this diagram on the voltage vector, V_1, powers are obtained which can be used in evaluating the speed and torque.

If the vector notation $(I_{1L})\cdot(V_1)$ is used to mean the scalar product of V_1 and the projection of I_{1L} on V_1, and if the primary resistance is assumed to be transferred into the

secondary, the following relations may be written

$$(I_{1L})\cdot(V_1)=(I_2+I_{11})\cdot({}_{ss}E_2+E_{11}) \quad (1)$$

= net power transferred from the primary to the stator and the adjusting windings

$$(I_{1s})\cdot(V_1)=(I_2+I_{11})\cdot({}_{ss}E_2) \quad (2)$$

= power transferred from the primary to the stator

$$(I_{1AW})\cdot(V_1)=(I_2+I_{11})\cdot(E_{11}) \quad (3)$$

= power transferred from the primary to the adjusting winding

$$(I_{1AW}\cos\beta)\cdot(V_1)=(I_2+I_{11})\cdot(E_{11}\cos\beta) \quad (4)$$

= power associated with the component of I_{1AW} which is collinear with I_{1s}

$$(I_{1AW}\sin\beta)\cdot(V_1)=(I_2+I_{11})\cdot(E_{11}\sin\beta) \quad (5)$$

= power associated with the component of I_{1AW} which is in quadrature with I_{1s}

The power described by equation 5 can be identified as a component of the I^2R loss in the machine. Since the resultant secondary voltage is equal to the IZ drop; and the dot product of the resultant current and IZ gives the I^2R loss, we may write

$$E_2+E_{11}=-(I_2+I_{11})Z$$

and

$$(I_2+I_{11})\cdot(E_2+E_{11})=-(I_2+I_{11})^2R$$

(See Figure 6b.) If (E_2+E_{11}) is divided into the quadrature components $(E_2+E_{11}\cos\beta)$ and $(E_{11}\sin\beta)$, the projection of (I_2+I_{11}) on each of these components gives a component of the total copper loss.

$$[(I_2+I_{11})^2R]_s=-(I_2+I_{11})\cdot(E_2+E_{11}\cos\beta) \quad (6)$$

$$[(I_2+I_{11})^2R]_t=-(I_2+I_{11})\cdot(E_{11}\sin\beta) \quad (7)$$

where

$$[(I_2+I_{11})^2R]_s+[(I_2+I_{11})^2R]_t=(I_2+I_{11})^2R$$

But from equation 5, $[(I_2+I_{11})^2R]_t$ is seen to be the product of V_1 and the projection of $(I_{1AW}\sin\beta)$ on V_1, so that $[(I_2+I_{11})^2R]_t$ can be evaluated, and since $[(I_2+I_{11})^2R]$ is known, the remaining component $[(I_2+I_{11})^2R]_s$ can be evaluated.

Obtaining the Torque

The power which is transferred directly from the primary to the stator is, from equation 2

$$(I_{1s})\cdot(V_1)=(I_2+I_{11})\cdot({}_{ss}E_2)$$

Since this power is transferred by a flux which reacts at synchronous speed with the primary

$$(I_{1s})\cdot(V_1)=(I_2+I_{11})\cdot({}_{ss}E_2)=\frac{2\pi N_{\text{sync}}T_{\text{dev}}}{33{,}000}\times 746$$

which can be solved for torque. This assumes the more conventional form if it is expressed in terms of N_o rather than N_{sync}, where N_o is the no-load speed when $E_{11}\times\sin\beta$ is made zero, leaving $E_{11}\cos\beta$ unchanged.

$$(I_{1s}+I_{1AW}\cos\beta)\cdot(V_1)=(I_2+I_{11})\cdot({}_{ss}E_2+E_{11}\cos\beta)=\frac{2\pi N_oT_{\text{dev}}}{33{,}000}\times 746 \quad (8)$$

This is true because

$$\frac{N_o}{N_{\text{sync}}}=\frac{{}_{ss}E_2+E_{11}\cos\beta}{{}_{ss}E_2}=\frac{I_{1s}+I_{1AW}\cos\beta}{I_{1s}}$$

From equations 1 and 5, it is seen that equation 8 must represent the developed power plus one component of the copper loss

$$\frac{2\pi N_oT_{\text{dev}}}{33{,}000}\times 746=P_{\text{dev}}+[(I_2+I_{11})^2R]_s$$

which can be solved for torque.

Obtaining the Speed

Since the slip from synchronous speed, in per cent of synchronous speed is $E_2/{}_{ss}E_2$, the speed can be predicted from E_2. As is seen from Figure 6b

$$E_2=E_{11}\cos\beta+[(I_2+I_{11})Z]_s$$

where $[(I_2+I_{11})Z_s]$ is the component of the impedance drop which is in phase with E_2, so that

$$\frac{E_2}{{}_{ss}E_2}=\frac{E_{11}\cos\beta}{{}_{ss}E_2}+\frac{[(I_2+I_{11})Z]_s}{{}_{ss}E_2}=S_1+S_2$$

= slip in per cent of synchronous speed

where S_1 is the slip caused by $E_{11}\cos\beta$ and S_2 is the slip caused by loading. The first term on the right hand side of this equation is constant for a given brush setting, and the second term varies with torque. This expression can be evaluated more simply if the slip is measured from N_o and expressed in per cent of N_o. This slip is

$$S=\frac{S_2N_{\text{sync}}}{N_o}=\frac{[(I_2+I_{11})Z]_s}{{}_{ss}E_2+E_{11}\cos\beta}\text{ per cent }N_o$$

Here the slip is expressed in terms of the ratio of two voltages. Taking the dot product of these voltages with the secondary currents puts this expression for slip into the conventional form:

$$S=\frac{[(I_2+I_{11})Z]_s\cdot(I_2+I_{11})}{({}_{ss}E_2+E_{11}\cos\beta)\cdot(I_2+I_{11})}$$

$$=\frac{[(I_2+I_{11})^2R]_s}{P_{\text{dev}}+[(I_2+I_{11})^2R]_s}\text{ per cent }N_o$$

Assumption Regarding Primary Resistance

In deriving the expressions for speed and torque, it was assumed that the primary resistance was replaced by an equivalent resistance in the secondary. Actually, the power consumed in the primary resistance does not cross the air gap. For this reason, the term $[(I_2+I_{11})^2R]_s$ in these expressions must be replaced by the term ${}_{\text{sec}}[(I_2+I_{11})^2R]_s$. This term, which is part of the copper loss in the secondary, was obtained in the manner commonly used for the ordinary induction motor. The division of the loss at blocked rotor was determined by resistance measurements, then it was assumed that the same division of losses occurred at all loads.

List of Symbols

E_{11}—The voltage inserted into the secondary element from the adjusting winding

E_2—The voltage induced in the secondary element by slip

I_{11}—The current flowing in the stator and adjusting winding, resulting from the voltage E_{11}

I_2—The current flowing in the stator and adjusting winding, resulting from the voltage E_2

I—The resultant secondary current I_2+I_{11}

${}_{ss}E_2$—The value of E_2 when the rotor is blocked

I_{mag}—The flux-producing component of the primary current

I_{1L}—The component of the primary current which cancels the magnetomotive forces of the stator and the adjusting windings

I_{1s}—The component of the primary current which cancels the magnetomotive force of the stator winding

I_{1AW}—The component of the primary current which cancels the magnetomotive force of the adjusting winding

I_1—The resultant primary current, or $I_{\text{mag}}+I_{1L}$

V_1—The applied voltage

N_1—The effective primary turns

N_2—The effective stator turns

N_{AW}—The effective adjusting winding turns

β—The angle in electrical degrees

(a). Between E_{11} and ${}_{ss}E_2$

(b). Between the magnetomotive forces of the stator and the adjusting winding

(c). That the brushes must be rotated about the commutator to retard E_{11} by β degrees

γ—The angle in electrical degrees

(a). Between I_{1s} and I_{1L}

(b). Between the magnetomotive force of the stator and the resultant magnetomotive force of the stator and the adjusting winding (c). Between ${}_{ss}E_2$ and $({}_{ss}E_2+E_{11})$

R—The resistance of the primary, secondary, and adjusting winding, reflected to the secondary

X—The standstill reactance of the primary, secondary, and adjusting winding, reflected to the secondary

Z—The secondary and adjusting winding impedance

T_{dev}—The developed torque

P_{dev}—The developed power

$(IZ)_s$—The component of the total secondary and adjusting winding IZ voltage which is in phase with E_2

$(IZ)_t$—The component of the total secondary and adjusting winding IZ voltage which is in quadrature with E_2: $(IZ)_t=-E_{11}\sin\beta$

${}_{\text{sec}}(I^2R)_s$—The component of the secondary I^2R loss which is given by $I\cdot(IZ)_s$

${}_{\text{sec}}(I^2R)_t$—The component of the secondary I^2R loss which is given by $I\cdot(IZ)_t$

N_o—The no-load speed at which the motor

Reactance and Skin Effect of Concentric Tubular Conductors

HERBERT B. DWIGHT
FELLOW AIEE

THE concentric arrangement of tubular conductors to carry heavy alternating currents gives compactness, low reactance drop, and reduced loss from skin effect or crowding of the current to the surface of the conductors. This arrangement is being used to a considerable extent.[12] In this paper formulas and curves are given to enable the reactance and the skin-effect resistance ratio of such conductors to be determined for three-phase and single-phase circuits.

Reactive Drop

In practical cases the reactance of concentric tubular conductors is very little affected by the variable current density which causes skin effect. When uniform current density is assumed, the "geometric mean distance" method of Clerk Maxwell may be used. Using values given in paragraph 692 of his "Electricity and Magnetism," for geometric mean distances of a tubular section from itself and from other sections, (references 1, 3, and equations 28 and 30 of reference 11) formulas for the reactance drop in each tube of a concentric, three-phase circuit are obtained.

The general formula for reactive drop in conductor 1 of a group of long, parallel conductors is (see reference 11, equation 55, page 39)

$$-j\omega 2\times 10^{-9}[I_1 \operatorname{logn} D_{s1}+I_2 \operatorname{logn} D_{12}+I_3 \operatorname{logn} D_{13}+\ldots] \text{ volts per centimeter} \quad (1)$$

where

$\omega = 2\pi\times$frequency,
logn denotes natural logarithm,
D_{s1} = self geometric mean distance of conductor 1,
D_{12} = geometric mean distance of the cross section of conductor 1 to that of conductor 2, and so forth.

The currents are in amperes. A conductor may have any shape of cross section.

The logarithm of the geometric mean distance between two cross sections is the average of the logarithms of all possible distances between points on one section and points on the other. The logarithm of the self geometric mean distance of the section of a conductor is the average of the logarithms of all possible distances between any two points of the section.

Formula 1 is subject to the condition that

$$I_1+I_2+I_3+I_4+\ldots=0$$

which is a relation usually obtained in any steady-state problem where a system consists of long, parallel conductors, and all the conductors are taken into account. In other words there is as much return current as there is going current in such a system. A system of this kind may be made up of any number of phases and any number of conductors in parallel.

Let the inside and outside diameters of the tubes, from the smallest to the largest, be d_1, d_2, d_3, d_4, d_5, and d_6. Let there be no neutral current.

The reactive drop in the inner tube, which carries I_a amperes, is, in volts per centimeter,

$$\frac{j\omega 2I_a}{10^9}\left[\frac{d_1^4}{(d_2^2-d_1^2)^2}\operatorname{logn}\frac{d_2}{d_1}-\frac{3d_1^2-d_2^2}{4(d_2^2-d_1^2)}\right]+\frac{j\omega 2I_b}{10^9}\left[\frac{1}{2}+\frac{d_3^2}{d_4^2-d_3^2}\operatorname{logn}\frac{d_3}{d_2}-\frac{d_4^2}{d_4^2-d_3^2}\operatorname{logn}\frac{d_4}{d_2}\right]+\frac{j\omega 2I_c}{10^9}\left[\frac{1}{2}+\frac{d_5^2}{d_6^2-d_5^2}\operatorname{logn}\frac{d_5}{d_2}-\frac{d_6^2}{d_6^2-d_5^2}\operatorname{logn}\frac{d_6}{d_2}\right] \quad (2)$$

The reactive drop in the intermediate tube, which carries I_b amperes, is

$$\frac{j\omega 2I_a}{10^9}\left[\frac{1}{2}-\frac{d_3^2}{d_4^2-d_3^2}\operatorname{logn}\frac{d_4}{d_3}\right]+\frac{j\omega 2I_b}{10^9}\left[\frac{d_3^4}{(d_4^2-d_3^2)^2}\operatorname{logn}\frac{d_4}{d_3}-\frac{3d_3^2-d_4^2}{4(d_4^2-d_3^2)}\right]+\frac{j\omega 2I_c}{10^9}\left[\frac{1}{2}+\frac{d_5^2}{d_6^2-d_5^2}\operatorname{logn}\frac{d_5}{d_4}-\frac{d_6^2}{d_6^2-d_5^2}\times\operatorname{logn}\frac{d_6}{d_4}\right] \text{ volts per centimeter} \quad (3)$$

Reactive drop in the outer tube, which carries I_c amperes, is

$$\frac{j\omega 2(I_a+I_b)}{10^9}\left[\frac{1}{2}-\frac{d_5^2}{d_6^2-d_5^2}\operatorname{logn}\frac{d_6}{d_5}\right]+\frac{j\omega 2I_c}{10^9}\left[\frac{d_5^4}{(d_6^2-d_5^2)^2}\operatorname{logn}\frac{d_6}{d_5}-\frac{3d_5^2-d_6^2}{4(d_6^2-d_5^2)}\right] \text{ volts per centimeter} \quad (4)$$

The phase currents I_a, I_b, and I_c may be unbalanced. Therefore, by putting one of the currents equal to zero, the single-phase case is included.

For deriving the first expression, note that

$$I_a \operatorname{logn} d_2 = -I_b \operatorname{logn} d_2 - I_c \operatorname{logn} d_2$$

since there is no neutral current, and similarly for d_4 in the second expression and for d_6 in the third.

If the thickness of the above tubes is considered negligible, regarding the effect on the reactive drop, and if, as before, there is no neutral current, the reactive drop in the inner tube is

$$-\frac{j\omega 2}{10^9}\left[I_b \operatorname{logn}\frac{d_4}{d_2}+I_c \operatorname{logn}\frac{d_6}{d_2}\right] \text{ volts per centimeter} \quad (5)$$

Reactive drop in the intermediate tube is

$$-\frac{j\omega 2}{10^9}I_c \operatorname{logn}\frac{d_6}{d_4} \text{ volts per centimeter} \quad (6)$$

Reactive drop in the outer tube $=0$. (7)

It does not matter in what units the diameters are given, in equations 2 to 6, so long as they are all in the same units, since only ratios of diameters occur.

For convenience in computation, it may be noted that there are

$$2.540\times 12{,}000 = 3.05\times 10^4 \text{ centimeters in 1,000 feet} \quad (8)$$

Paper 42-78, recommended by the AIEE committee on basic sciences for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted February 11, 1942; made available for printing March 24, 1942.

HERBERT B. DWIGHT is professor of electrical machinery, department of electrical engineering, Massachusetts Institute of Technology, Cambridge, Mass.

The author acknowledges the work of S. B. Vindsberg in his master of science thesis written under the author's supervision, especially the work on the formulas and curves for the outer conductor.

would operate if the brushes were shifted to eliminate $E_{11} \sin\beta$, leaving $E_{11}\cos\beta$ unchanged

Also,

$$\log n\, u = 2.3026 \log_{10} u \tag{9}$$

The resistance drop in each tube is added vectorially to the reactance drop to give the impedance drop in that tube.

Example 1. Find the reactance drop in each tube of the following concentric, three-phase circuit. The inside and outside diameters of the inner tube are 1.2 and 3.0 inches; those of the intermediate tube are 4.0 and 4.5 inches, and those of the outer tube are 5.6 and 6.0 inches. The current of the inner tube is one ampere; that of the intermediate tube is

$$\cos 120° + j \sin 120° = -0.5 + j0.866$$

and that of the outer tube is

$$\cos 240° + j \sin 240° = -0.5 - j0.866$$

The reactive drop in the inner tube is

$$\frac{j\omega 2}{10^9}\,[0.188 - 0.349(-0.5+j0.866) - 0.660 \times (-0.5-j0.866)]$$

$$= \frac{j\omega 2}{10^9}(0.692+j0.270) \text{ volts per centimeter}$$

to compare with $j\omega 2(0.55+j\,0.25)/10^9$ by the approximate formula 5.

The reactive drop in the intermediate tube is

$$\frac{j\omega 2}{10^9}\,(0.164+j0.253)$$

to compare with $j\omega 2(0.14+j0.25)/10^9$ by the approximate formula 6.

The reactive drop in the outer tube is

$$\frac{j\omega 2}{10^9}\,(0.028+j0.048)$$

to compare with 0 by the approximate formula 7.

For the resistance drop in each tube see example 2.

Skin Effect at Low Frequency

Let there be a tubular conductor of inner radius q and outer radius r, as in Figure 1. Let there be uniform current density a_o abamperes per square centimeter in the tube and let there be a current I_p in a wire at the center of the tube.

Following the procedure of reference 5, beginning at equation 1 of that paper

$$\text{Flux density at } dx = (\text{current inside } dx)\frac{2}{q+x}$$

$$= 2\pi a_o q\left(\frac{2x}{q} - \frac{x^2}{q^2} + \frac{x^3}{q^3} - \frac{x^4}{q^4} + \ldots\right) + \frac{2I_p}{q}\left(1+\frac{x}{q}\right)^{-1} \tag{10}$$

Integrate from x to t and multiply by $j\omega$ where $\omega = 2\pi \times$ frequency.

Put

$$\frac{4\pi\omega}{\rho} = m^2 \tag{11}$$

where ρ = resistivity of the metal in abohms per centimeter cube. Reactive drop at dx caused by flux inside radius r due to a_o and I_p

$$= \frac{jm^2t^2}{2!}a_o\rho\left[1 - \frac{1}{3}\frac{t}{q} + \frac{1}{4}\frac{t^2}{q^2} - \ldots - \frac{x^2}{t^2} + \frac{1}{3}\frac{x^3}{t^2q} - \frac{1}{4}\frac{x^4}{t^2q^2} + \ldots\right] + \frac{j\omega 2I_p t}{q}\left[1 - \frac{1}{2}\frac{t}{q} + \frac{1}{3}\frac{t^2}{q^2} - \ldots - \frac{x}{t} + \frac{1}{2}\frac{x^2}{tq} - \frac{1}{3}\frac{x^3}{tq^2} + \ldots\right] \tag{12}$$

Let a current density $a_1 + a_1'$ flow, such that its resistance drop will be equal and opposite to the terms in x of equation 12, in order to keep the voltage drop from all causes uniform over the section, as it is in actual fact.

$$a_1 = \frac{jm^2t^2}{2!}a_o\left(\frac{x^2}{t^2} - \frac{1}{3}\frac{x^3}{t^2q} + \frac{1}{4}\frac{x^4}{t^2q^2} - \ldots\right) \tag{13}$$

$$a_1' = \frac{j\omega 2I_p}{q\rho}\left(x - \frac{1}{2}\frac{x^2}{q} + \frac{1}{3}\frac{x^3}{q^2} - \frac{1}{4}\frac{x^4}{q^3} + \ldots\right) \tag{14}$$

These currents will in turn produce flux in the metal and from the terms in x of the resulting voltage drops there are obtained values of current densities a_2 and a_2' and so on. The resulting values are

$$a_2 = \frac{(jm^2t^2)^2}{4!}a_o\left[\frac{x^4}{t_4} - \frac{2}{5}\frac{x^5}{t^4q} + \frac{3}{10}\frac{x^6}{t^4q^2}\ldots\right]$$

$$a_3 = \frac{(jm^2t^2)^3}{6!}a_o\left[\frac{x^6}{t^6} - \frac{3}{7}\frac{x^7}{t^6q} + \frac{9}{28}\frac{x^8}{t^6q^2}\ldots\right]$$

$$a_4 = \frac{(jm^2t^2)^4}{8!}a_o\left[\frac{x^8}{t^8} - \frac{4}{9}\frac{x^9}{t^8q} + \frac{1}{3}\frac{x^{10}}{t^8q^2}\ldots\right]$$

$$a_2' = \frac{jm^2t^2}{3!}\frac{j\omega 2I_p}{\rho}\left[\frac{x^3}{t^2q} - \frac{1}{2}\frac{x^4}{t^2q^2} + \frac{7}{20}\frac{x^5}{t^2q^3} - \frac{11}{40}\frac{x^6}{t^2q^4}\ldots\right]$$

$$a_3' = \frac{(jm^2t^2)}{5!}\frac{j\omega 2I_p}{\rho}\left[\frac{x^5}{t^4q} - \frac{1}{2}\frac{x^6}{t^4q^2} + \frac{5}{14}\frac{x^7}{t^4q^3} - \frac{2}{7}\frac{x^8}{t^4q^4}\ldots\right]$$

$$a_4' = \frac{(jm^2t^2)^3}{7!}\frac{j\omega 2I_p}{\rho}\left[\frac{x^7}{t^6q} - \frac{1}{2}\frac{x^8}{t^6q^2} + \frac{13}{36}\frac{x^9}{t^6q^3} - \frac{7}{24}\frac{x^{10}}{t^6q^4}\ldots\right]$$

Let the total current in the tube be I. By integrating the complete expression for current density over the cross section of the tube

$$I = \pi a_o(2qt+t^2)\left[1 + c_1\frac{jm^2t^2}{3!} + c_2\frac{(jm^2t^2)^2}{5!} + \ldots\right] + I_p\left[d_1\frac{jm^2t^2}{2!} + d_2\frac{(jm^2t^2)^2}{4!} + d_3\frac{(jm^2t^2)^3}{6!} + \ldots\right] \tag{15}$$

where

$$c_1 = 1 - \frac{1}{20}\frac{t^2}{q^2} + \frac{1}{20}\frac{t^3}{q^3} - \frac{11}{280}\frac{t^4}{q^4} + \ldots$$

$$c_2 = 1 - \frac{1}{14}\frac{t^2}{q^2} + \frac{1}{14}\frac{t^3}{q^3} - \ldots$$

$$c_3 = 1 - \frac{1}{12}\frac{t^2}{q^2} + \ldots$$

$$c_4 = 1 - \frac{1}{11}\frac{t^2}{q^2} + \ldots$$

as in reference 5, and where

$$d_1 = 1 + \frac{1}{3}\frac{t}{q} - \frac{1}{12}\frac{t^2}{q^2} + \frac{1}{30}\frac{t^3}{q^3} - \ldots$$

$$d_2 = 1 + \frac{2}{5}\frac{t}{q} - \frac{1}{10}\frac{t^2}{q^2} + \frac{3}{70}\frac{t^3}{q^3} - \ldots$$

$$d_3 = 1 + \frac{3}{7}\frac{t}{q} - \frac{3}{28}\frac{t^2}{q^2} + \frac{1}{21}\frac{t^3}{q^3} - \ldots$$

$$d_4 = 1 + \frac{4}{9}\frac{t}{q} - \frac{1}{9}\frac{t^2}{q^2} + \ldots$$

This gives the value of a_o in terms of I and I_p.

If the tube were not present, the center conductor carrying I_p would supply its resistance loss including its own eddy-current loss. Then, as stated by Waldo V. Lyon[6] at the top of page 1377, AIEE TRANSACTIONS, 1921, in his paper on eddy-current losses in armature conductors, if the outer tube and its current I be introduced, it does not change the eddy-current loss in the inner conductor, and the total additional power supplied by the circuits to the two conductors is equal to the resistance loss of the tube. There is a transfer of power from the inner conductor to the tube. These amounts of power can be computed.

In the work so far, magnetic flux outside the tube has not been considered as it would not change any of the current densities. It will be included now in computing the transfer of power, and, as would be expected, it will be shown that it has no effect on the expression for eddy-current loss.

The voltage drop in all elements of the tube is the same as that at its outer surface and is

$$j\omega 2(I+I_p)\log n\,\frac{s}{r} + \rho i_{(t)} \tag{16}$$

where $i_{(s)}$ is the current density at the outer surface and where s is a certain large distance to which flux is counted. Since the expression in s will finally cancel out, the result is the same no matter how large a value of s is chosen.

Let conj I be the conjugate of I, that is, the same complex quantity except with j changed to $-j$. Multiply equation 16 by conj I and take the real part, to obtain the power delivered to the tube from its own circuit, per centimeter of the tube. This is

$$\text{Re conj } I\, j\omega 2(I+I_p)\,\text{logn}\,\frac{s}{r}+\text{Re conj } I\, a_o\rho\left[1+b_1\frac{jm^2t^2}{2!}+b_2\frac{(jm^2t^2)^2}{4!}+\ldots\right]+Re\text{ conj } I\, I_p\frac{j\omega 4t}{2q+t}\left[e_1+e_2\frac{jm^2t^2}{3!}+e_3\frac{(jm^2t^2)^2}{5!}+\ldots\right] \quad (17)$$

where Re denotes "real part of." Note that in this paper conj applies only to the single letter which follows it, but Re applies to the complete expression which follows.

$$b_1=1-\frac{1}{3}\frac{t}{q}+\frac{1}{4}\frac{t^2}{q^2}-\ldots=\frac{1}{2}+\frac{q}{t}-\frac{q^2}{t^2}\,\text{logn}\left(1+\frac{t}{q}\right)$$

$$b_2=1-\frac{2}{5}\frac{t}{q}+\frac{3}{10}\frac{t^2}{q^2}-\frac{17}{70}\frac{t^3}{q^3}\ldots$$

$$b_3=1-\frac{3}{7}\frac{t}{q}+\frac{9}{28}\frac{t^2}{q^2}-\frac{11}{42}\frac{t^3}{q^3}\ldots$$

$$b_4=1-\frac{4}{9}\frac{t}{q}+\frac{1}{3}\frac{t^2}{q^2}\ldots$$

$$b_5=1-\frac{5}{11}\frac{t}{q}+\frac{15}{44}\frac{t^2}{q^2}\ldots$$

as in reference 5.

$$e_1=1+\frac{1}{12}\frac{t^2}{q^2}-\frac{1}{12}\frac{t^3}{q^3}+\frac{3}{40}\frac{t^4}{q^4}-\frac{1}{15}\frac{t^5}{q^5}\ldots=\left(\frac{1}{2}+\frac{q}{t}\right)\text{logn}\left(1+\frac{t}{q}\right)$$

$$e_2=1+\frac{1}{10}\frac{t^2}{q^2}-\frac{1}{10}\frac{t^3}{q^3}+\frac{51}{560}\frac{t^4}{q^4}\ldots$$

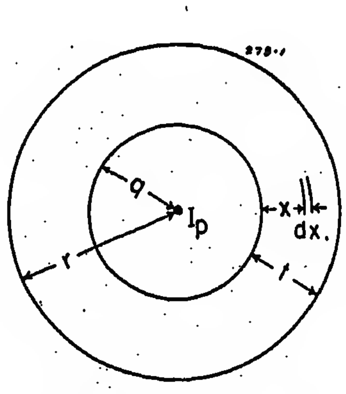

Figure 1. Tubular conductor and central wire

$$e_3=1+\frac{3}{28}\frac{t^2}{q^2}-\frac{3}{28}\frac{t^3}{q^3}\ldots$$

$$e_4=1+\frac{1}{9}\frac{t^2}{q^2}-\frac{1}{9}\frac{t^3}{q^3}\ldots$$

The total flux caused by the current in the tube, as far as radius s, is

$$2I\,\text{logn}\,\frac{s}{r}+4\pi a_o t^2\left[\frac{b_1}{2!}+b_2\frac{jm^2t^2}{4!}+b_3\frac{(jm^2t^2)^2}{6!}+\ldots\right]+\frac{4I_p t}{2q+t}\left[e_2\frac{jm^2t^2}{3!}+e_3\frac{(jm^2t^2)^2}{5!}+\ldots\right] \quad (18)$$

Multiply by $j\omega$ to obtain the voltage induced in the central conductor. Then multiply by conj I_p and take the real part to obtain the additional power supplied by the circuit of the central conductor. This power is transferred to the tube and helps supply the resistance loss in the tube. By adding equation 17, the total resistance loss in the tube is found to be

$$\text{Re conj } I(I)\,j\omega 2\,\text{logn}\,\frac{s}{r}+\text{Re conj } I\, a_o\rho\times\left[1+b_1\frac{jm^2t^2}{2!}+b_2\frac{(jm^2t^2)^2}{4!}+\ldots\right]+\text{Re conj } I\, I_p\frac{j\omega 4t}{2q+t}\times\left[e_1+e_2\frac{jm^2t^2}{3!}+e_3\frac{(jm^2t^2)^2}{5!}+\ldots\right]+\text{Re conj } I_p(I)\,j\omega 2\,\text{logn}\,\frac{s}{r}+\text{Re conj } I_p a_o\rho\left[b_1\frac{jm^2t^2}{2!}+b_2\frac{(jm^2t^2)^2}{4!}+\ldots\right]+\text{Re conj } I_p I_p\frac{j\omega 4t}{2q+t}\left[e_2\frac{jm^2t^2}{3!}+e_3\frac{(jm^2t^2)^2}{5!}+\ldots\right] \quad (19)$$

Now conj II is a real quantity, $|I|^2$, since

$$(a-jb)(a+jb)=a^2+b^2+j0$$

conj $I\,I_p+I$ conj I_p is also a real quantity, since

$$(a-jb)(c+jd)+(a+jb)(c-jd)=2ac+2bd+j0$$

It is the sum of a complex quantity and its conjugate. Therefore, the terms in logn s/r have no real part and disappear.

The resistance loss in the tube, then, is

$$\text{Re conj } Ia_o\rho+\text{Re}(\text{conj } I+\text{conj } I_p)a_o\rho\times\left[b_1\frac{jm^2t^2}{2!}+b_2\frac{(jm^2t^2)^2}{4!}+\ldots\right]+\text{Re}\,\frac{j\omega 4t}{2q+t}\left[\text{conj } I\, I_pe_1+I_p(\text{conj } I+\text{conj } I_p)\left\{e_2\frac{jm^2t^2}{3!}+e_3\frac{(jm^2t^2)^2}{5!}+\ldots\right\}\right] \quad (20)$$

Note that the real parts of the entire expressions are taken.

Equations 15 and 20 can be applied to the three tubes in succession of a three-phase concentric circuit, thus obtaining the skin-effect resistance ratio of each tube, that is, the ratio of the resistance loss in the tube compared to the loss with direct current of the same amperage.

The power lost in a tube with direct current of amperage I is

$$\frac{|I|^2\rho}{\pi(2qt+t^2)} \quad (21)$$

The skin-effect resistance ratio of the inner tube is the same as that of an isolated tube, since the surrounding tubes do not affect its current density. In this case, $I_p=0$. The formulas and curves were published in reference 5.

Dividing equation 20 by equation 21 and substituting the value of a_o given by equation 15.

$$\frac{R_{ac}}{R_{dc}}=\text{Re}\,\frac{1+b_1\frac{jm^2t^2}{2!}+b_2\frac{(jm^2t^2)^2}{4!}+\ldots}{1+c_1\frac{jm^2t^2}{3!}+c_2\frac{jm^2t^2}{5!}+\ldots} \quad (22)$$

for the inner tube.

For the intermediate tube

$$\frac{R_{ac}}{R_{dc}}=\text{Re}\,\frac{LM}{Q}+\text{Re}S \quad (23)$$

where

$$L=1+\left(1+\frac{\text{conj } I_p}{\text{conj } I}\right)\left\{b_1\frac{jm^2t^2}{2!}+b_2\frac{(jm^2t^2)^2}{4!}+\ldots\right\} \quad (24)$$

$$M=1-\frac{I_p}{I}\left\{d_1\frac{jm^2t^2}{2!}+d_2\frac{(jm^2t^2)^2}{4!}+\ldots\right\} \quad (25)$$

$$Q=1+c_1\frac{jm^2t^2}{3!}+c_2\frac{(jm^2t^2)^2}{5!}+\ldots \quad (26)$$

(Same as equation 16, reference 5, or denominator of 22)

$$S=\frac{I_p}{I}e_1\frac{jm^2t^2}{1!}+\left(\frac{I_p}{I}+\left|\frac{I_p}{I}\right|^2\right)\times\left\{e_2\frac{(jm^2t^2)^2}{3!}+e_3\frac{(jm^2t^2)^3}{5!}+\ldots\right\} \quad (27)$$

In balanced three-phase circuits, for the two opposite phase rotations

$$\frac{I_p}{I}=-\frac{1}{2}+j\frac{\sqrt{3}}{2}\ \text{ or }\ -\frac{1}{2}-j\frac{\sqrt{3}}{2} \quad (28)$$

$$1+\frac{\text{conj } I_p}{\text{conj } I}=\frac{1}{2}-j\frac{\sqrt{3}}{2}\ \text{ or }\ \frac{1}{2}+j\frac{\sqrt{3}}{2}$$

$$\frac{I_p}{I}+\left|\frac{I_p}{I}\right|^2=\frac{1}{2}+j\frac{\sqrt{3}}{2}\ \text{ or }\ \frac{1}{2}-j\frac{\sqrt{3}}{2}$$

The two opposite phase rotations produce slightly different amounts of eddy-cur-

rent loss, that is, different values of R_{ac}, depending on whether the greater current density is produced in the inner or the outer surface of the intermediate tube. See Figure 3.

For the outer tube

$I_p = -I$, and

$$\frac{R_{ac}}{R_{dc}} = \text{Re}\frac{1+d_1\frac{jm^2t^2}{2!}+d_2\frac{(jm^2t^2)^2}{4!}+\dots}{1+c_1\frac{jm^2t^2}{3!}+c_2\frac{(jm^2t^2)^2}{5!}+\dots} \qquad (29)$$

Equations 22, 23, and 29 give the skin-effect resistance ratio of the three tubes of a three-phase concentric tubular circuit. They are applicable up to about $mt=4$ and $t/d=0.2(t/q={}^2/_3)$, as in reference 5.

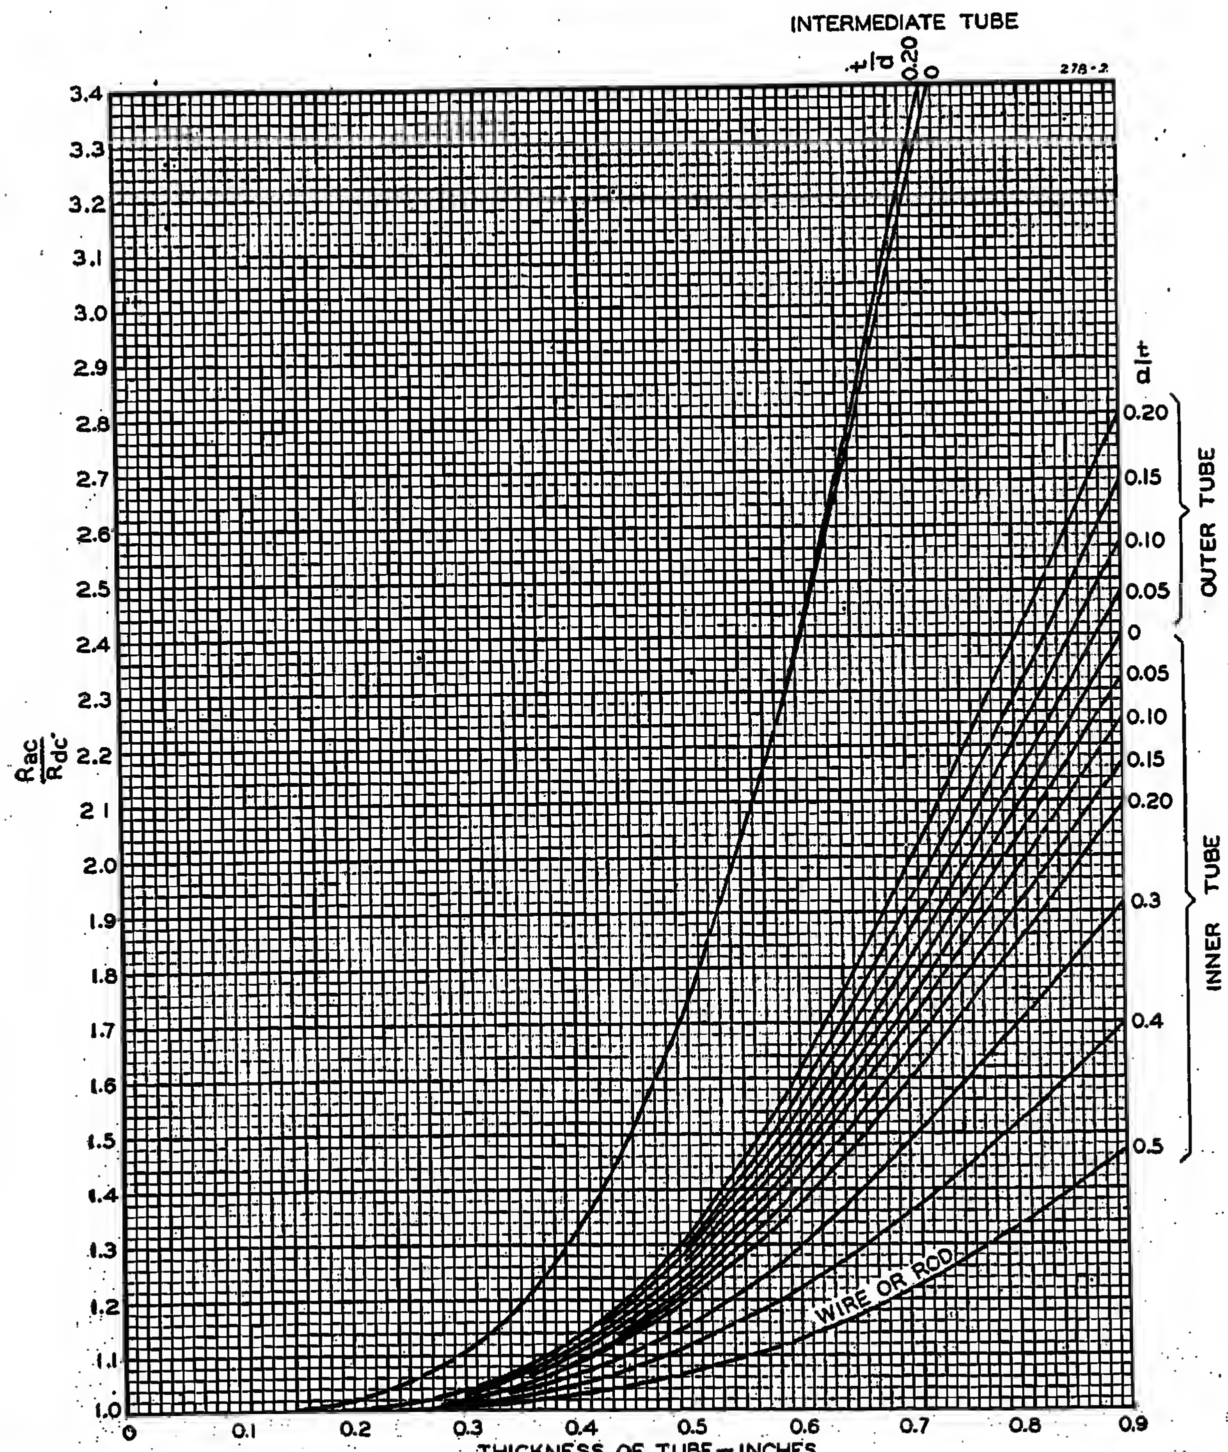
The values of the ratios are plotted in Figure 2 on a base of thickness of copper tube, for standard frequency and temperature. This can save the work of computing by the formulas, in cases where the curves apply. For a frequency f such as 25 or 50 cycles, multiply the tube thickness by $\sqrt{f/60}$ before reading from the curves.

In order to show that there is a larger skin-effect ratio for the intermediate tube than for the others, the current density in the three phases is plotted in Figure 3, as computed by equation 13 and following formulas. The case chosen is that of three flat straps, which is the same as that of three concentric tubes with extremely large radii.

The skin-effect resistance ratio of the outer tube of a single-phase concentric circuit is the same as the ratio for the outer tube of a three-phase concentric circuit as given by Figure 2 or equation 29, since the total current inside the tube in either case is $-I$. The resistance ratio of the inner tube of a single-phase concentric circuit, and also the ratio of an isolated tube, are the same as that of the inner tube of a three-phase circuit, as given by Figure 2 or equation 22. See also references 5 and 7.

Figure 2. Skin-effect ratios for solid copper tubes, 75 degrees centigrade, 60 cycles, three phase

Thickness $=t$ and outside diameter $=d$, of the tube being considered



Example 2. Find the effective resistance at 60 cycles and 75 degrees centigrade of the three copper tubes described in example 1.

The inner tube, whose inside and outside diameters are 1.2 and 3.0 inches, has a resistance to direct current of 5.47×10^{-8} ohm per centimeter. From Figure 2, taking $t=0.9$ inch and $t/d=0.3$, the skin-effect resistance ratio is 1.92. Then R_{ac} for 60 cycles is

$$5.47\times10^{-8}\times1.92=1.050\times10^{-7} \text{ ohm per centimeter}$$

This is to be used for resistance drop and copper loss in the inner tube.

For the intermediate tube, with inside and outside diameters 4.0 and 4.5 inches, and thickness 0.25 inch, the resistance to direct current is 9.74×10^{-8}. From Figure 2, $R_{ac}/R_{dc}=1.059$ and therefore $R_{ac}=1.030\times10^{-7}$ ohm per centimeter.

For the outer tube, the inside and outside diameters are 5.6 and 6.0 inches. The resistance ratio, from Figure 2, is 1.008 and

$$R_{ac}=8.92\times10^{-8}\times1.008=8.99\times10^{-8} \text{ ohm per centimeter}$$

Bessel-Function Formulas for Single-Phase Concentric Circuits and Isolated Tubes

The well-known solution for skin effect in an isolated tube in terms of Bessel functions is as follows.[2,7]

$$\frac{R_{ac}}{R_{dc}} = \text{Re}\frac{\alpha t(q+r)}{2r}\times \frac{I_0(\alpha r)K_0'(\alpha q)-K_0(\alpha r)I_0'(\alpha q)}{I_0'(\alpha r)K_0'(\alpha q)-K_0'(\alpha r)I_0'(\alpha q)} \qquad (30)$$

where I_0 and K_0 are modified Bessel functions of the first and second kinds, of order zero, Re denotes real part of

r = outside radius
q = inside radius
t = thickness of tube $=r-q$
$a^2=\frac{j4\pi\omega}{\rho}=jm^2$
$\alpha=me^{\frac{j\pi}{4}}$
$j=\sqrt{-1}$
$\omega=2\pi\times$frequency
ρ = resistivity of the metal, in abohms per centimeter cube

Note that

$$I_0(\alpha r)=\text{ber } mr+j\text{ bei } mr \qquad (31)$$

$$K_0(\alpha r)=\text{ker } mr+j\text{ kei } mr \qquad (32)$$

$$I_0'(\alpha r)=e^{-j\pi/4}(\text{ber}' \,mr+j\text{ bei}' \,mr) \qquad (33)$$

$$K_o'(\alpha r)=e^{-j\pi/4}\,(\text{ker}'\,mr+j\,\text{kei}'\,mr) \qquad (34)$$

Equation 30 is applicable to the inner tube of a concentric circuit, and to a nonconcentric circuit in which the conductors are separated by more than a few diameters and proximity effect is considered negligibly small.

For the outer tube of a concentric circuit, where all the return conductors are within the outer tube[2,4]

$$\frac{R_{ac}}{R_{dc}}=\text{Re}\,\frac{-\alpha t(q+r)}{2q}\times \frac{I_o(\alpha q)K_o'(\alpha r)-K_o(\alpha q)I_o'(\alpha r)}{I_o'(\alpha q)K_o'(\alpha r)-K_o'(\alpha q)I_o'(\alpha r)} \qquad (35)$$

This is the same as formula 30 for an isolated tube, except interchange q and r and multiply by -1. Both formulas 30 and 35 may be derived by following the general method used in references 7 and 4

Formulas 30 and 35 may be used for direct computation of numerical problems, using tabulated values from references 7, 8, 9, or 10.

For very small or very large values of the argument, or for tubes whose thickness is small compared to their radius, series formulas, as given in this paper, may be shorter to use.

High-Frequency Formulas

For frequencies higher than 60 cycles, formulas derived from the asymptotic expansions of Bessel functions are often convenient. Except that they do not give any effect of radiation, and that they apply only to the dominant mode of transmission in a coaxial line, they are applicable to very high frequency since they are series with powers of the frequency in the denominators of the terms. As is usual with power series, their applicability depends on the rapidity with which the terms of the series become smaller and smaller.

Formulas of this type for the inner and outer conductors are given here. They are applicable to single-phase, concentric circuits and the formula for the inner conductor is applicable also to all the tubular conductors of circuits which are not concentric and in which the conductors are separated by more than a few diameters. With high frequency, such circuits are more likely to occur than three-phase concentric circuits.

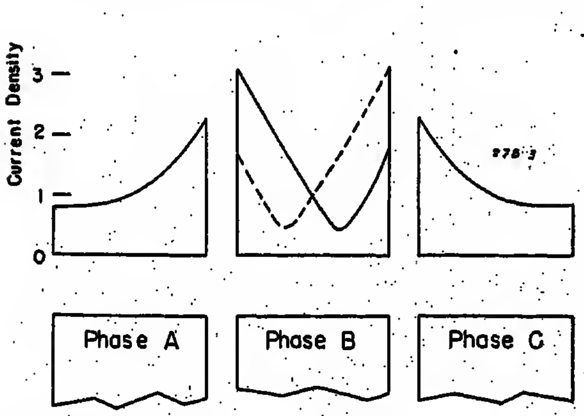


Figure 3. Current density in three-phase strap conductors, closely adjacent

Current density for same amperage of direct current=1. $mt=\sqrt{6}$. The dotted line is for opposite phase rotation

To express equation 30 as a power series using asymptotic expansions (see reference 10, items 810.6, 810.7, 816.1, and 816.2) we have

$$-\frac{I_o'(\alpha q)}{K_o'(\alpha q)}=\frac{I_1(\alpha q)}{K_1(\alpha q)}$$

$$=\frac{e^{2\alpha q}}{\pi}\,\frac{1-\dfrac{3}{1!8\alpha q}-\dfrac{3\times 5}{2!(8\alpha q)^2}-\dfrac{3^2\times5\times7}{3!(8\alpha q)^3}\cdots}{1+\dfrac{3}{1!8\alpha q}-\dfrac{3\times 5}{2!(8\alpha q)^2}+\dfrac{3^2\times5\times7}{3!(8\alpha q)^3}\cdots}.$$

$$=\frac{e^{2\alpha q}}{\pi}\left[1-\frac{6}{8\alpha q}+\frac{18}{(8\alpha q)^2}-\frac{204}{(8\alpha q)^3}\cdots\right]$$

$$\frac{Z_{ac}}{R_{dc}}=\frac{\alpha t(q+r)}{2r}\,\frac{N}{D}$$

where

$$N=e^{\alpha r}\left\{1+\frac{1}{8\alpha r}+\frac{9}{2(8\alpha r)^2}+\frac{75}{2(8\alpha r)^3}\cdots\right\}+ e^{2\alpha q-\alpha r}\left\{1-\frac{1}{8\alpha r}+\frac{9}{2(8\alpha r)^2}-\frac{75}{2(8\alpha r)^3}\cdots\right\}\times \left\{1-\frac{6}{8\alpha q}+\frac{18}{(8\alpha q)^2}-\frac{204}{(8\alpha q)^3}\cdots\right\}$$

and

$$D=e^{\alpha r}\left\{1-\frac{3}{8\alpha r}-\frac{15}{2(8\alpha r)^2}-\frac{105}{2(8\alpha r)^3}\cdots\right\}- e^{2\alpha q-\alpha r}\left\{1+\frac{3}{8\alpha r}-\frac{15}{2(8\alpha r)^2}+\frac{105}{2(8\alpha r)^3}\cdots\right\}\times \left\{1-\frac{6}{8\alpha q}+\frac{18}{(8\alpha q)^2}-\frac{204}{(8\alpha q)^3}\cdots\right\}$$

Then

$$\frac{Z_{ac}}{R_{dc}}=\frac{\alpha t(q+r)}{2r}\left[1+\frac{4}{8\alpha r}+\frac{24}{(8\alpha r)^2}+\frac{192}{(8\alpha r)^3}\cdots+ 2e^{-2\alpha t}\left\{1+\frac{6}{8\alpha r}+\frac{42}{8\alpha r)^2}+\frac{348}{(8\alpha r)^3}\cdots\right\}\times \left\{1-\frac{6}{8\alpha q}+\frac{18}{(8\alpha q)^2}-\frac{204}{(8\alpha q)^3}\cdots\right\}+ \text{terms in } e^{-4\alpha t}\cdots\right]=\frac{t(q+r)}{r^2}\times$$

$$\left[\frac{\alpha r}{2}+\frac{1}{4}+\frac{3}{16\alpha r}+\frac{3}{16\alpha^2 r^2}\cdots+e^{-2\alpha t}\times \left\{\alpha r+\frac{3}{4}+\frac{21}{32\alpha r}\cdots\right\}\left\{1-\frac{3}{4\alpha q}+ \frac{9}{32\alpha^2 q^2}\cdots\right\}+\text{terms in } e^{-4\alpha t}\cdots\right]$$

omitting the final terms of the last two brackets. Now

$$\alpha=me^{j\pi/4}=m\left(\frac{1}{\sqrt{2}}+\frac{j}{\sqrt{2}}\right)$$

$$\frac{1}{\alpha}=\frac{1}{m}e^{-j\pi/4}=\frac{1}{m}\left(\frac{1}{\sqrt{2}}-\frac{j}{\sqrt{2}}\right)$$

$$\frac{1}{\alpha^2}=\frac{1}{m^2}e^{-j\pi/2}=\frac{1}{m^2}(0-j)$$

$$e^{-2\alpha t}=e^{-mt\sqrt{2}}(\cos mt\sqrt{2}-j\sin mt\sqrt{2})$$

(See reference 10, item 408.05) Taking the real part, the resistance ratio for an isolated tube is

$$\frac{R_{ac}}{R_{dc}}=\frac{t(q+r)}{r^2}\left[\frac{mr}{2\sqrt{2}}+\frac{1}{4}+\frac{3}{16mr\sqrt{2}}+\frac{0}{r^2}\cdots+ e^{-mt\sqrt{2}}(\cos mt\sqrt{2})\left\{\frac{mr}{\sqrt{2}}-\frac{3}{4}\frac{t}{q}+ \frac{3}{32mr\sqrt{2}}\left(7-6\frac{r}{q}+3\frac{r^2}{q^2}\right)\cdots\right\}+ e^{-mt\sqrt{2}}(\sin mt\sqrt{2})\left\{\frac{mr}{\sqrt{2}}-\frac{3}{32mr\sqrt{2}}\times \left(7-6\frac{r}{q}+3\frac{r^2}{q^2}\right)\cdots\right\}+\text{terms in } e^{-2mt\sqrt{2}}\cdots\right] \qquad (36)$$

The first line is seen to be the series that is applicable to solid wire. Formula 36 was given a number of years ago in his Master of Science thesis at Massachusetts Institute of Technology by J. M. Roberts, now professor of electrical engineering at the University of Louisville, Louisville, Kentucky.

The expansion of formula 35 for large values of m is not obtained by interchanging q and r in formula 36, for $e^{-mt\sqrt{2}}$ would become $e^{mt\sqrt{2}}$. The expansion is made by taking $K_o(\alpha q)/K_o'(\alpha q)$ as the initial part. The result is:

High-frequency formula for resistance ratio of outer tube:

$$\frac{R_{ac}}{R_{dc}}=\frac{t(q+r)}{q^2}\left[\frac{mq}{2\sqrt{2}}-\frac{1}{4}+\frac{3}{16mq\sqrt{2}}+\frac{0}{q^2}\cdots+ e^{-mt\sqrt{2}}(\cos mt\sqrt{2})\left\{\frac{mq}{\sqrt{2}}-\frac{3}{4}\frac{t}{r}+ \frac{3}{32mq\sqrt{2}}\left(7-6\frac{q}{r}+3\frac{q^2}{r^2}\right)\cdots\right\}+ e^{-mt\sqrt{2}}(\sin mt\sqrt{2})\left\{\frac{mq}{\sqrt{2}}-\frac{3}{32mq\sqrt{2}}\times \left(7-6\frac{q}{r}+3\frac{q^2}{r^2}\right)\cdots\right\}+\text{terms in } e^{-2mt\sqrt{2}}\cdots\right] \qquad (37)$$

The Penetration Formula

The "penetration formula" is a well-known and useful method for computing the a-c resistance of conductors at moder-

ately high frequencies. However, special precautions should be taken in using it for tubes, and these will now be described.

A convenient statement of the penetration formula, arranged so as to give a close approximation to the Bessel function solution at high frequencies, is that the alternating current is taken to penetrate, at uniform current density, to a depth δ_1 and the a-c resistance is taken to be equal to the d-c resistance of a tube consisting of the surface layer of metal of thickness δ_1. The formula for the thickness is

$$\delta_1 = \sqrt{2}/m \qquad \text{centimeters} \quad (38)$$

where

$$m = \sqrt{(4\pi\omega/\rho)}$$

and where ρ is in abohms per centimeter cube (see equation 11).

For an isolated round wire or tube of outside radius r, the effective resistance, then, is that of a tube of cross section

$$\pi\{r^2-(r-\delta_1)^2\} = 2\pi r\delta_1\left(1-\frac{\delta_1}{2r}\right) = \frac{2\pi r\sqrt{2}}{m}\left(1-\frac{1}{mr\sqrt{2}}\right) \quad (39)$$

from equation 38.

The resistance ratio by the penetration formula is the ratio of the two cross sections, which is

$$\frac{\pi(r^2-q^2)m}{2\pi r\sqrt{2}}\left(1-\frac{1}{mr\sqrt{2}}\right)^{-1} = \frac{t(q+r)}{r^2}\times \left(\frac{mr}{2\sqrt{2}}+\frac{1}{4}+\frac{1}{4mr\sqrt{2}}+\ldots\right) \quad (40)$$

by the binomial expansion of $(1-x)^{-1}$.

The first two terms of the series in equation 40 are the same as in formula 36. These two terms give the equation of the straight line which is the asymptote of the curve of R_{ac}/R_{dc} plotted on mt, as in Figure 3, reference 5.

In order for equation 40 to agree with the corresponding portion of formula 36 within what might be called slide-rule accuracy, or about 0.5 per cent, it is necessary for $1/8m^2r^2$ to be less than 0.005. That is

$$\frac{\delta_1}{r}<\frac{1}{4} \quad (41)$$

This is often expressed by stating that the penetration depth δ_1 should be a small fraction of the radius of curvature, and under such a condition it can apply to conductors that are not round.

In the case of round tubes, another requirement is found from equation 36, namely, that the penetration depth δ_1 should be a small part of the thickness t. Equation 40 plainly does not take care of the terms in $e^{-mt\sqrt{2}}$ of formula 36, and so, if the penetration formula is to be a good approximation, these terms should be proportionately small. This leads to the condition that

$$\frac{\delta_1}{t}<0.3 \text{ approximately} \quad (42)$$

In most cases, if equation 42 is complied with, then the requirement of equation 41 also is met.

The penetration formula can be applied to the inner surface of the outer tube of a concentric circuit.

Example 3. Find the skin-effect resistance ratio for an outer tube in which $mt=3.2$, $mq=4.8$, and $mr=8$.

$$\frac{q+r}{2q}=\frac{4}{3}, \quad \alpha t = mte^{j\pi/4}$$

$$I_0(\alpha q) = \text{ber } mq + j \text{ bei } mq = \text{ber } 4.8+j \text{ bei } 4.8 = -5.45+j0.884$$

$$K_0'(\alpha r) = e^{-j\pi/4}(\text{ker}' \ 8.0+j \text{ kei}' \ 8.0) = e^{-j\pi/4}(-0.000880-j0.001336)$$

By equation 35,

$$\frac{R_{ac}}{R_{dc}} = \text{Re}\left\{-3.2(0+j)\times\frac{4}{3}\right\}\frac{-0.447+j0.376}{0.629} = 2.55 \text{ by equation 35}$$

From equation 37

$$\frac{t(q+r)}{q^2}=1.777$$

First line of equation 37

$$=1.697-0.25+0.0276 = 1.475$$

$$mt\sqrt{2}=4.525 \qquad e^{-4.525}=0.01083$$

$$\cos 4.525 = -0.1858$$

Second line of equation 37

$$=0.01083\times(-0.1858)(3.39-0.30+0.062\ldots) = -0.00634$$

Third line of equation 37

$$=0.01083\times(-0.983)(3.39-0.062) = -0.0354$$

$$\frac{R_{ac}}{R_{dc}}=1.777(1.475-0.0063-0.0354) = 2.55$$

Thickness of tube in inches, for copper at 75 degrees centigrade and 60 cycles

$$m^2=\frac{4\pi\omega}{\rho}=\frac{4\pi\times120\pi}{1{,}724}\times\frac{234+20}{234+75} = 2.26$$

$$m=1.504$$

$$\text{thickness}=\frac{3.2}{1.504}\times\frac{1}{2.54}=0.838 \text{ inch}$$

$$t/d=\frac{3.2}{2\times8}=0.2$$

From Figure 2

$R_{ac}/R_{dc}=2.54$

By the penetration formula, the section of the equivalent tube of thickness δ_1 is

$$\pi\{(q+\delta_1)^2-q^2\} = 2\pi q\delta_1\left(1+\frac{\delta_1}{2q}\right) = \frac{2\pi q\sqrt{2}}{m}\left(1+\frac{1}{mq\sqrt{2}}\right)$$

by equation 38

$$\frac{R_{ac}}{R_{dc}} = \frac{\pi t(q+r)m}{2\pi q\sqrt{2}\left(1+\frac{1}{mq\sqrt{2}}\right)} = \frac{3.2\times12.8}{2(6.78+1)}=2.63$$

which is three per cent too large.

$$\delta_1=\frac{\sqrt{2}}{1.504}=0.94 \text{ centimeter or } 0.37 \text{ inch}$$

$$\frac{\delta_1}{t}=\frac{0.37}{0.838}=0.44$$

which is somewhat too large for the employment of the penetration formula.

Standardized Load-Center Unit Substations for Low-Voltage A-C Systems

E. M. HUNTER
MEMBER AIEE

J. C. PAGE
ASSOCIATE AIEE

THE tremendous expansion of production facilities necessitated by American defense and war efforts has given the manufacturer of electrical equipment a serious challenge. Entire large defense projects, such as manufacturing plants, navy yards, drydocks, air depots, and office buildings, have been built in incredibly short times. Any one of these projects will not be complete without an electrical distribution system. One of the many tasks before the electrical manufacturer is to produce the necessary apparatus for the electrical distribution systems, and have it available by the time the project is ready to receive it.

In most of the recent projects power has been distributed to ultimate loads by means of the load-center power distribution systems. This type, although only recently applied to low-voltage systems, has been used successfully for years on high-voltage systems in the central station field. The essentials of load-center distribution for low-voltage a-c systems are

1. A large load area is divided into small load areas, each ranging from 600 to 1,000 kva at 480 volts for example.

2. Power is distributed at medium voltage (2.4 to 13.2 kv) to substations, located near the electrical load center in each of the small areas where the voltage is transformed to utilization voltage to service the area loads.

It has been found that the load-center distribution system when properly applied is superior to other systems from a performance standpoint, and less costly. One of the most important contributions of the electrical manufacturer to the field of low-voltage a-c systems in recent years has been the development and standardization of the load-center unit substation to service the small load areas described above. To the purchaser of electrical apparatus, the development and standardization of the load-center unit substation means that a complete, co-ordinated, pre-engineered step-down substation for a low-voltage a-c system may be ordered in the same manner as a standard motor or standard motor-control equipment.

It is the purpose of this paper to present

1. A definition of a load-center unit substation.

2. The general requirements which have been met by the standardized line with which the writers are most familiar.

3. A description of units with illustrations.

4. Tables for the ready selection of load-center unit substations.

For clarity the term "load-center unit substation" is defined here as follows:

A completely metal-enclosed integrated substation equipment incorporating

1. The required high-voltage switching, control, and incoming circuit termination facilities.

2. Transformer section or sections to transform a-c power from the medium-voltage range (2,400 to 15,000 volts) to the low-voltage range of 600 volts and below.

3. The required low-voltage switching, control, and outgoing feeder circuit termination facilities.

An installation view of a load-center unit substation is shown on Figure 1.

General Considerations

The load-center distribution system is generally thought of in connection with servicing a fairly large area with power. Thus the ultimate areas to be served usually consist of large buildings, mines, yards, docks, piers, camps, and so forth.

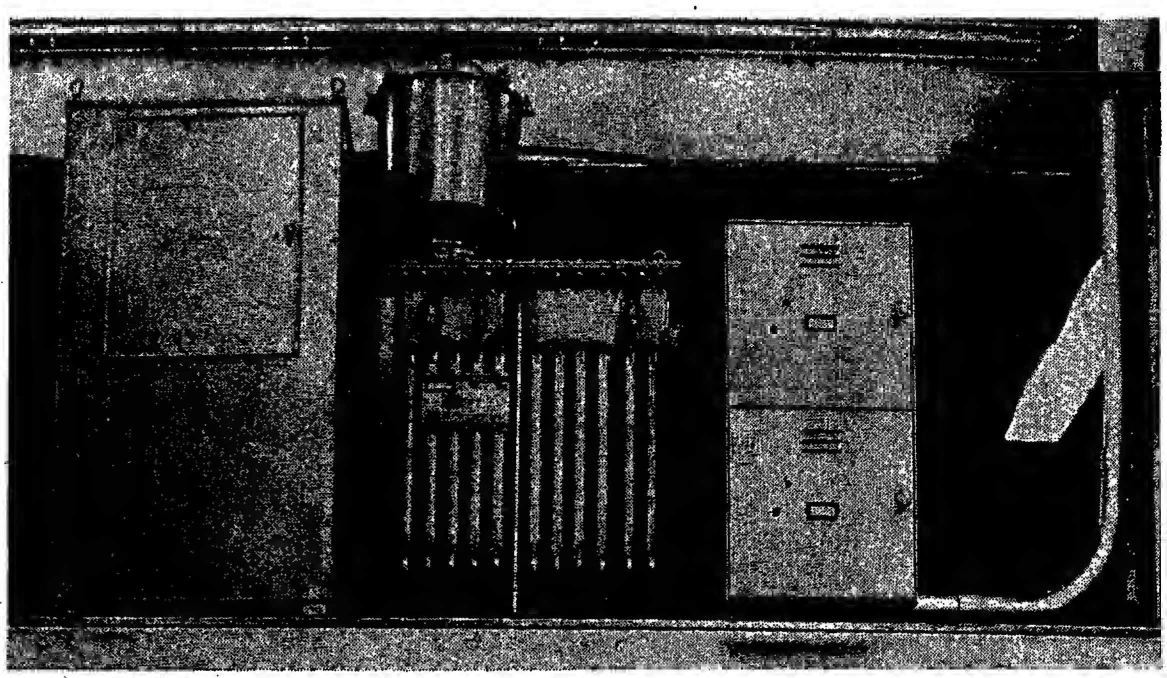
Safety considerations usually limit the highest voltage at which power may be carried within the load area to 13.2 kv. It is usually uneconomical to carry power to load-center locations at less than 2,400 volts because of the large cable required to carry the higher currents. Thus, for a given application any one of the medium voltages may be selected for this service, depending on local conditions and the requirements to be met. Consequently, from the electrical manufacturer's point of view, equipment must be available for the medium voltages, such as 2,400, 4,160, 4,800, 7,200, 12,000, and 13,200 volts.

When the circuit voltage of the available power supply is above 13.2 kv, it is generally advisable to step this down to a voltage in the medium-voltage range for distribution to the load area. This can be conveniently accomplished by means of a multicircuit unit substation, such as is shown on Figure 2. Where many such load areas are to be served, and service reliability is at a premium, two sources of supply may be brought in, or the master substations can be networked to form a primary network. A mobile substation can be used to serve as a spare, similar to the one shown on Figure 3.

From the standpoint of the load-center distribution, there are four types of basic

Figure 1. Indoor installation view of load-center unit substation, Pyranol-filled, rated three-phase, 60 cycles, 100 kva, 2,400 to 208/120 volts

Unit has two sets of primary cutouts for alternate supply and two low-voltage air circuit breakers for feeder protection. Located under crane rails, and supplies power to fluorescent lamps



Paper 42-85, recommended by the AIEE committee on industrial power applications for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted March 2, 1942; made available for printing March 23, 1942.

E. M. HUNTER is application engineer, protective devices, central station engineering department, and J. C. PAGE also is with central station engineering department, both of General Electric Company, Schenectady, N. Y.

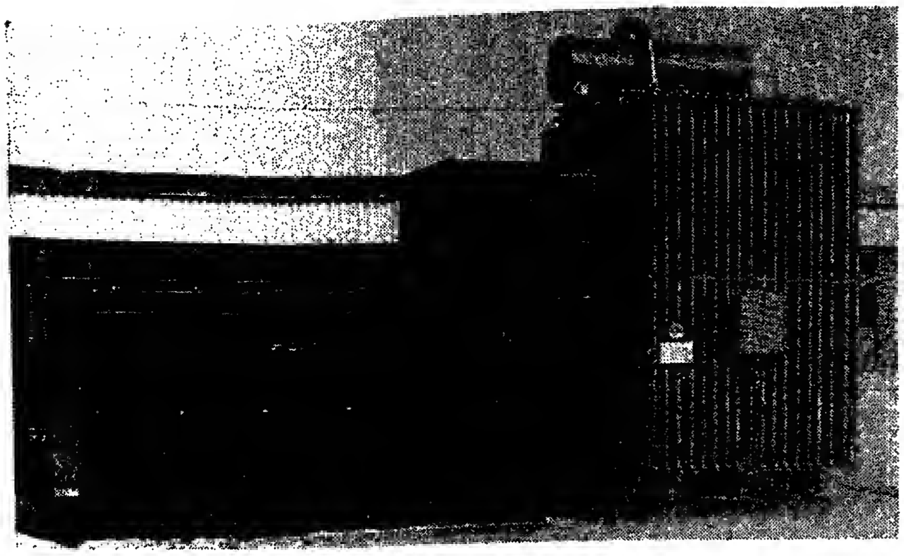


Figure 2. Outdoor unit substation rated three-phase, 60 cycles, 4,500 kva self-cooled, 6,000 kva forced air-cooled, 13,800 to 2,400 volts

Unit has four outgoing feeder circuit breakers and is located next to building it serves

circuit arrangements used.[1] These may be described as

1. The straight radial system.

2. The primary-selective system which comprises two primary lines brought into each load-center unit substation, usually with provision for connection to only one line at a time.

3. The radial-primary secondary-selective system, which involves bringing in only one source of primary power, while utilizing normally open secondary tie circuits to other substations to obtain power for emergency operation.

Table I. General Requirements of Load-Center Unit Substations

Requirement Item	Rating or Description of Substation
Frequency	Practically all 60 cycles
Phases	Three
Kva ratings	100, 200, 300, 450, 500, 600, 750, 1,000, 1,200, 1,500, 2,000
Primary voltage	2,400, 4,160, 4,800, 7,200, 12,000, 13,200
Secondary voltage	600, 480, 240, 208/120
Transformer coolant	Pyranol, oil, air
Incoming primary feeders	One or two (switches or circuit breakers)
Outgoing secondary feeders	Any number (usually less than ten air circuit breakers)
Enclosures	Indoor: general purpose outdoor: weatherproof
System type	
1. Straight radial	One incoming primary circuit to substation, radial secondary feeders
2. Primary selective	Preferred and emergency incoming primary circuits to substation, radial secondary feeders
3. Secondary selective	One incoming primary circuit to substation, radial secondary feeders with secondary emergency tie circuits to other substations
4. Secondary network	One incoming primary circuit to substation, secondary-network protector, radial secondary feeders, secondary tie circuits

4. The low-voltage network scheme.

Any one or several of these basic systems may be used in a given application, depending upon the requirements to be met.

The low-voltage ratings of load-center unit substations are fixed by the American Standards Association standard three-phase transformer voltages which are 600, 480, 240, and 208/120 Y volts. It has been found that the ASA standard kilovolt-ampere ratings, from 100 through 2,000 kva inclusive, cover nearly 100 per cent of the application requirements for this type of equipment.

The requirements as to location are such that it is essential to have available units for both indoor and outdoor service. These two types allow the distribution engineer to locate the substation in electrical load-center locations, often in space that would otherwise be worthless. An installation view of an outdoor unit is shown on Figure 4.

Thus, the general requirements to be met by such equipment may be tabulated as in Table I.

Description of Equipment

The transformer section of the load-center unit substation consists of a three-phase transformer with leads from the high- and low-voltage windings brought out of the tank through side-wall bushings to metal-enclosed bus connections known as throats. The throats are built integral with the transformer tanks, with the low-voltage throat located on one short-dimension side of the tank and the high-voltage throat located on the opposite side of the tank. The high-voltage throat is arranged so that any one of a number of high-voltage arrangements of switching equipment and cable-termination apparatus may be connected to it, while the low-voltage throat is arranged for connection to metal-enclosed low-voltage switchgear.

The high-voltage equipment may consist of metal-enclosed switchgear. Circuit breakers are available with interrupting ratings from 25,000 to 150,000 kva in 5-kv metal-clad equipments, and 250,000

Figure 3. Side view of 1,000-kva mobile substation

Figure 4. Outdoor installation view of load-center unit substation, Pyranol-filled, rated three-phase, 60 cycles, 1,500 kva, 13,800 to 575 volts

Unit has primary liquid-filled disconnecting switch and ten low-voltage air circuit breakers for protection of feeders supplying office building. Transformer at right is spare

75-AL-2	75,000	2,000, 2,500, 3,000
100-AL-2	100,000	4,000, 5,000, 6,000

to 500,000 kva in 15-kv metal-clad equipments. The vertical-lift removable type of breaker is standard in these equipments. Instruments, meters, and relays, mounted on steel panels, may be part of the equipment.

The metal-clad switchgear may have only one breaker as shown in Figure 5. Again there may be two breakers to meet the requirements of the primary-selective scheme as shown in Figure 6. A modification of the primary-selective scheme comprises two breaker positions and only one breaker, as shown in Figure 7. One removable breaker is arranged so that it can be inserted in either of the two breaker positions. This, of course, results in a lower installed cost and has proved attractive for some applications.

In place of the high-voltage metal-enclosed switchgear a set of three flange-mounted gang-operated oil-filled cutout switches may be used, as shown in Figure 8. This type of switch is rated five kilovolts, 250 amperes continuous. Most applications of the switch have utilized the switch as a disconnect only, with copper disconnecting blades in place of fuse links. The cutouts may be fused in the smaller ratings, when co-ordination with the low-voltage circuit breakers can be obtained such that the low-voltage circuit breakers will clear secondary faults before primary fuses are damaged. Cutouts may be fused up to 100 amperes at 5 kv and 200 amperes at 2.5 kv, with inter-

rupting ratings of 5,000 amperes rms at 5 kv, and 10,000 amperes rms at 2.5 kv.

For a five-kilovolt primary-selective system two sets of cutouts are available in a free-standing metal house. All of the cutouts have gang-operating mechanisms, usually interlocked so that only one set can be closed at a time. This arrangement is shown in Figure 9.

A liquid-filled 15-kv disconnecting switch arrangement is shown in Figure 10. This switch is the one developed for network transformers. It is suitable for circuits with normal currents up to 200 amperes. The switch may be filled with either oil or Pyranol, depending upon the application.

In addition to these high-voltage arrangements, the load-center unit substation may be equipped with a cable terminal and junction box without any disconnecting means. These may be oil- or Pyranol-filled for either 5-kv or 15-kv circuits, or air-filled for 5-kv circuits. This arrangement is shown in Figure 11.

The transformer section itself is available in all standard three-phase kilovolt-ampere ratings from 100 to 2,000 kva. Transformers rated above 250 kva are equipped with four $2^1/_2$ per cent taps spaced two above and two below normal high voltage. Automatic voltage-regulating equipment is not included in the transformer section, because there has been no demand for this equipment.

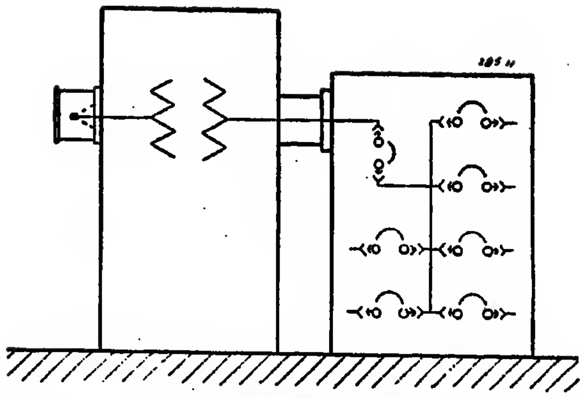

Figure 11. Load-center unit substation with primary junction box only

The transformer may be liquid-filled with the medium of cooling either oil or Pyranol. The Pyranol coolant is generally preferred for both indoor and outdoor load-center applications, but oil-filled transformers are often used outdoors. The Pyranol transformer has been a big factor in the development of the load-center distribution idea. Pyranol will not burn, and thus the Pyranol load-center unit substation can be located indoors near production centers without an expensive fireproof vault.

The dry type of transformer, cooled by the natural circulation of air through the windings, has also been developed for load-center unit substations.

Metal enclosed low-voltage switchgear is used in load-center unit substations. Usually, a number of branch circuits radiate from a single load-center unit substation. These branch circuits are controlled by means of air circuit breakers, mounted in compartments in the low-voltage switchgear. Air circuit breakers, with current interrupting ratings of 15,000, 25,000, 50,000, 75,000, and 100,000 amperes rms, are available in these equipments. The breakers may be either manually or electrically operated. The majority of the applications have required the use of manually operated breakers only. All circuit breakers operate with a time delay on overload currents, but trip instantaneously on short circuit. The breakers may be of either the stationary or the draw-out type. The draw-out type has been used extensively because of the interchangeability of draw-out breakers, which is an important factor in avoiding production delays during routine inspection. The breakers are available in stacks of one, two, three, and four high, depending on the size of the breaker. Two or more stacks can be located side by side to give the required number of breakers. These equipments are used with radial types of systems. For network applications, the standard network protector replaces two of the air circuit breakers in one of the stacks.

Load-Center Unit-Substation Application Tables

The interrupting rating of a circuit breaker is the maximum current which it is able to interrupt adequately and safely. It is important to use circuit breakers of adequate interrupting rating on load-center unit-substation circuits, as well as on any other circuits in which circuit breakers are used, in order to assure reduced arcing time with minimum damage to equipment when faults do occur. Contrary to a former rather widespread belief that low-voltage circuits will not produce short-circuit currents in excess of 20,000 amperes, tests have shown that short-circuit currents of several times this value may occur.[2] These values can be predicted by calculation with reasonable accuracy. Tentative rules for the calculation of these currents have been established by the AIEE.[3]

The load-center unit-substation application tables given here are based on the occurrence of a three-phase secondary fault near the terminals of the unit substation. The only source of power to the secondary, except for secondary motors, is assumed to be through the load-center unit substation. It is assumed that the total connected motor kilovolt-amperes will not exceed 50 per cent of the transformer rating on 208/120-volt systems and 100 per cent of the transformer kilovolt-ampere rating on 240-, 480-, and 600-volt systems. See Tables II, III, IV, and V.

The calculations for the short-circuit currents are based on the following:

1. Systems with voltages of 208/120, 240, 480, and 600 volts, because these are ASA standard voltages given in tentative standards *C*-57.1, dated March 1940.

2. Transformer reactances have been selected to give the most economical balance between transformer reactance and circuit-breaker interrupting rating consistent with reasonable voltage regulation. The actual values of reactance are indicated in the tables.

3. Calculations are based on proposed AIEE standard rules, that is: the symmetrical three-phase rms short-circuit current is increased by a factor of 1.25 to allow for an average d-c component. For the motor contribution, 50 per cent connected motor kilovolt-amperes is assumed to be capable of supplying a short-circuit current of 2.5 times the normal full load current of the transformer, and 100 per cent connected motor kilovolt-amperes is assumed to be capable of supplying a short-circuit current of 5.0 times the normal current of the transformer.

Standard load-center unit-substation breaker arrangements are shown on Figures 12, 13, and 14. The basis of selection of the magnetic air circuit breaker used in the tables for these three arrangements are as follows:

Any air circuit breaker directly connected to the power source (*A'* or *A*) can be used up to 100 per cent of its interrupting rating only.

Any magnetic circuit breaker (*B*) which is backed up by a properly co-ordinated main breaker of adequate interrupting rating (*A'*) can be used up to 200 per cent of its interrupting rating.

Breakers arranged as in Figure 14 are said to be in "cascade."[4] The back-up breaker (*A'*) must be properly co-ordinated with the cascaded breaker (*B*), so that the breaker (*A'*) will trip instantaneously on short-circuit currents in excess of the interrupting rating of the breaker (*B*).

The cascade arrangement of air circuit breakers shown in Figure 14 often results in a lower-cost substation than is obtained with the arrangement shown in Figure 13. However, the cascade arrangement has the limitation that a heavy short circuit on any of the branch breakers may open the main air circuit breaker and result in an interruption of service to all of the branch feeders. Thus, when lower cost can be obtained with the cascade arrangement, careful consideration should always be given to the value of continuity of service.

ASSOCIATE AIEE

Synopsis: Coaxial cables insulated with solid dielectric are used for transmitting electric energy over wide ranges of frequency. During the development of such cables it was important to be able to predict the characteristics of finished cable by calculations based upon the known dimensions and physical properties of the conductors and the insulation. Many comparatively simple formulas were known to be valid at high frequency, but their applicability at lower frequencies was questioned.

In the first part of this paper we have presented:

1. The general relations which hold under all conditions of operation.

2. The conditions under which "skin-effect" tables offer a convenient method for obtaining values of resistance and inductance, as well as the conditions under which relatively simple equations for these quantities are sufficiently accurate.

3. The conditions under which the complete expression for attenuation may be considerably simplified to the form generally used in high frequency practice.

In the second part of the paper we have presented formulas and graphs for the ratio of terminal voltages as a function of the phase angle of the line for several types of load for both dissipationless and dissipative lines. These relations are helpful in understanding observed voltage variations with frequency caused by reflections, particularly on short lengths of line.

In the third part of the paper a derivation is indicated leading to a general equation for the efficiency of transmission. Simplifications are made which are often applicable in practice, and curves are plotted showing the effect of mismatch in reducing efficiency.

A. Transmission-Line Relations

THE electrical characteristics of a concentric transmission line with distributed constants are given by the relations

Propagation coefficient $= \gamma = \alpha + j\beta = \sqrt{ZY}$ (1)

Characteristic impedance $= Z_0 = \sqrt{Z/Y}$ (2)

where

α = attenuation per centimeter length of line
β = phase shift per centimeter length of line
$Z = R + j\omega L = z \angle \theta_z$ = impedance per centimeter length
$Y = G + j\omega C = y \angle \theta_y$ = admittance per centimeter length
R = series resistance per centimeter length
L = series inductance per centimeter length
G = parallel conductance per centimeter length
C = parallel capacitance per centimeter length

Separating real and imaginary terms in equation 1 we have[1]

$$\alpha = \sqrt{zy}\cdot\cos {}^1/_2(\theta_z+\theta_y) = A\cos(\theta/2) \quad (3)$$

$$\beta = \sqrt{zy}\cdot\sin {}^1/_2(\theta_z+\theta_y) = A\sin(\theta/2) \quad (4)$$

or in terms of the distributed properties of the line

$$\alpha = \sqrt[4]{(RG-\omega^2LC)^2+(G\omega L+R\omega C)^2}\cdot \cos {}^1/_2\left[\tan^{-1}\left(\frac{G\omega L+R\omega C}{RG-\omega^2 LC}\right)\right] \quad (5)$$

$$\beta = \sqrt[4]{(RG-\omega^2LC)^2+(G\omega L+R\omega C)^2}\cdot \sin {}^1/_2\left[\tan^{-1}\left(\frac{G\omega L+R\omega C}{RG-\omega^2 LC}\right)\right] \quad (6)$$

Also since it is the magnitude of characteristic impedance which is of interest in cable design we have from equation 2

$$Z_0^2 = (z/y) = \sqrt{(RG+\omega^2LC)^2+(G\omega L-R\omega C)^2}/(G^2+\omega^2C^2) \quad (7)$$

Equations 1 through 7 are general for any frequency and for any transmission line to which a sinusoidal voltage is applied, so long as the proper coefficients R, L, G, and C are used. We shall therefore consider next the relations by which these four quantities can be calculated.

1. Admittance Per Centimeter Length

Our past experience[2] has shown the convenience of expressing the admittance of a capacitor of any shape as follows:

$$Y = G + j\omega C = \omega C_v(\epsilon'' + j\epsilon')$$

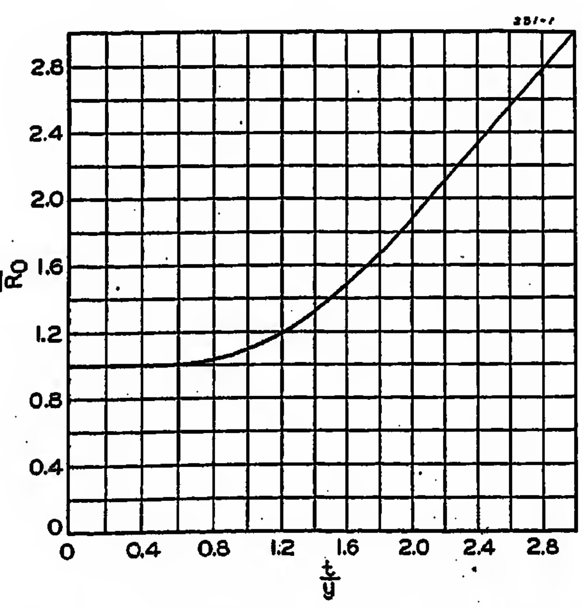

Figure 1. Ratio of a-c to d-c resistance R/R_0 as a function of the ratio of thickness to depth of penetration t/y for a cylindrical outer conductor in a coaxial line

from which we have the following definitions of unit quantities characterizing the dielectric

$\epsilon' = C/C_v$ = dielectric constant (8)

$\epsilon'' = G/\omega C_v$ = loss factor (9)

where C_v = capacitance of the same size and shape of electrodes in vacuum. For coaxial cylinders of radii r_1 and r_2

$$C_v = 0.241\times10^{-12}/\log_{10}(r_2/r_1) \text{ farads/cm} \quad (10)$$

$$\therefore C = 0.241\times10^{-12}\epsilon'/\log_{10}(r_2/r_1) \text{ farads/cm} \quad (11)$$

and

$$G = 1.515\times10^{-12} f\epsilon''/\log_{10}(r_2/r_1) \text{ mhos/cm} \quad (12)$$

Both coefficients ϵ' and ϵ'' may vary with frequency and must be known or assumed for the insulating material for the frequency range being considered.

2. Impedance Per Centimeter Length

The resistance and the inductance of both the inner and outer conductors will vary with frequency because of "skin effect." Therefore there are no simple general relations which can be used at all frequencies.

If the inner conductor is a round wire, the skin effect at low frequencies can be obtained from Table I, which has been worked out from complicated exact formulas.[3–5] This table gives the ratios R/R_0 and L/L_0 (where R_0 and L_0 represent the resistance and inductance at zero frequency) as functions of the parameter

$$x = 2\pi r_1\sqrt{2\mu f/\rho} \quad (13)$$

For copper $\mu = 1$, $\rho = 1{,}724$ abohmcentimeters and

$$x = 0.214 r_1\sqrt{f} \quad (14)$$

The depth of penetration y is defined as the thickness of shell to give the same d-c resistance and is given by the relation

$$y = \sqrt{\rho}/2\pi\sqrt{\mu f} \quad (15)$$

or

$$y = 6.62/\sqrt{f} \text{ centimeter (for copper)} \quad (16)$$

If the outer conductor is a hollow cylinder of thickness t (where $r_2 > 5t$), the corresponding values for the ratio R/R_0 were worked out by J. R. Whinnery and are given in Figure 1 as a function of t/y where y is the depth of penetration[6] (equation 16).

Paper 42-81, recommended by the AIEE committee on basic sciences for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted February 17, 1942; made available for printing April 8, 1942.

H. H. Race is research engineer in the research laboratory, and C. V. Larrick is in the general engineering laboratory, both with General Electric Company, Schenectady, N. Y.

The resistances of the inner and outer conductors are added together to give the total resistance per unit length

$$R_t=0.548\times10^{-6}\left[\underset{\text{inner}}{\left(\frac{R/R_0}{r_1^2}\right)}+\underset{\text{outer}}{\left(\frac{R/R_0}{2tr_2}\right)}\right]$$
ohm per centimeter length (17)

where (R/R_0) for the inner conductor is taken from Table I and (R/R_0) for the outer conductor is taken from Figure 1.

If the parameter x is greater than 20, a condition which is normally satisfied at high frequency, then the depth of penetration is so small that it is not necessary to use Table I. Likewise if t/y for the outer conductor is greater than 3, then the inner and outer resistances vary inversely as the radii of the conductors as follows:[3]

$$R=\sqrt{\rho\mu f}\left(\frac{1}{r_1}+\frac{1}{r_2}\right)\times10^{-9} \text{ ohm per centimeter length} \quad (18)$$

For copper conductors this reduces to

$$R=4.15\times10^{-8}\sqrt{f}\left(\frac{1}{r_1}+\frac{1}{r_2}\right)$$
ohm per centimeter length (19)

If the inner conductor is stranded and the outer conductor braided, the above calculations will be optimistic, since they do not take into account contact resistance between strands, which may be very important, especially if the copper is dirty or becomes corroded or oxidized. After considerably more empirical evidence is obtained, perhaps multiplying factors can be assigned to indicate a proportionate increase of resistance above the values given by equation 17 caused by stranded inner conductors and braided or wrapped outer conductors. For example, we have found by experience that in coaxial cables built with 0.2-centimeter-diameter inner conductors the attenuation is about one decibel per 100 feet greater at 315 megacycles with a stranded inner conductor than it is with a solid inner conductor.

The expression for inductance[3] at zero frequency is

$$L_0=\left\{4.6\log_{10}(r_2/r_1)+0.5+\left[\frac{4.6r_3^4}{(r_3^2-r_2^2)^2}\log_{10}(r_3/r_2)-\frac{3r_3^2-r_2^2}{2(r_3^2-r_2^2)}\right]\right\}\times 10^{-9} \text{ henry per centimeter} \quad (20)$$

where r_3 = outer radius of outer conductor in centimeters. The first term gives the inductance between the conductors; the second and third terms give the inductance within the inner and outer conductors respectively.

To show the relative magnitudes of the several terms in equation 20, assume the physical dimensions for cable 1 for which the complete calculations are shown in Table II (next section). Substituting in equation 20 we obtain:

$$L_0=[2.62+0.5+(8.9092-8.8752)]\times 10^{-9} \text{ henry per centimeter}$$

Both terms of the inductance within the outer conductor were obtained using five-place logarithms, and the numbers have been recorded in order to indicate that the calculation involves a small difference between two nearly equal quantities. However, this also demonstrates that the inductance within the outer conductor may be neglected in comparison with the other terms of equation 20. Since the inductance within the conductors decreases as frequency increases, we have

$$L=[4.6\log_{10}(r_2/r_1)+0.5(L/L_0)]\times 10^{-9} \text{ henry per centimeter} \quad (21)$$

where L/L_0 for the inner conductor is obtained from Table I. At high frequencies the inductance within the inner conductor also becomes negligible so that we may use the simple relation

$$L=4.6\log_{10}(r_2/r_1)\times10^{-9} \text{ henry per centimeter} \quad (22)$$

3. Approximations Leading to Simplified Formulas

In order to show the conditions under which the general equations 1–7 can be reduced to the commonly used simplified forms, we have shown in Table II the important terms involved for two cables at two frequencies.

Table II shows that at 315 megacycles items 10, 12, and 13 are negligible compared to item 11, that is:

$$\omega^2LC\gg RG \quad (23)$$

and

$$(\omega^2LC)^2\gg(G\omega L+R\omega C)^2 \quad (24)$$

If equation 5 is simplified assuming the above inequalities

$$\alpha\cong\sqrt{\omega^2LC}\cdot\cos\frac{\theta}{2}\cong\sqrt{\omega^2LC}\sin\left(\frac{\delta}{2}\right)\cong\sqrt{\omega^2LC}\left(\frac{\delta}{2}\right) \quad (25)$$

where

$$\theta=180°-\delta \quad (26)$$

and

$$\tan\delta\cong\left(\frac{G\omega L+R\omega C}{\omega^2LC}\right)\cong\sin\delta\cong\delta \quad (27)$$

or

$$\alpha\cong(G\omega L+R\omega C)/2\sqrt{\omega^2LC} \quad (28)$$

or

$$\alpha\cong\alpha_d+\alpha_c\cong{}^1/_2G\sqrt{L/C}+{}^1/_2R\sqrt{C/L} \quad (29)$$

where α_d = contribution to attenuation by dielectric loss only

and α_c = contribution to attenuation by copper loss only

α_d may also be obtained directly from equation 5 by assuming $R=0$, and α_c may be obtained by assuming $G=0$ in this same equation. Therefore, we have shown that under the conditions for which equations 23 and 24 are true, the contributions to attenuation of the copper losses and the dielectric losses may be calculated separately and considered to be additive.

Substituting in equation 25 the rela-

Error using approximate equation	−17%			−13%

tions for R, L, C, and G given in equations 19, 22, 11, and 12 respectively, we have

$$\alpha_c \cong 1.50\times10^{-10}\sqrt{f\epsilon'}\left(\frac{1}{r_1}+\frac{1}{r_2}\right)/\log_{10}\times(r_2/r_1) \text{ neper per centimeter} \quad (30)$$

or

$$N_c \cong 3.98\times10^{-6}\sqrt{f\epsilon'}\left(\frac{1}{r_1}+\frac{1}{r_2}\right)/\log_{10}\times(r_2/r_1) \text{ decibel per 100 feet} \quad (31)$$

and

$$\alpha_d \cong 1.05\times10^{-10} f\epsilon''/\sqrt{\epsilon'} \text{ neper per centimeter} \quad (32)$$

or

$$N_d \cong 2.78\times10^{-6} f\epsilon''/\sqrt{\epsilon'} \text{ decibel per 100 feet} \quad (33)$$

where

$$N_{\text{total}} \cong N_c \text{(copper loss only)} + N_d \text{ (dielectric loss only)} \quad (34)$$

If equation 7 is simplified assuming the inequalities, equations 23 and 24, we have

$$Z_0 = \sqrt{L/C} = 138 \log_{10}(r_2/r_1)/\sqrt{\epsilon'} \quad (35)$$

which is the expression usually used for characteristic impedance at high frequency.

Likewise assuming the inequalities, equations 23 and 24, equation 6 reduces to

$$\beta \cong \sqrt{\omega^2 LC} \cong \omega C Z_0 \quad (36)$$

The trigonometric term in equation 5 is important, because it is zero if the losses are zero. Thus an approximate evaluation at high frequencies for this term (although it is small) leads to the useful relation given in equation 25.

On the other hand, the trigonometric term in equation 6 is unimportant, since it is unity for zero losses, and losses at high frequencies simply decrease this term slightly below unity. The recognized effect of high losses in increasing the phase constant must appear, because some of the factors in the first term of equation 6 are not negligible compared to $\omega^2 LC$. However, when the inequalities, equations 23 and 24, are true, the losses do not appreciably increase the phase constant.

Similarly equation 29 can be expressed in terms of Z_0

$$\alpha \cong (GZ_0/2) + (R/2Z_0) \quad (37)$$

The frequency above which the simplified relations, equations 25–37, can be used depends upon the error which can be tolerated. Table II shows that appreciable errors result if the approximate relations are used at 25 kilocycles. However these relations should be sufficiently

accurate for frequencies in the broadcast band or above.

B. Voltage Relations

In a transmission line of length l, having uniformly distributed constants, the complex expression for the ratio of the voltage at the sending end E_1 to the voltage at the receiving end E_2 is given by the relation

$$\frac{E_1}{E_2}=\cosh \gamma l+\frac{Z_0}{Z_2}\sinh \gamma l \tag{38}$$

which upon expansion becomes

$$\frac{E_1}{E_2}=\left(\cosh \alpha l+\frac{Z_0}{Z}\sinh \alpha l\right)\cos \beta l+ j\left(\sinh \alpha l+\frac{Z_0}{Z_2}\cosh \alpha l\right)\sin \beta l \tag{39}$$

where Z_0 = surge impedance of line
and Z_2 = impedance across receiving end of line

From this general relation several special cases lead to usable simplifications.

1. Dissipationless Case

$$\begin{pmatrix} G=R=\sinh \alpha l=0 \\ \cosh \alpha l=1,\ Z_0=\text{real}\end{pmatrix}$$

(*a*). Assuming pure resistance termination, (Z_2=real), the absolute value of the voltage ratio given by equation 39 can be reduced to

$$\left|\frac{E_1}{E_2}\right|=\sqrt{\frac{1}{2}\left[1+\left(\frac{Z_0}{Z_2}\right)^2\right]+\frac{1}{2}\left[1-\left(\frac{Z_0}{Z_2}\right)^2\right]\cos 2\beta l} \tag{40}$$

(*b*). Assuming complex termination ($Z_2=\sqrt{R_2^2+x_2^2}$) equation 39 becomes

$$\left|\frac{E_1}{E_2}\right|=\sqrt{\frac{1}{2}\left[1+\left(\frac{Z_0}{Z_2}\right)^2\right]+\frac{1}{2}\left[1-\left(\frac{Z_0}{Z_2}\right)^2\right]\cos 2\beta l+\frac{X_2Z_0}{Z_2^2}\sin 2\beta l} \tag{41}$$

The last two equations have been used to calculate the data given in Figure 2 which show the ratio of receiving to sending voltage E_2/E_1 for the dissipationless line for several types of load impedance.

2. Dissipative Line

For a line having high losses, particularly at low frequency, the surge impedance (Z_0) may have an appreciable reactive component. But in lines for which equations 23 and 24 apply, the reactive component of Z_0 is negligible as indicated by equation 35.

(*a*). Assuming pure resistance termination (Z_2=real) equation 39 reduces to

$$\left|\frac{E_1}{E_2}\right|=\sqrt{\frac{Z_0}{Z_2}\sinh 2\alpha l+\frac{1}{2}\left[1+\left(\frac{Z_0}{Z_2}\right)^2\right]\cosh 2\alpha l+\frac{1}{2}\left[1-\left(\frac{Z_0}{Z_2}\right)^2\right]\cos 2\beta l} \tag{42}$$

(*b*). Assuming complex termination, ($Z_2=\sqrt{R_2^2+x_2^2}$) equation 39 becomes

$$\left|\frac{E_1}{E_2}\right|=\sqrt{\frac{RZ_0}{Z_2^2}\sinh 2\alpha l+\frac{1}{2}\left[1+\left(\frac{Z_0}{Z_2}\right)^2\right]\cosh 2\alpha l+\frac{1}{2}\left[1-\left(\frac{Z_0}{Z_2}\right)^2\right]\cos 2\beta l+\frac{X_2Z_0}{Z_2^2}\sin 2\beta l} \tag{43}$$

Figure 3 shows plots of the last two relations for a total attenuation of six decibels for the same terminating impedances as were used in Figure 2.

3. High-Loss Lines

As the total attenuation is increased, the variation in the ratio of E_2/E_1 with line angle decreases. For a line having an attenuation of 20 decibels, $\alpha l=2.3$, and there is only about two per cent error in the relation

$$\cosh \alpha l=\sinh \alpha l={}^1/_2\epsilon^{\alpha l} \tag{44}$$

Under these conditions equation 39 can be further simplified.

(*a*). Assuming pure resistance termination (Z_2 = real)

$$\left|\frac{E_1}{E_2}\right|=\frac{\epsilon^{\alpha l}}{2}\left(1+\frac{Z_0}{Z_2}\right) \tag{45}$$

(*b*). Assuming complex termination ($Z_2=\sqrt{R_2^2+x_2^2}$)

$$\left|\frac{E_1}{E_2}\right|=\frac{\epsilon^{\alpha l}\sqrt{Z_2^2+2R_2Z_0+Z_0^2}}{2Z_2} \tag{46}$$

The simplest relation for the ratio E_1/E_2 is obtained when the line is terminated in a load which is exactly equal to its surge impedance ($Z_2=Z_0$) in which case

$$\left|\frac{E_1}{E_2}\right|=\epsilon^{\alpha l} \tag{47}$$

Equations 38–47 were derived in order to interpret voltage data taken during measurements of attenuation in commercial high-frequency solid dielectric coaxial cables.[7]

C. Efficiency of Transmission

The efficiency of transmission is defined as the ratio of output to input power; however, the mathematical expression is simpler if the reciprocal relations are used. The most general case is that for which both the characteristic and load impedances of the line are complex. This case has been solved by E. W. Hamlin (unpublished report, General Electric Company). The essential steps and final relation are:

$$\text{Characteristic impedance}=Z_0=R_0+jX_0 \tag{48}$$

$$\text{Load impedance}=Z_2=R_2+jX_2 \tag{49}$$

then the input impedance is given by[8]

$$Z_1=Z_0\left[\frac{Z_2\cosh \gamma l+Z_0\sinh \gamma l}{Z_0\cosh \gamma l+Z_2\sinh \gamma l}\right] \tag{50}$$

and the input current as a function of the load current is given by

$$I_1=\frac{I_2}{Z_0}(Z_0\cosh \gamma l+Z_2\sinh \gamma l) \tag{51}$$

$$\text{The input power}=|I_1|^2\times\text{real component of } Z_1 \tag{52}$$

$$\text{and the output power}=|I_2|^2R_2 \tag{53}$$

Hamlin takes the ratio of these last two relations and upon expansion and simplification obtains the general equation:

$$\frac{W_1}{W_2}=\frac{R_0}{R_2|Z_0|^2}[(R_2R_0+X_2X_0)\cosh 2\alpha l+{}^1/_2(|Z_2|^2+|Z_0|^2)\sinh 2\alpha l]+\frac{X_0}{R_2|Z_0|^2}[(X_0R_2-X_2R_0)\cos 2\beta l+{}^1/_2(|Z_2|^2-|Z_0|^2)\sin 2\beta l] \tag{54}$$

As a simplification of equation 54, let $X_0=0$, that is, assume that the reactive component of the characteristic impedance is negligible, as is usually the case in high-frequency transmission. Then equation 54 reduces to

$$\frac{W_1}{W_2}=\cosh 2\alpha l+{}^1/_2\left(\frac{R_2}{R_0}+\frac{R_0}{R_2}+\frac{X_2^2}{R_2R_0}\right)\sinh 2\alpha l \tag{55}$$

When the reactive component of the load impedance is also negligible, the last term in the parenthesis drops out.

The last equation has been used to calculate the efficiency of transmission for several values of total attenuation for a range of values of mismatch. (Z_0/Z_2 or Z_2/Z_0 from 1 to 10) as shown in Figure 4. An important observation is that for a mismatch as large as 2/1, the efficiency is 90 per cent or more of the efficiency which could be obtained with perfect matching of characteristic and load impedances.

The curves of Figure 4 express only the increase in power losses in the line caused by standing waves on the line resulting from reflections at the load end. Unless the attenuation of the line is high, the

Calorimetric Method for Determining Efficiencies of Electric Machines

VICTOR SIEGFRIED
MEMBER AIEE

CHARLES W. THULIN
ASSOCIATE AIEE

AMONG the methods available for determining losses and efficiencies of electric machines, many have been developed to their utmost capabilities. Some measure individual losses separately and with good accuracy,[1–10] but many have inherent drawbacks. There still remains the desirability of a satisfactory over-all test which will rate the performance of all sizes of machinery under actual conditions of loading and yet yield highly accurate results. This aim is largely met by the calorimetric method and is justified by its basic character. A simplification of the classical testing technique can be introduced in which the important measurements are all electrical. By this means, accurate measurements of heat values are obviated, and the calorimeter becomes in reality only a comparator for a substitution process. Test results of calorimetric measurements on small induction and d-c motors show excellent agreement with other tests on the same machines. Analysis of the method indicates that it is equally applicable to all classes of machines of any size and that it can be used more generally for over-all loss and efficiency measurements under loaded conditions.

Paper 42-84, recommended by the AIEE committee on electrical machinery for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted March 11, 1942; made available for printing March 31, 1942.

VICTOR SIEGFRIED is assistant professor of electrical engineering, Worcester Polytechnic Institute, Worcester, Mass., and CHARLES W. THULIN, now with Bell Telephone Laboratories, Inc., New York, N. Y., was instructor in electrical engineering at Worcester Polytechnic Institute when this paper was written.

The authors acknowledge the contribution of three groups of senior students in electrical engineering at Worcester Polytechnic Institute in the construction of the apparatus and the collection of much of the data reported: H. S. Blauvelt and G. V. Pearson; G. M. Moore and F. W. Wackerbarth; R. L. DeLisle and D. E. Greene, Jr. All were AIEE Enrolled Students at the time. Except for an unwieldy title, they would all be included as joint authors of this paper.

Calorimetric Method

The classical form of the calorimetric method makes use of the basic principle that all losses are converted into heat. Measurements of thermal values from specific heat of the coolant, its volume, and temperature rise, have involved uncertainties and difficulties which have tended to discredit the method. However, these can be avoided by a simplification possible with electric machinery, in which the volume of the cooling medium is kept constant, and the temperature rise is measured under load and again with calibrating power input, thus giving a direct indication of the total losses within the system. The method is applicable to many types of machines, motor or generator, d-c or a-c, with only slight revisions in detail for each. Since total losses may be determined by it, and all other losses can be measured separately, stray load loss can be determined by this type of test. The American Standards Association Standards[8] and the test codes recognize the use of the calorimetric method, although reports of its use are rather scarce in the American literature. European tests reported to the International Electrotechnical Commission meetings at Prague in 1934 and Scheveningen in 1935 by the late Edouard Roth[2,11] show the development of simplifications in the calorimetric method. The procedure was to enclose the machine under test in a trunking or duct, through which a constant quantity of air was blown. Temperature rises from inlet to outlet were determined by the resistance of grids in the air stream, and losses to produce equal rises were introduced by means of heaters. Elaborate interpolation of data was required, because of difficulty in adjusting to exact equality.

Further extension of these simplifications is made in the tests being reported in this paper. Where possible, the calibrating losses are introduced directly into the machine under test so as to simulate actual losses exactly. A succession of points is taken so that a graphical determination of equal temperature-rise conditions may be made between the loaded and calibrating runs, thus minimizing the work of calibration. The use of differential thermocouples makes possible direct readings on a microammeter without the necessity of delicate potentiometer readings.

Equipment and Procedure

The test work was done on two machines, one an induction motor and the other a d-c motor of comparable size. The equipment consists principally of:

A double-walled calorimetric box of heat-insulating material to enclose the machine under test, in this case reversible so as to be usable on either end of the set.

A constant-speed blower to force air through the box.

Thermocouples differentially connected between inlet and outlet ports.

Power-measuring instruments in the leads to the test box.

Heaters inside the box near the test machine.

Figures 1 and 2 show the arrangement of parts.

The pair of machines is mounted on a wooden base with an iron subbase, and bolts are staggered so as to prevent any direct path of high thermal conductivity to the outside. A layer of insulating board is fitted around the machine feet, and the box is sealed to it. A slot on one side makes provision for a close-fitting air seal around the shaft, the coupling being outside of the enclosure. Dead air spaces

mismatch at the load end will affect the input impedance of the line, and in any practical case the coupling between the line and the generator will have to be adjusted to give the best power transfer.

are filled with rock wool. A terminal plate provides electrical connections to the inside. Thermocouples are connected differentially in series between the blower pipe at the inlet and an insulated outlet at the diagonally opposite corner. Small ports are used to insure thorough mixing of the air, thus keeping all parts at a uniform temperature. This was verified by test and by observing the air stream through a window at the top of the box when smoke was injected.

As indicated in the introductory discussion, this method uses the calorimetric quantities for a comparison of the power values which will produce the same temperature conditions:

1. The machine is operated under load, and electric power input and thermocouple measurements are made. All losses of the machine, whether in electrical or mechanical form, are dissipated within this box and eventually contribute to the heating of the air. No measurement of shaft output is made unless desired as a check.

2. The coupling between machines is broken, and a set of measurements is made with the machine running idle to find the power input that is required to duplicate previous thermal conditions.

Finding the loss input which gives exactly the previous (loaded) temperature difference is unnecessarily tedious. For satisfactory results and minimum time used on a test, the better procedure is to

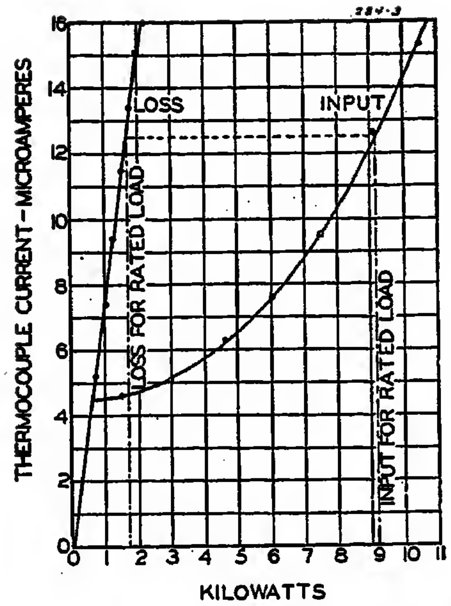

Figure 3. Temperature differences under load and calibrating conditions

Value of loss for corresponding input indicated by equal temperature differences

take two curves of temperature difference (microamperes) for several values of heating, the air volume being held constant. One curve is taken as a function of total input under loaded conditions, and another is taken as a function of total losses. Such a set of curves is shown in Figure 3, with both curves plotted to the same scale for illustrative purposes. The total losses for any input are then determined from the curve of calibrating loss at the corresponding temperature difference. The machine output is found by subtraction and efficiency is computed in the usual manner.

As may be expected, time must be allowed for the thermocouple currents to become stabilized. Figure 4 shows typical curves for one run (air rate different from Figure 3). In the case of this thermal system, about one hour was required per reading, although this time could be shortened by changing the air rate during the transition period, gradually returning to the standard value. The air rate must be selected so that a total difference between inlet and outlet temperatures does not exceed about 20 degrees centigrade to approximate nominal ambient conditions. Since actual thermal values are not re-

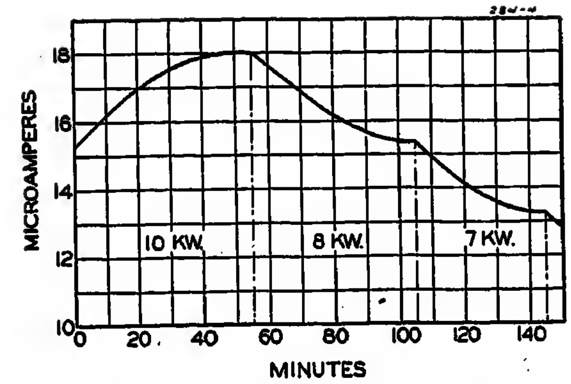

Figure 4. Typical temperature-difference curves for three values of total input to box with machine loaded

Readings taken at end of intervals

quired, blower speed need be kept constant only during any one set of measurements. Air density and humidity should remain constant within the same period or not change appreciably. Inlet air temperature may vary slightly without error, but care should be taken to keep loading and control rheostats reasonably distant from the inlet. Because the method requires only repeatable conditions, even slight air leaks are not serious so long as they stay constant. Speed of the machine under test may vary slightly without serious error, due to changing the ventilation pattern within the calorimeter.

Up to this point, the procedure is perfectly general for any type of apparatus. The loaded temperature determination is likewise general, but consideration must now be given to methods of introducing the no-load or calibrating power into the calorimeter. The test machine is disconnected from the load, and it is allowed to run at its nominal speed. Additional heat may be introduced by heaters so placed that the internal ventilation will circulate the heated air. The calibrating power is thus the sum of the no-load input to the machine and the power to the heaters. In the case of induction machines, the entire power may be introduced into the machine by raising the applied voltage so that increased running-light losses will duplicate those at full load. This has the advantage of placing all the loss within the machine, although current

limitations may require partial use of the heaters. Synchronous machines permit similar abnormal adjustments by field control of reactive currents, but it must not be overlooked that field copper loss contributes to the total heat within the calorimeter. D-c machines are the least amenable to this treatment, and heaters have to suffice.

Test on Induction Motor

An induction motor which had been thoroughly calibrated by many tests was available for test by the calorimetric method. This was fortunate, because the induction motor illustrates the good features of this test to the utmost, and illustrates the *method* well. In the calibration of the box, all of the necessary no-load losses can be confined to the machine itself by raising the applied voltage and exciting current until copper and rotational losses are of the order of total loaded losses, provided the stator current is not dangerously large. This permits the nearest approach to the ideal of having all losses identical in the two tests. The squirrel-cage machine used is rated 10 horsepower, 220/440 volts, 26.6/13.3 amperes, 60 cycles, 1,710 rpm squirrel-cage motor, and was operated at 220 volts.

Complete data were obtained from which separation of losses could be made, the calorimetric tests providing only the total loss value. Slip, stator resistance, and rotation losses were measured in addition to line current, voltage, and power usually measured in the efficiency test. Thermocouple current is the indication of temperature difference and is plotted in Figure 3 for the steady-state deflections given by a certain total input in the load run, and by a certain total loss input in the unloaded run. Since corresponding deflection currents indicate corresponding power values, the total loss for a given input is found by following across the proper ordinate to pick off the loss abscissa. The dotted lines indicate test data for rated load on the machine. It may be seen that deflection is proportional to loss in the box for constant blower speed. This is to be expected so long as the heat is dissipated in the same manner at all loads. As the box gets hotter however, other factors appear to permit heat to escape by conduction, with a resultant flattening of the curve. These make an actual calibration for each test very essential. An additional test using heaters for no-load input was made with identical results.

The final curves of total losses and efficiency derived from the data of Figure 3 are shown in Figure 5, with output as the abscissa. The full-load efficiency of this machine is 81.5 per cent as compared with 81.7 per cent from other test methods using conventional losses plus stray load loss measured separately.

As a demonstration of the accuracy possible with the calorimetric method, a set of values of stray load loss found by this test is plotted in Figure 6. The experimental points are obtained by two groups of observers. The solid curve is the stray load loss as determined by other methods,[4,5] several curves not widely different being averaged together. These results are quite consistent, especially when it is appreciated that stray load loss here is found as an indirect measurement by subtracting all other known losses from the total determined by the calorimetric method.

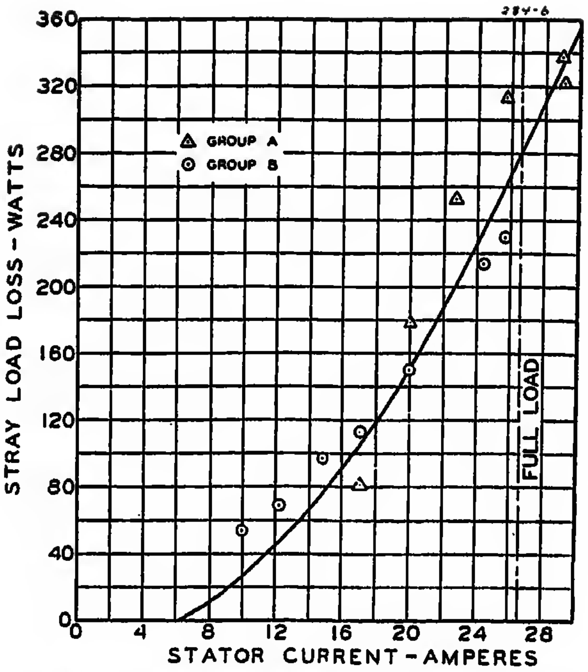

Figure 6. Stray load loss of induction machine tested

Solid curve average of tests by other methods.[5] Experimental points determined by calorimetric method by two groups of observers

Test on D-C Machine

The calorimetric set used was reversible; so the box was turned around on the base, and measurements were made with the d-c machine as the test machine. The induction motor acting as a generator was loaded by operating it from a separate alternator. In this test, the calibrating losses were supplied by heaters in addition to the running-light input. The full-load efficiency by this method was 83.1 per cent, whereas the efficiency by conventional methods plus stray load loss[10] was 83.4 per cent.

Conclusions

The calorimetric method described in this paper consists of two fundamental steps only:

1. Determination of a temperature rise of the cooling medium under loaded conditions.

2. Substitution of an equivalent measurable loss which will produce the same temperature rise under no-load conditions.

This is a comparison or substitution method which determines with high accuracy the total losses of a machine under conditions of actual loading. The method permits good comparative data to be taken even under poor calorimetric conditions, although refinements improve the ease of obtaining good results.

Losses measured by it compare directly and favorably with those of other methods of high accuracy and show a final stray load-loss value very close to those from other tests. Although tests of only two machines are reported, the method has been demonstrated to be workable and fundamentally sound. Since it depends on a basic principle, the accuracy which may be expected will be determined by the care and techniques employed. Further attention to the calorimetric method will doubtless bring forth other advances in its use.

High-Voltage Fusing of Transformer Banks

H. H. MARSH, JR.
MEMBER AIEE

G. B. DODDS
ASSOCIATE AIEE

Synopsis: The paper summarizes some 15 years' experience with the high-side fusing of 11-, 22-, and some 66-kv transformer banks. The original purpose of fusing has through this experience been expanded to cover functions that are deemed desirable, and the authors feel that their approach to the specific protection field served by fuses has resulted in satisfactory protection at minimum cost.

The results of some faults occurring in fused and unfused banks are described briefly, and the various factors taken into consideration in selecting the proper fuse to use are discussed. The conclusions drawn are that fuses, when applicable, are a satisfactory economical means of obtaining reasonable coverage for faults in and beyond transformer banks.

THE experience of the Duquesne Light Company with what we shall call modern high-voltage power fuses began in 1926 when Schweitzer and Conrad liquid fuses were applied to the high-voltage side of several 22-kv banks in stations serving customers from a radial transmission line. The previous outages to this particular line were the determining factor in these fuse applications as an effort to improve service to the remainder of the line in cases of station trouble.

Early Experience

For the first few years our experience with these fuse installations was anything but satisfactory. These fuses deteriorated, causing uncalled for operations, and many justified blowings resulted in failures to clear, flashover of inadequate spacings, and flashover of inadequate insulators. These fuse operations were carefully followed, and such conditions of installation as contributed to unsatisfactory performance were eliminated. Mountings were replaced with higher insulation, spacing and clearances generally increased, and 34.5-kv fuses standardized upon for our 22-kv service. These changes, together with the manufacturers' changes of liquid, cap design, fuse element changes, and other advances, had made it possible to place considerable confidence in high-voltage fuses such that by 1937 our experience justified an extension of our fusing applications and the development of a general policy of fusing where applicable.

Experience up to 1937—Fused Versus Unfused Stations

By 1937 our number of fused banks had increased in proportion to our growing confidence in high-voltage fuses, and at that time we had 32 power applications in both customer and company distribution stations. An analysis of performance of fused and unfused stations for the years 1930 to 1937, as disclosed by fault records, brings out a striking comparison, and the records are tabulated in Table I for parallel consideration.

In the fused group we had had no fires, no explosions, no serious damage and, in many cases, immediate return to service of the faulted equipment, since prompt clearing had prevented permanent faults. Contrasted with this in the unfused group we had had three fires, one explosion, and had lost nineteen transformers such that they were either scrapped or completely rewound.

Origin of High-Voltage Fusing Policy

The original purpose of the high-side fusing of transformer banks was to minimize outages to multicustomer circuits where one customer fault would otherwise involve a total line outage.

An analysis of the above performance record disclosed that the fuses, in performing this original function, had provided additional benefits by preventing fires, explosions, or serious damage.

Based on this analysis, a policy has been established to provide adequate protection for all new bank installations and, over a period of years, to cover existing stations using fuses wherever applicable.

Experience 1937 to the Present

Our fuse installations now number well over 126, cover banks ranging in size from 50 kva at 22 kv, up to 10,000 kva at 66 kv, and involve the use of Schweitzer and Conrad types *D*, *C*, and *SM*, and Westinghouse type *BA*.

From 1937 to the present we have had 59 faults involving 87 fuse operations all functionally correct, and several of these,

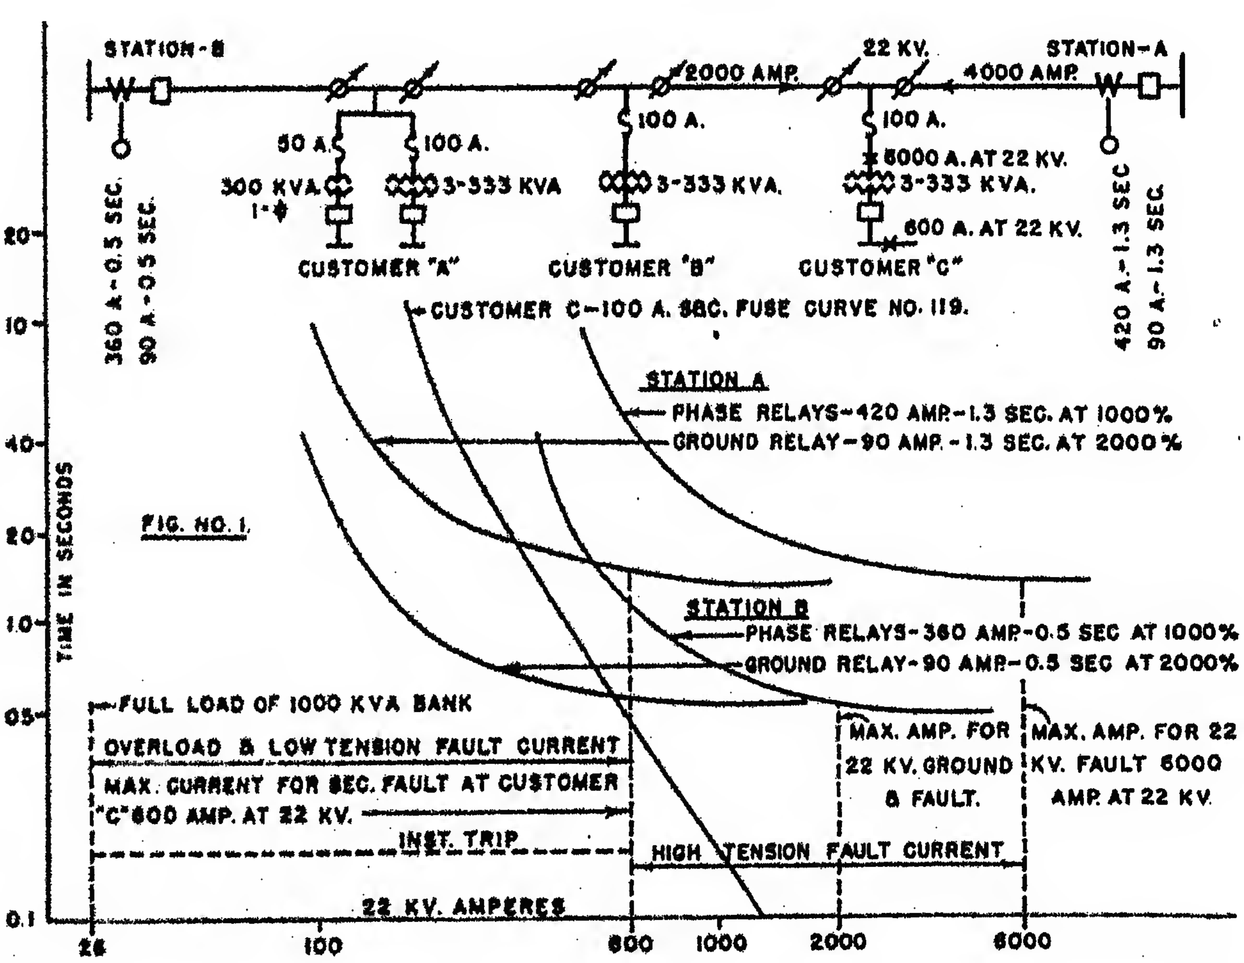

Figure 1. Selection curves of transmission-line relays, transformer-bank fuses, and low-voltage protection

Paper 42-80, recommended by the AIEE committees on power transmission and distribution and protective devices for presentation at the AIEE North Eastern District meeting, Schenectady, N. Y., April 29–May 1, 1942. Manuscript submitted February 11, 1942; made available for printing March 19, 1942.

H. H. MARSH, JR. is assistant general superintendent, substations and shops, and G. B. DODDS is relay protection engineer, Duquesne Light Company, Pittsburgh, Pa.

we feel, have avoided possible explosions and fires, and in addition, have prevented interruptions to other customers served from the lines involved. Many of these fuse operations have cleared low-voltage faults, where customer protection has been inadequate or inoperative, and where such faults could not have drawn sufficient current to operate the high-voltage protective relays until after winding breakdown. Such fuse operations have avoided transformer-winding burnout.

In one station fuses were used on each of four 10,000-kva, 66/11-kv transformer banks to avoid the installation of a high-voltage breaker and relaying, and, in final analysis, to give the customer better service. On two occasions these fuses have performed as intended, once by blowing to clear a fault not covered by the customer's low-voltage protection, and once by not blowing on a similar type of fault which was cleared by such protection. In the first instance high-voltage breaker protection would have given a complete interruption until performance of switching to segregate the defective low-voltage equipment, while the fuse application caused no interruption to three fourths of the service and segregated the fault promptly and properly.

The success we have had with our fuse installations has not been due alone to the improvement in the fuses themselves, nor to better installation conditions, but has been the result of these factors together with a judicious selection of the proper fuse for the existing conditions, and to a rigid inspection policy, and the practice of removing such fuses that give any indication of suspicion as to their condition.

Control of Fuse Applications (Design Stage)

In deciding all protective layouts, our design engineers seek the advice and recommendations of the protection engineer, and whether the problem involves that of the more complicated types of reactance relays, pilot-wire schemes, differential protection, or fuses, the procedure is the same. In following this policy, the simplest fuse installation gets the necessary careful consideration it requires, and all of the factors entering into proper selection get uniform attention.

Our protection policy, based on experience, is that all portions of an electrical system should be covered by protection of some sort to clear whatever fault may develop. This policy cannot always be met on an economically justified basis by relays and breakers. Where this condition is encountered, high-voltage fuses frequently provide a reasonably satisfactory solution.

Selection of Fuses for Transformer-Bank Protection

In selecting fuses for transformer-bank protection, investigation is made of the fault current obtained for faults, both on the high-voltage and low-voltage side of the transformer bank, and consideration is given to the protection that is provided on the low-voltage side of the transformer bank. A fuse is then selected with a time-current curve and a current-carrying capacity that will provide the desired time of operation for low-voltage faults.

In many cases, transformers that are fused supply industrial customers, and a variety of types of protection are used by the customer on his own breakers. Settings of these protective devices are determined, and high-voltage bank fuses are chosen to select with the low-voltage equipment. In some cases where customers' equipment is involved, it has been found that the protective equipment has been set unnecessarily high in current and time, and these settings have been lowered to the mutual advantage of the utility and the customer.

The fuse-current rating in relationship to full-load current of the protected transformers is not selected as any arbitrary value in relationship to the size of the transformer bank, but is selected as required with due consideration of the time-current characteristics of the different fuses available.

Since the application of these fuses is for the clearing of faults in and beyond the transformers, no attempt is made to protect the transformers against overloads. In this connection the current rating of fuses on our system varies from $1^1/_2$ to 4 times the bank full-load rating. The time delay and current-carrying capacity of the fuses are inseparable and are varied in order to obtain the necessary time delay for clearing of low-voltage faults. In practice the time delay provided for low-side faults varies from a minimum of 0.3 second on some lighting transformers to a maximum of 1.5 seconds on some power banks.

Time Selection of Fuses With High-Voltage Relays

While fuses are installed primarily to obtain clearing of faults in transformer-

Table I. Comparison of Performance of Fused and Unfused Substations

Fused Stations	Unfused Stations
1. Two fuses operated to clear a defective transformer caused by water entering the winding through a leaky low-voltage bushing.	1. Entire station, consisting of three 2/1 transformers and housing, destroyed by fire as result of transformer failure. Evidence of original failure lost.
2. All fuses operated to clear a defective bank of three 667-kva units during flood.	2. Three 333-kva transformers destroyed, fortunately without fire, when a customer low-voltage fault held on, the customer's breaker found inoperative.
3. One fuse operated to clear a failure of customer static capacitor on 2,300-volt side of bank.	3. Three 100-kva units destroyed, necessitating complete replacement as result of low-voltage winding failure.
4. On two different occasions one fuse operated to clear a defective nonautomatic breaker bushing which had flashed over during storms.	4. Three transformers destroyed as result of low-voltage customer-equipment failure. Fault held on until breakdown of high-voltage winding, when 22-kv protective relays operated. Fortunately no fire.
5. Three fuses operated to clear a high-voltage bus flashover.	5. Failure of one transformer resulted in oil fire which destroyed the entire station on customer premises.
6. Two fuses operated on initial cut-in to clear a low-voltage potential transformer which had been connected reversed with 115-volt winding on the customer's 2,300-volt bus.	6. Transformer failed and exploded at the station, resulting in fire which involved three other units and loss of all electrical equipment. Several intermittent grounds had been indicated at the supply station.
7. On three different occasions fuses operated to clear trouble on customer-owned high-voltage transformers.	7. Low-voltage disconnects pulled under load, fault held on until winding breakdown. Three 500-kva units complete winding loss.
8. Two fuses operated to clear a 2,300-volt bus fault caused by boys having thrown wire across a bare low-voltage bus.	8. On two occasions customer low-voltage cables caused failure of low-voltage bushings, due to fault hanging on and ultimately communicating to the high-voltage side of the bank.
9. One fuse operated to clear an internal flashover of high-voltage lead in one transformer.	
10. One fuse operated to clear defective low-voltage customer breaker and again three fuses operated to clear a flooded three-phase unit, leaving line in service.	
11. On four different occasions fuses operated to clear internal flashovers in transformers during storms.	
12. On three occasions fuses operated to clear faults on four-kilovolt circuit fed from bank. Low-voltage breaker inoperative.	
13. One fuse operated to promptly clear an accidental contact with a ground chain being handled with rubber gloves.	

bank windings or on secondary busses that would not otherwise be cleared properly, other benefits are sometimes obtained. These are:

(*a*). To prevent or decrease outages to other customers.

(*b*). To reduce damage to high-voltage bushings of transformers due to quick clearing.

In connection with item *a*, selection is not always obtained between the transformer fuses and the protective relays on the transmission system. In many cases, however, selection is obtained, particularly for short-circuit faults, and there are many instances where long outages to other tap or nonautomatic loop stations have been prevented by fuses clearing transformer faults before relays operated.

In some instances, the fuse and transmission-line relays may operate together, in which case the transmission line can be returned to service, as the fuses will have cleared the fault.

On many faults, however, the transmission-line ground relays do not select with fuses during line-to-ground faults, if the fault currents are of a low value. This nonselection is recognized and accepted.

With regard to item *b*, many transformer-bank high-voltage bushing flashovers have been cleared so quickly that service could be restored immediately.

Illustration of Specific Application

In Figure 1 is shown one example of application of fuses to three relatively small customers, supplied with tap service from a 22-kv loop circuit. In this particular case the distance between automatic stations is only about $1^1/_2$ miles and is close to a large 66/22-kv substation; as a result the current for 22-kv faults is relatively high.

Time-current curves of phase and ground relays at stations *A* and *B* and the melting time of fuses at customer *C* are shown. Maximum current of 6,000 amperes at 22 kv for a fault on the high-voltage side of transformer at customer *C* is indicated and a current of 600 amperes at 22 kv for fault on the low-voltage side of the same transformer.

These curves show that for a fault on the low-voltage side of the transformer at customer *C*, the melting time of a certain 100-ampere fuse is 0.45 second. This is adequate time to permit the low-voltage bank oil circuit breaker, with instantaneous trip coils, to operate. The curves also show that the phase relays at stations *A* and *B* select with this fuse at all current values. It is shown that the ground relays at the two stations do not select with the fuses at all currents. However, as the fault current is supplied from both ends of this circuit, the fuse obtains more current than either of the ground relays and may select. Also for any ground fault current above 1,000 amperes, the fuse will properly select with the ground relays. As it is possible to obtain 2,000 amperes ground current at this location, the probability of the ground relays selecting with the fuses is very good.

From the above it is seen that in this case the fuses not only serve to protect the transformer banks, but also to protect service to the adjacent customers.

The above illustration is only one of numerous similar conditions on our system.

Miscellaneous Factors to Be Considered in Applying Fuses

In applying fuses for the protection of transformers that supply various types of loads, different factors must be considered, depending on the type of load.

For example, fuses on the high-voltage side of a furnace transformer should have a continuous carrying capacity above the value of current that can be obtained for the condition of shorted electrodes in the furnace, as this is a condition that may exist for a considerable period of time during normal operation of the furnace. In this case, the fuses do not adequately protect the transformer bank in event of low-side failures, but do serve to disconnect the equipment from the system in event of severe faults in the furnace transformer.

In applying fuses for the protection of a transformer bank that supplies distribution circuits that are protected with oil circuit breakers, care must be taken to obtain sufficient time selection between the breaker opening and the blowing of fuse, so that the fuse will not operate incorrectly on normal reclosure of the oil circuit breaker on a faulted distribution circuit. Our present practice is to allow from 0.7 to 1.0 second selection between low-voltage reclosing feeder relaying and high-side bank fuses and while we have experienced no difficulty with this difference in selection, we realize it is open to question and to reconsideration as experience requires.

Conclusion

It is not intended to convey the impression that high-voltage fuses should be used for the protection of transformer banks in preference to relays and oil circuit breakers. Where this equipment is available or can be justified, it should be used. In many cases, the cost of oil circuit breakers cannot be justified, and in such cases, fuses, if applicable, can be used.

In general, it is felt that, in the voltage range of our experience, the modern high-voltage fuse, properly applied and not forgotten, is a reliable protective device that should be added to the other protective schemes, and that it has a definite place in meeting requirements at moderate cost that cannot otherwise be economically justified.

A 600-Volt Enclosed Limiter for Network Use

Synopsis: The extension of the conventional network system to industrial plants has established requirements for a higher-voltage limiter.

The network system has been adopted as a standard by many utilities for 120–208-volt distribution, whereas industrial-plant distribution is usually at higher voltages up to 600 volts due to the predominance of power load. The requirements of a limiter for this service are more severe, due to the proximity of operating personnel and increased interrupting duty associated with higher voltages and shorter cable runs.

A new totally enclosed limiter has been developed for this application. This limiter embodies new principles of operation and will interrupt fault currents in excess of 50,000 amperes at 600 volts without perceptible noise or visible demonstration.

NETWORK systems as originally conceived and installed did not make use of limiters, for the systems were based on the premise that cable-insulation failures encountered on 120–208-volt circuits would be self-clearing. Experience has proved this premise to be generally correct.[1] Obviously, however, there can be solid metal-to-metal faults that are not self-clearing. Furthermore, faults, although self-clearing, could persist until heating of the cable resulted in permanent damage to the cable insulation. Usually, such persistent faults would spread to adjacent cables, materially increasing the resultant damage. The large amount of power liberated in these extensive faults often produced combustible gases in sufficient quantities to cause manhole explosions.[2] These factors led to the development of the limiter which consists of a fusible section located at the ends of cable runs to guarantee the clearing of any fault on the cable before its insulation is damaged or the fault spreads to other cables. The correct analysis and solution of this problem is due largely to the work of C. P. Xenis of the Consolidated Edison Company of New York.[3]

Paper 42-99, recommended by the AIEE committee on industrial power applications for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 8, 1942; made available for printing April 23, 1942.

P. O. LANGGUTH (now in military service) is assistant manager, circuit breaker and protective devices division, H. L. RAWLINS is section engineer, and J. M. WALLACE is design engineer, switchgear engineering department, all of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Limiters have been in service on 120–208-volt network systems for several years and have been found ideal for the application.[4] Factors contributing to the rapid adoption of limiters on network systems are as follows:

1. The limiter requires no maintenance. It has no contacts or adjustments and consists of a simple conductor having swedged or bolted connections. It can be connected into the cable and forgotten. The rapid adoption of the limiter has been due principally to this one factor of simplicity and reliability.

2. It eliminates damage to unfaulted portions of the cable. Being a thermal device, it is ideally suited to the protection of cable insulation from heating due to fault currents.[5]

3. The limiter insures the rapid clearing of heavy fault currents, thereby minimizing system disturbances and localizing all faults.

4. In networks having two or more cables per phase, proper selectivity between limiters is automatic. Co-ordination with network protector fuses can be easily obtained by proper planning.[6,7]

5. A quick reclosing device in place of the limiter would be of no particular benefit, for considerable maintenance must be performed on the cable after a fault.

6. The limiter is relatively inexpensive and renders a service out of all proportion to its cost. It may be used at both ends of all cables. Consequently, a fault will disable only a short section of cable.

Previous Limiters

Until the advent of industrial networks the application of limiters was confined almost exclusively to 120–208-volt networks for city distribution. The requirements of limiters connected in these systems were not too severe. The low system voltage combined with short-circuit currents which seldom reached 30,000 amperes represented moderate interruption duty. Since the limiters were usually placed in underground vaults, there were no strict requirements on noise or demonstration. In addition, the limiters were not the only line of defense, for most faults at this low voltage are self-clearing.

The limiter developed for this service consists of a reduced metallic or fusible section incorporated in a connector lug

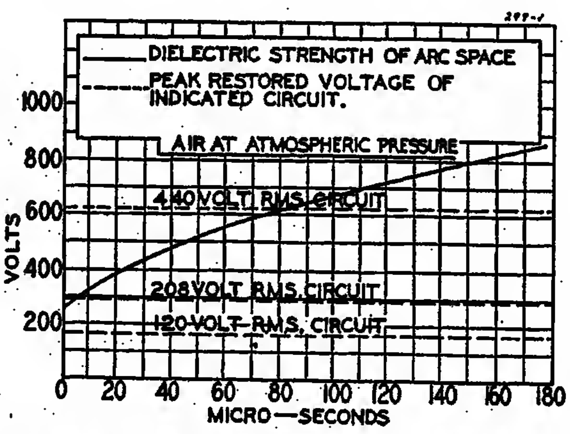

Figure 1. Recovery of dielectric strength of arc space of short arcs with reference to the peak restored voltage of standard systems

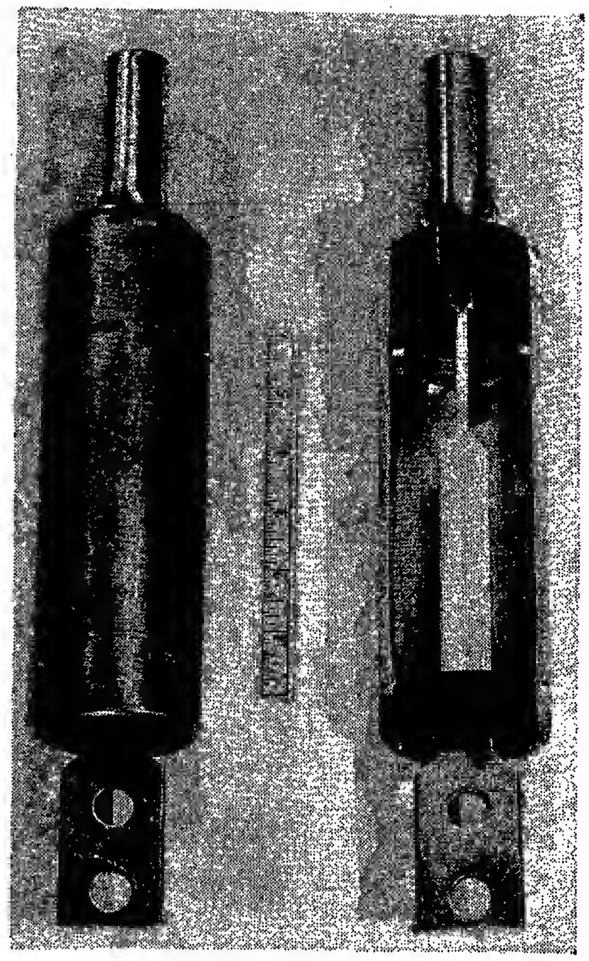

Figure 2. Assembled and sectional view of new limiter

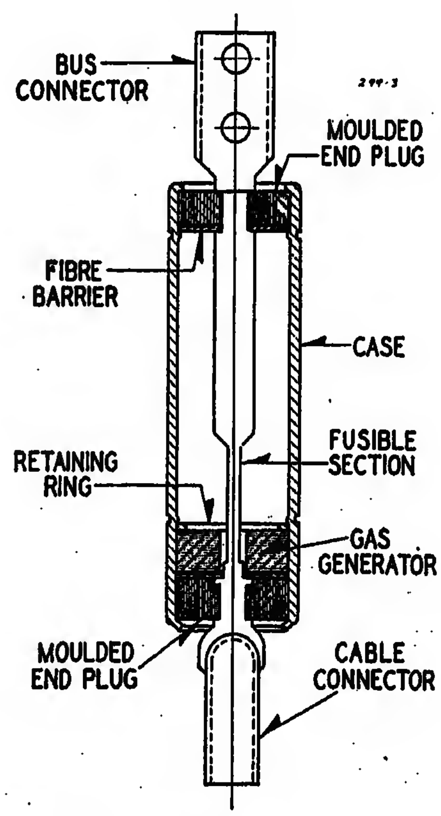

Figure 3. Cross section of new limiter

or other connecting device. The fusible section is surrounded with heat-resistant insulation, and the whole assembly is placed in a rubber sleeve and securely taped to prevent the escape of hot gases or flame during interruption. These limiters, when operating within their current and voltage limits, have given successful interruptions without demonstration. They have been found admirably suited to the service for which they were designed.

Requirements for a New Limiter

The entrance of the network distribution system into the industrial field created several new problems. Systems up to 600 volts were encountered, cable runs were considerably shorter, and power concentrations were greater. All of this led to greatly increased short-circuit currents which had to be interrupted at these higher voltages. Under these conditions, faults are seldom self-clearing.[8] Referring to Figure 1, it is seen that an arc space recovers a dielectric strength of about 250 volts instantly at current zero. This is sufficient to cause interruption of arcs on a 120–208-volt circuit. Considerable time is required for the arc space to recover sufficient dielectric strength to cause circuit interruption at higher voltages; hence, faults on a 440-volt system must be cleared by an interrupting device. Limiters, therefore, were necessary to guarantee the interruption of the circuit. Strict requirements concerning noise and demonstration were imposed on the limiters, because they were required to operate in close proximity to factory personnel. Furthermore, the limiters for industrial application could not present any fire hazard whatsoever.

In accordance with these requirements, it was decided that a limiter for this new service should have the following characteristics:

1. It must be totally enclosed and have minimum space requirements.

2. It must have an interrupting rating of 50,000 amperes at 600 volts, 60 cycles.

3. It must have a low temperature rise to permit bunching of limiters in confined spaces.

4. It must have a time-current characteristic to permit co-ordination with other limiters, co-ordination with its cable insulation, and co-ordination with the network protector fuses.

5. It must have suitable terminals to permit coupling with the proper cable.

Design of a 600-Volt Limiter

The design of a totally enclosed limiter of the required small size presented the dilemma usually associated with engineering problems. On one hand the device must have five times the interrupting ability of a cartridge fuse of comparable current rating, and on the other hand, not only must it be made smaller, but the demonstration attendant to circuit interruption must be eliminated.

The design was accomplished by solving two problems:

1. The metallic vapors and gases from the heavy fusible element had to be accommodated. Tests revealed that a copper sheath or cover around the fusible element would supply a condensing surface on which the fused metal would be deposited, thus eliminating high internal pressures.

2. Totally enclosed interrupting means had to be provided to insure positive interruption of all currents up to the interrupting rating. Further development evolved a concentric fiber gas generator, which would supply the necessary turbulence to cause deionization of the arc.

Figures 2 and 3 show the final design of the limiter. The conducting element is made from copper tubing which is

Figure 5. Interruption of moderate current

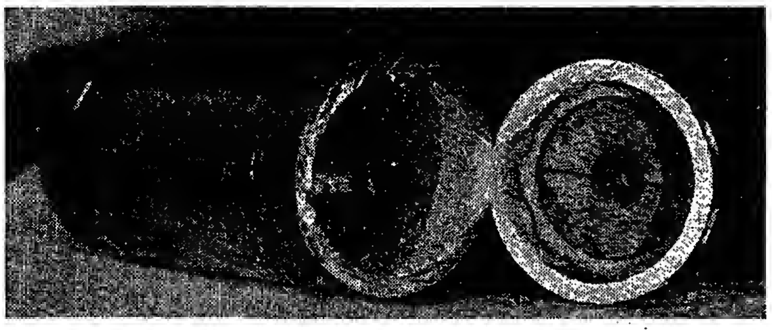

Figure 8. View of limiter cut open after interrupting moderate current

Note deposition of copper on inside surface of case

flattened and sized to produce the proper fusible element and terminal connectors. The closure plugs are moulded on the conducting element in an extrusion-type mould with the retaining ring in place. Split fiber washers are used as barriers to prevent arc flame from burning the moulded material and to produce the gas generating structure. This structure is held from moving under the stress of interruption by the retaining ring which fits up against embossed shoulders on the outside casing. A copper tube forms the case of the limiter and in addition furnishes the condensing surface for the metal vapors. The conducting element is restrained from sliding by embossing the copper tubing, after which the entire assembly is sealed by swedging in the ends of the case. Figure 4 compares the size of the limiter with a 600-volt cartridge fuse of the same current-carrying ability.

Tests

Repeated interruption tests were made throughout the entire current range. In many tests, the limiter was completely surrounded by surgical cotton in accordance with the procedure established by the Underwriters' Laboratories, Inc. In no test was the cotton discolored, thus proving the absence of flame or hot gases external to the limiter. Figure 5 is an oscillogram showing an interruption at a moderate current value. In Figure 6 the interruption of a current in excess of the rating of the limiter is shown. Note the shift in power factor of the circuit caused by the relatively high arc voltage. This characteristic of the limiter is an advantage in that it aids in the interruption of the circuit and protects the system from voltage stresses. Internal pressure is recorded on the oscillogram in Figure 7. The short duration of the pressure is caused by the rapid condensation of the metallic vapor by the copper case and by the cooling of the generated gas. The condensed metal vapor is seen in Figure 8 as irregularities on the inside surface of the blown limiter. Voltage tests were made on blown limiters by putting them on overvoltage immediately after interruption. In all cases the limiters withstood voltages above 2,200 volts continuously for several days until removed from test.

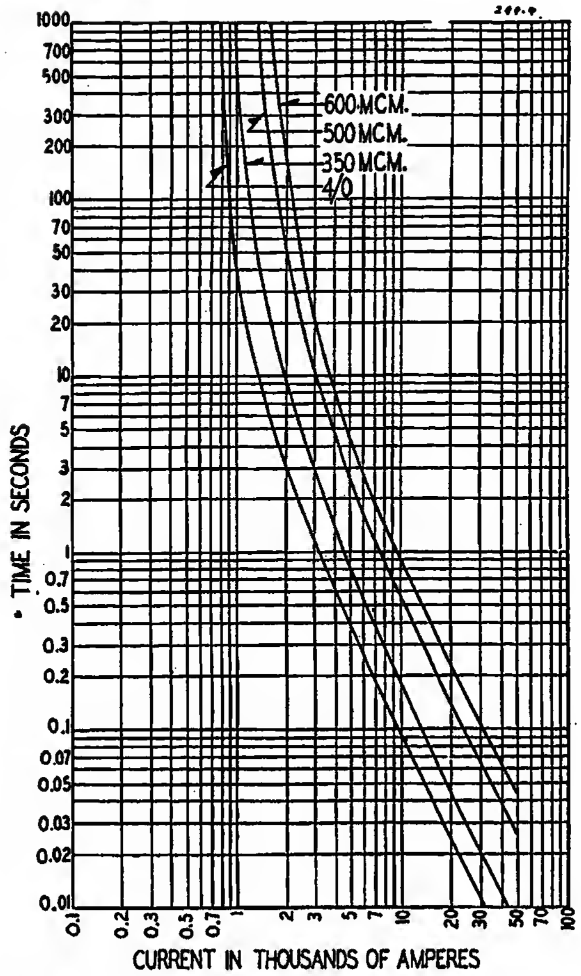

Figure 9. Time–current curves for new limiter

The limiter is designated by the size of cable for which it is intended

The sizes of fusible elements were determined by the co-ordination requirements. Time-current curves for several common sizes are shown in Figure 9. A study of the curves will reveal that any one limiter will be blown without damage to the other limiters on the system, if the fault current is fed to the limiter which interrupts the circuit through at least two other limiters in parallel. This is the case in a properly designed network system, where there are two or more cables per phase, as will be seen by reference to Figure 10, a schematic diagram of a typical load bus unit.

Temperature-rise tests were made with the limiter connected to the supply by eight-foot lengths of the proper size type-*R* cable. The limiter was supported in free air and was shielded from air currents by a canvas screen placed completely around the device. Temperature rises were found to be less than 30 degrees centigrade for all sizes at the maximum current ratings of the cable.

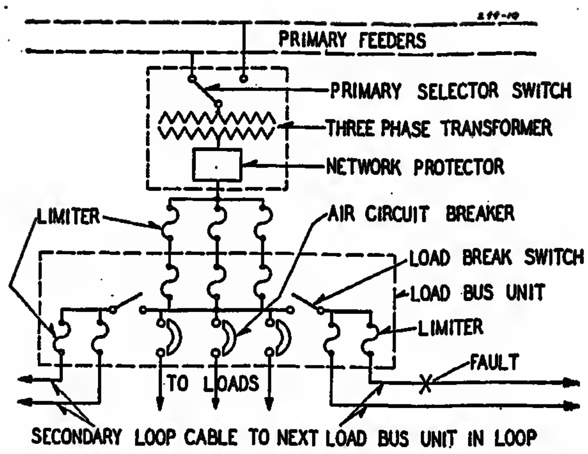

Figure 10. Unit of network system in which selectivity between limiters is automatic

Note that current flows in parallel through all other limiters on the bus to the limiter clearing the fault

Conclusions

Past experience has shown the desirability of a network system and the effectiveness of limiters in providing the proper protection. The new 600-volt limiter described in this paper is serving in a number of industrial plants at the present time, and all experience has been satisfactory. In addition, extensive laboratory testing has adequately proved the new limiter's ability to perform its functions. There has been provided a new 600-volt limiter, small in size, but capable of interrupting large currents without perceptible noise or visible demonstration.

Modern Impulse Generators for Testing Lightning Arresters

THEODORE BROWNLEE
ASSOCIATE AIEE

NATURAL lightning is very destructive and so elusive that it cannot readily be used for testing. However, the behavior of materials or equipment which are subject to lightning may be studied with artificial lightning from the impulse generator. In impulse testing of insulation strength, it is necessary to control only the wave shape and magnitude of the impulse voltage. There are numerous papers[1-5] describing methods of producing and measuring impulse voltages, and other papers[1,2,6-9] show how to calculate the circuit constants required to produce such waves.

The complete testing of lightning arresters requires, in addition to means for obtaining voltage waves, facilities for the accurate control of both magnitude and wave shape of discharge current. A variety of these impulse current waves are needed to simulate service conditions reasonably. The newly revised AIEE Lightning Arrester Standards No. 28 include tests with 10x20-microsecond waves of 5,000, 10,000, and 20,000 amperes; 5x10-microsecond waves of 65,000 and 100,000 amperes; and 10,000, 15,000, and 20,000 ampere tests with a nominal wave steepness of 5,000 amperes per microsecond. Since the internal impedance of the arrester is a factor affecting the impulse current, the complete testing of various types and ratings of arresters requires impulse generators with considerable flexibility and facility for quick adjustment. This paper describes several impulse generators designed primarily for lightning-arrester testing, and which have proved over years of constant use to have the desirable features of safety, flexibility, reliability, and convenience.

The circuit constants necessary to produce various current waves cannot be calculated exactly, because the resistance of the arrester valve element is not constant but a function of the voltage or current. So far as the author is aware, the methods for determining such circuit constants have not been published although there have been described impulse generators[10,11] which are adapted for lightning-arrester testing with different current waves. Through long experience, methods of approximate calculation have been developed, chiefly by the use of curves, which enable circuit constants to be selected roughly with a minimum of cut-and-try procedure. These methods are general in character and are applicable to unidirectional or oscillatory waves, including, of course, those specified in the AIEE Standards.

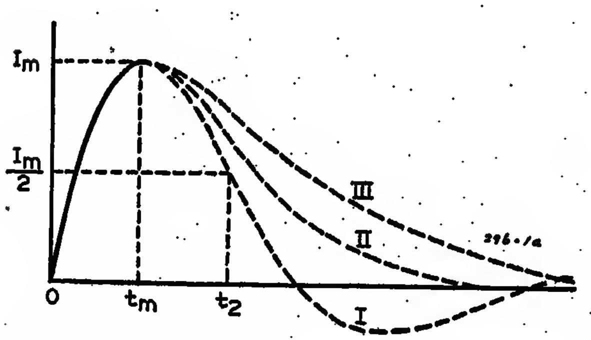

Figure 1a. Typical impulse-current waves

The time to crest for all three waves is designated by t_m, but t_2, as shown, represents the time to half value for wave I only

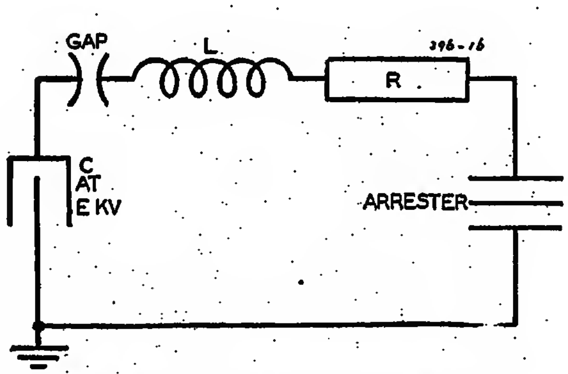

Figure 1b. Typical *RLC* impulse circuit

List of Symbols

The following symbols refer to the impulse-generator waves or circuit of Figure 1:

C = capacitance in microfarads
E = initial voltage on C in kilovolts
L = inductance in microhenrys
R = constant resistance in ohms
R_A = resistance of arrester*
R_T = total circuit resistance $= R + R_A$*
R_1 = critical resistance below which oscillations are produced
I_m = crest of current wave in kiloamperes
t_m = time in microseconds corresponding to I_m
t_2 = time in microseconds corresponding to $0.5I_m$ (on tail)
Δ = ratio of crest current for any half cycle to that of the preceding half cycle in an exponentially damped sine wave
E_m = crest of voltage wave produced by current wave through R_T

Typical Waves and Circuits

Figure 1a shows three current waves** and Figure 1b the customary circuit for producing such waves. The wave shapes I, II, and III are produced by circuits in which the total resistance is respectively

---

Paper 42-96, recommended by the AIEE committees on protective devices, and power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22-26, 1942. Manuscript submitted April 13, 1942; made available for printing May 19, 1942.

THEODORE BROWNLEE is research engineer in the lightning arrester engineering department of the General Electric Company, Pittsfield, Mass.

* R_A and R_T are not constant but functions of voltage (or current) and time. Consequently R_A and R_T can only be represented completely as curves of instantaneous resistance plotted as a function of time. Such curves have a minimum at or a little after the maximum current.

** For time measurements in Figure 1a and throughout this paper, the actual zero is used. AIEE Standards No. 28 use the virtual zero which is the intersection on the time axis of a straight line projected through the 10 and 90 per cent points on the front of the wave. There is little practical difference, amounting to the order of only 1 per cent of the time to half value on the tail, for the waves here considered.

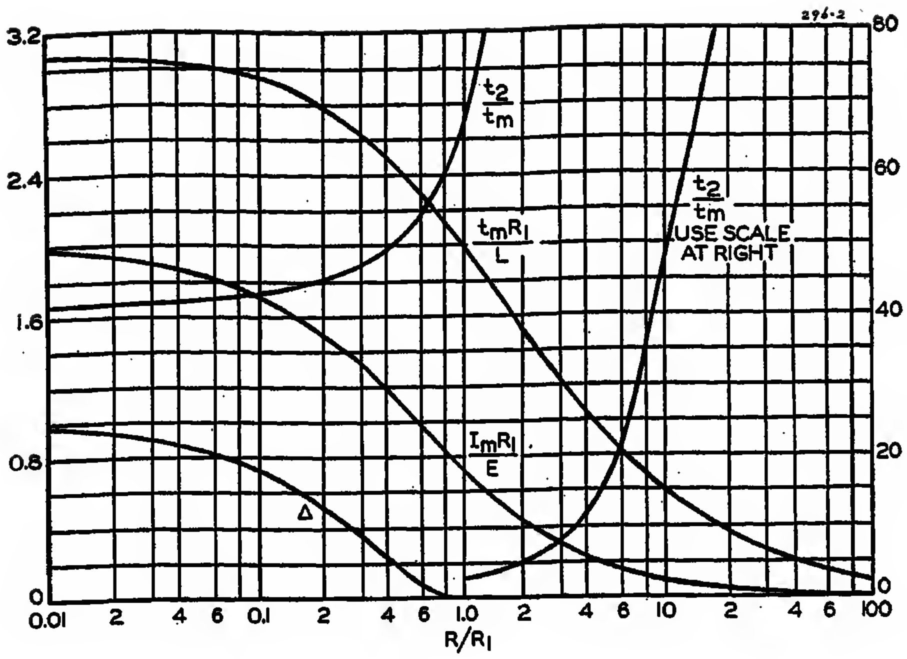

Figure 2. Effect of resistance on waves in *RLC* circuit

less than, equal to, or greater than the critical resistance. This total resistance R_T is composed of the constant resistance R and the nonlinear resistance R_A of the arrester. Valve-type arresters are designed to have a variable resistance R_A which is low at high currents but high at low currents, and R_A is the principal stumbling block to straightforward calculations of impulse circuits.

While both types of resistance may be present in any proportion, it will be shown how to compute the circuit constants when the resistance is predominantly linear or predominantly variable; from these, rough interpolations can be made for various combinations.

Before specific cases are considered, the principles of similarity and proportionality of circuit constants should be emphasized. Waves having similar shapes are those which can be represented by a single plot if either or both co-ordinate scales are multiplied by the necessary factors. In an *RLC* circuit as shown in Figure 1b the wave shape depends only upon $R_T/\sqrt{4L/C}$. If R_A is negligible, R_T is a constant and the above expression is a simple ratio of definite constants. However, if R_A is not negligible, R_T is really a function of time, as explained in the list of symbols. In this condition the expression is of little use; but with different waves of similar shape, the curves of R_T versus time also are similar, and any two corresponding values of R_T, such as those at maximum current, can be used for comparison purposes.

For current waves of similar shape, the circuit constants and wave specifications are so related that the following ratios are constant.

1. $t_m/\sqrt{LC}$
2. $t_2/\sqrt{LC}$
3. E/I_mR_T
4. E/E_m
5. I_mt_2/CE

It is possible to determine experimentally circuit constants to produce various wave shapes and by use of the above principles to calculate directly the constants required for other waves, similar in shape, but of different magnitudes or durations. Since the resistance may be a function of the current or voltage, the wave shape depends upon the voltage of the impulse generator as well as upon its other constants.

Calculations When Arrester Resistance Is Low in Comparison With Total Circuit Resistance

For the cases where the arrester resistance can be neglected (or lumped with the circuit resistance) the current for any particular circuit can be found easily from the well-known equations:

$$I=(E/\omega L)\epsilon^{-at}\sin\omega t \quad \text{where } R<R_1 \qquad (1)$$

$$=\frac{Et\epsilon^{-at}}{L} \quad \text{where } R=R_1 \qquad (2)$$

$$=\frac{E}{L}\,\frac{\epsilon^{-mt}-\epsilon^{-nt}}{n-m} \quad \text{where } R>R_1 \qquad (3)$$

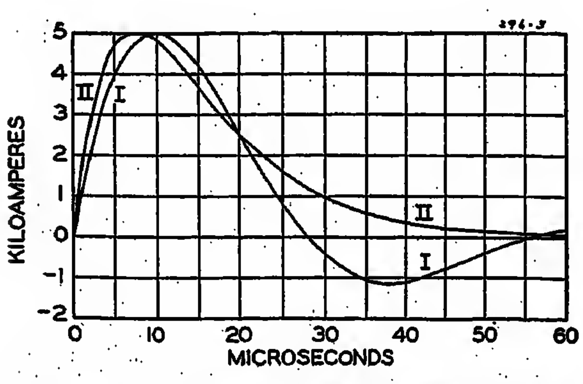

Figure 3. Impulse-current waves calculated by curves of Figure 2

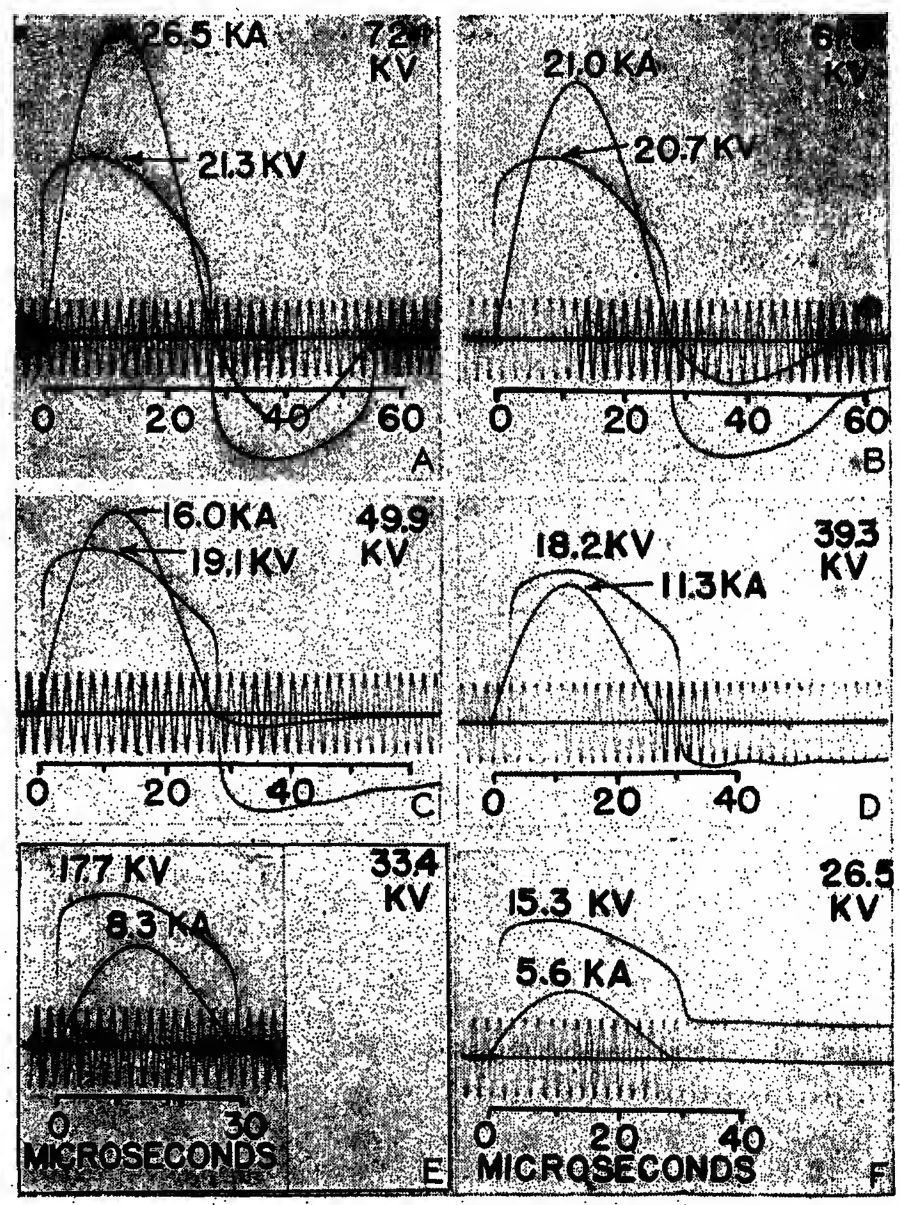

Figure 4. Current and voltage oscillograms on lightning-arrester element in *RLC* circuit of Figure 1b

$C=4.41$, $L=15.4$, $R=0.142$. The same arrester element was used for all six waves with the wave shape determined only by E which is listed in upper right-hand corner of each oscillogram

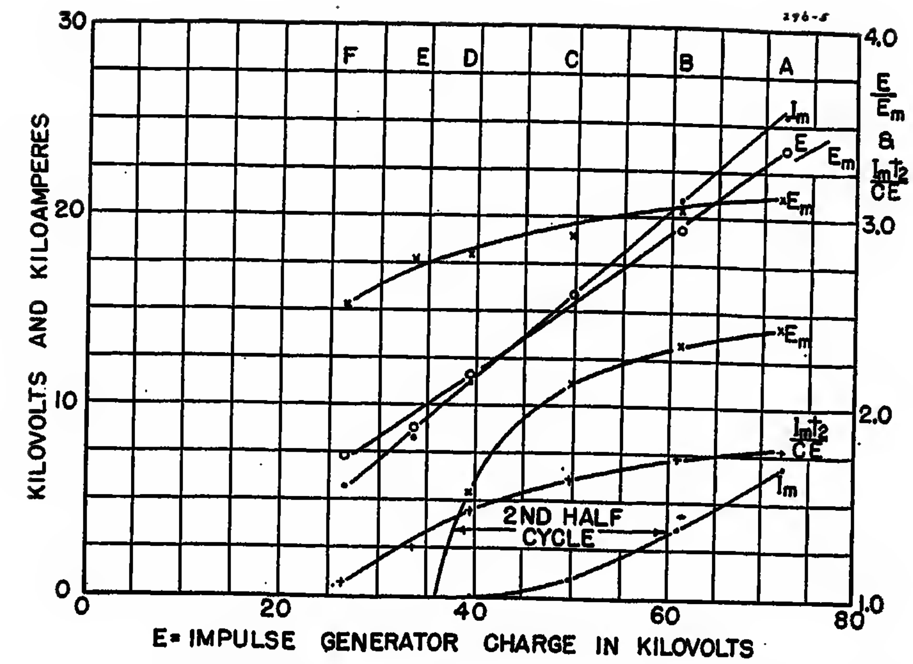

Figure 5. Curves of E_m and I_m taken from oscillograms of Figure 4

Curves of E/E_m and I_mt_2/CE are computed from these results, but are applicable for any other combinations of circuit constants which can produce similar wave shapes

$$a=\frac{R}{2L};\quad \omega=\sqrt{\frac{1}{LC}-a^2};\quad m=\frac{R-\sqrt{R^2-R_1^2}}{2L};$$

$$n=\frac{R+\sqrt{R^2-R_1^2}}{2L}$$

Equation 1 defines an oscillatory wave such as wave I in Figure 1a, while equations 2 and 3 are for the nonoscillatory waves II and III, respectively.

Equations 1, 2, and 3 are transcendental and it is not possible to calculate directly the equation for a specified impulse such as a 5,000-ampere 10x20-microsecond wave. It is best to assume various circuit constants and plot curves which then can be used directly. It is found that for the *RLC* circuits the shape of the current wave depends only upon the ratio R/R_1 and this ratio is the most convenient parameter for abscissa of the curves. Figure 2 shows a set of such curves with ratios of R/R_1 from 0.01 to 100. The left-hand side of Figure 2 represents oscillatory conditions and the right-hand side nonoscillatory conditions. For a 5x10- or 10x20-microsecond wave, $t_2/t_m=2$, and it is found that such a relation holds only for oscillatory waves for which $R/R_1=0.43$ and $\Delta=0.22$. For the critically damped waves $R/R_1=1$ and $t_2/t_m=2.68$.

An infinite number of circuits and voltages will produce any possible wave, and at the start one constant must be arbitrarily fixed. Usually the first selected constant is either the impulse-generator capacitance or voltage, but in some circumstances the limiting value might be inductance or resistance. Figure 3 shows two waves for which the impulse-generator capacitance was fixed and the remaining constants determined by use of the curves in Figure 2. It is seen that the two waves are not greatly different, but considerably more charge was required for the critically damped wave. For any nonoscillatory wave, the area under the ampere–time wave in ampere-seconds is equal to the charge CE (C in farads and E in volts) but for oscillatory waves an integration for the first half cycle shows the ampere-seconds to be $CE(1+\Delta)$, and providing the resistance can be kept low enough, it is possible to get in the first half cycle nearly twice the ampere-seconds originally stored in the capacitance. This means, however, that the wave will oscillate for many half cycles, which frequently is not a desirable condition.

Empirical Calculations to Include Nonlinear Resistance of Arrester

Valve-type lightning arresters are designed to have low resistance at high currents and high resistance at low currents, and rigorous calculations of circuits containing such resistances are not possible. Figure 4 shows the types of waves which can be obtained in the circuit shown in Figure 1b where the variations in waves are caused only by variations in the charging voltage. Considering only the first half cycle, the current waves are remarkably similar in shape and are all approximately 12.5x22-microsecond waves. This ratio of t_2/t_m of about 1.75 is typical of impulse-generator circuits in which the arrester-valve element comprises most of the resistance, and so the specified ratio of two for 5x10- or 10x20-microsecond waves can be fulfilled approximately without difficulty. If a closer agreement is desired, it can be obtained by using some additional constant resistance.

In addition it should be observed that the first quarter cycle is practically a sine wave and the time to crest of 12.5 microseconds is a close approximation of the calculated time to crest for no resistance where:

$$t_m=0.5\pi\sqrt{LC} \tag{4}$$

which gives $0.5\pi\sqrt{4.41\times15.4}=13$ microseconds. In Figure 5 are plotted the crest measurements of current and voltage from Figure 4, and in addition the ratios E/E_m and I_mt_2/CE.

The curves for I_m and E_m apply only for the circuit constants listed for Figure 4, but the ratios E/E_m and I_mt_2/CE are universal in application for circuits wherein the resistance is chiefly arrester valve element. The absolute magnitudes and durations are immaterial for these ratios which depend only upon the wave shapes. The points for the ratios are identified with letters A–F corresponding to the oscillograms A–F in Figure 4. Hence, in any circuit if the wave shape of Figure 4E is desired, E/E_m must be 1.97. and I_mt_2/CE must be 1.31. In the calculation of such a circuit, it is necessary to know or assume the maximum voltage across the arrester and resistance expected at the desired current. The following example shows the general method of attack.

Example

A 75-kv impulse generator is available with a maximum capacitance of seven microfarads and a minimum inductance of two microhenrys. Determine if this equipment is capable of producing a 100,000-ampere 5x10-microsecond discharge through an arrester having approximately 18-kv crest on this wave. Here $I_mt_2/CE=1.9$.

The curve of I_mt_2/CE in Figure 5 goes only to 1.8 so the desired wave, if at all

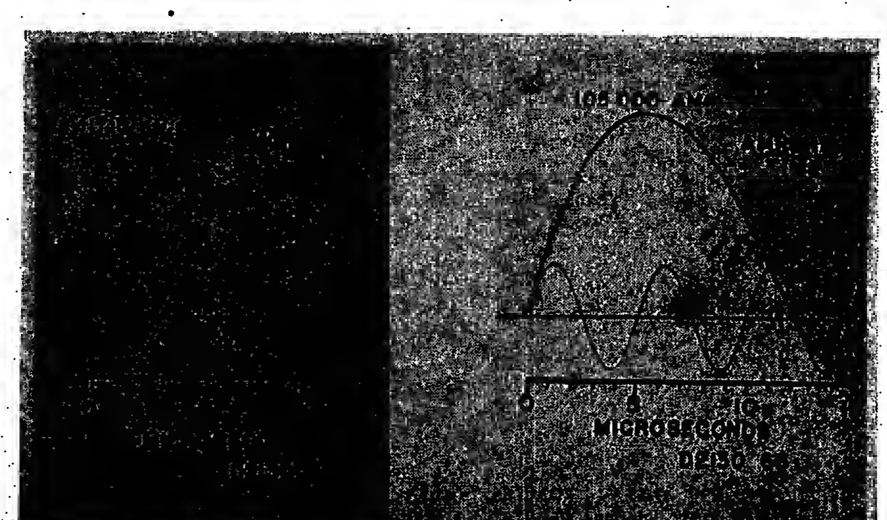

Figure 6. Voltage and current oscillograms for nominal 100,000 - ampere 5 x 10-microsecond current wave through a valve-type lightning arrester

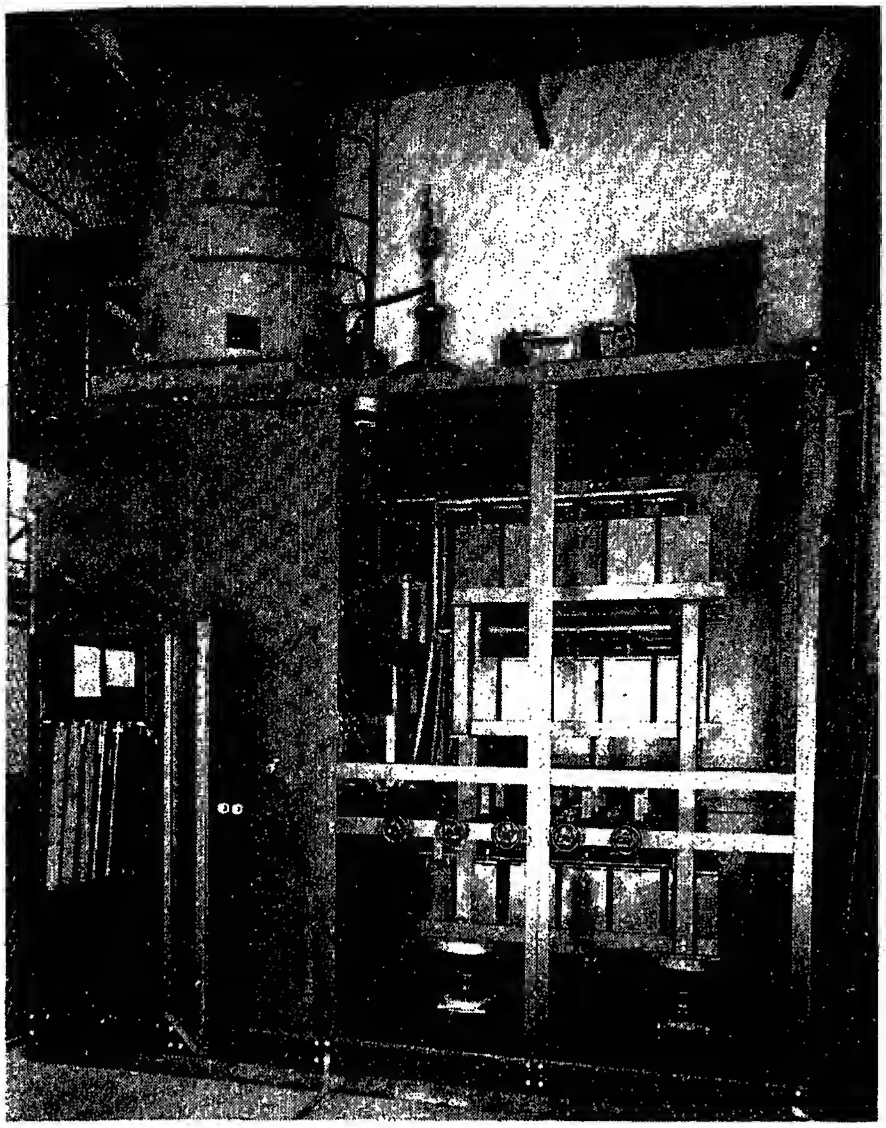

Figure 7. Adjustable-capacitance impulse generator number 1

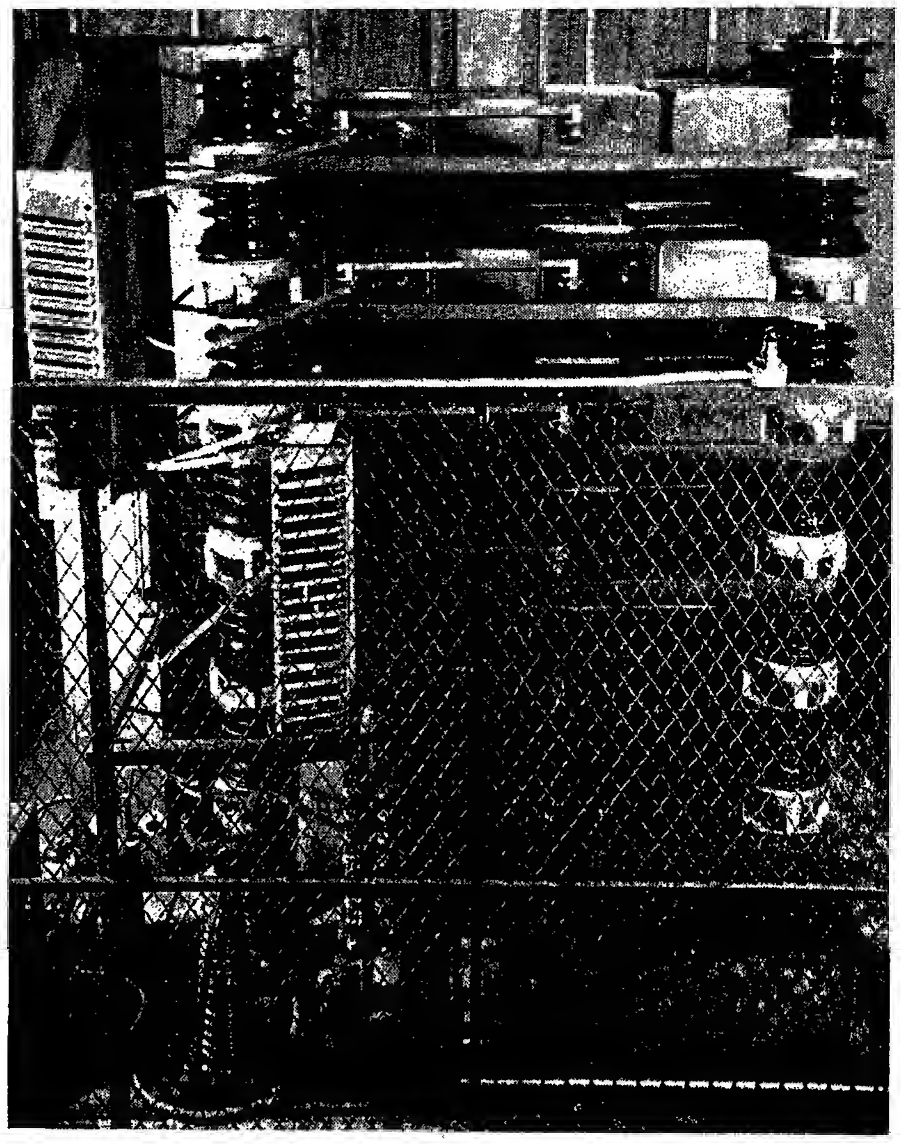

Figure 9. Marx-circuit impulse generator number 2

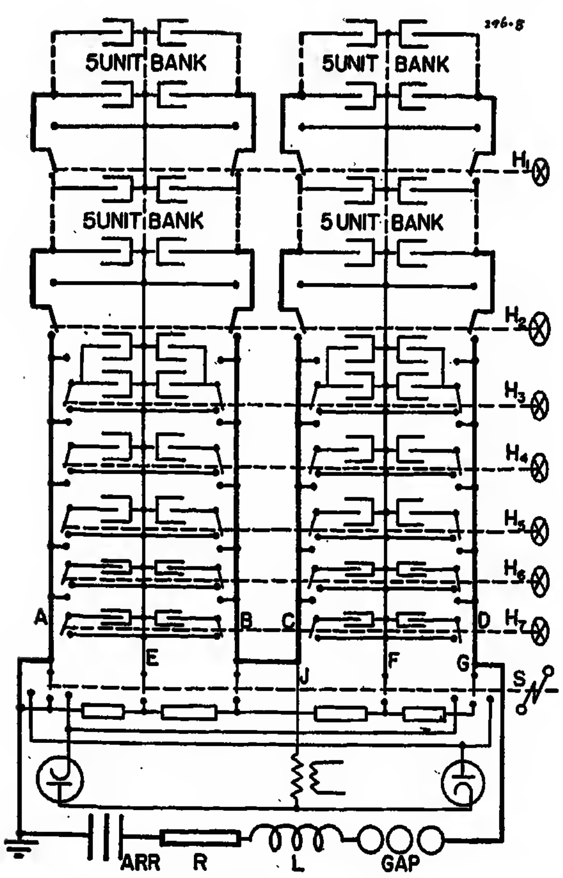

Figure 8. Circuit diagram of impulse generator number 1

Hand-operated switches H_1–H_7 throw capacitor units or banks on the busses *ABCD* or disconnect and short-circuit the terminals to the cases, *EF*. Solenoid-operated switch *S* has three positions: "left" for positive generator charge; "right" for negative generator charge; "middle" automatically grounds all live capacitor points except during charging periods

possible, will be more oscillatory than that shown in Figure 4A. Since some tolerance is allowed, a 4.7x9.4-microsecond wave is acceptable, which gives $I_m t_2/CE=1.8$. Hence there is sufficient charge available to produce a 4.7x9.4-microsecond wave similar in shape to Figure 4A.

Using equation 4, $t_m=0.5\pi\sqrt{LC}=5.9$ microseconds, which is close enough for practical purposes.

For $I_m t_2/CE=1.8$, the corresponding value of E/E_m is 3.38. This means that sufficient additional resistance should be added to the circuit so that $E_m = 75/3.38=22$ kv.

Figure 6 shows waves actually produced under the conditions specified in the above example. However, no resistance was added, so that for the waves of Figure 6 the current is higher and the oscillations greater than in the example.

The foregoing example shows that it is not always possible to fulfill the exact requirements determined by calculation, and in order to test various types and ratings of arresters over a range of currents and wave shapes, the impulse-generator constants and charging voltage must be adjustable over a wide range.

When several ratings of arresters are to be tested with the same wave, the circuit adjustments are minimized by setting up to test the highest rating first, and when other ratings of lower internal resistance are substituted, sufficient resistance is added to keep the total resistance constant.

Often it is found impossible, with existing equipment, to get aperiodic waves coming rapidly to zero as in Figure 4E. If the maximum charging voltage E is too low for a particular arrester rating, the waves will look like Figure 4F. If there is current to spare, the voltage wave can be brought down to zero by the use of a constant resistor in parallel with the arrester or generator capacitance. If the product CE is too small to produce the required wave like Figure 4E, the current can be increased in low ratings of arresters by letting it oscillate somewhat as was done in Figure 6 or Figure 4 (A–D).

Calculation for a Wave of Specified Crest and Nominal Steepness

For a wave specified by steepness instead of duration, it is only necessary to redesignate it in the usual way and calculate the circuit constants as previously shown. For circuits where R is low compared to R_T, the first quarter cycle is almost a sine wave. The nominal steepness, or the slope of the line through the

10 per cent and 90 per cent points, is approximately

$$\text{Nominal steepness} = 1.2I_m/t_m \quad (5)$$

or with $t_2/t_m = 1.75$ as in the waves of Figure 4

$$\text{Nominal steepness} = 2.1I_m/t_2 \quad (6)$$

For critically damped waves in circuits where R_A is low compared to R_T, similar approximate equations are

$$\text{Nominal steepness} = 1.4I_m/t_m \quad (7)$$

or

$$\text{Nominal steepness} = 3.7I_m/t_2 \quad (8)$$

for intermediate wave shapes an approximate equation is

$$\text{Nominal steepness} = 1.3I_m/t_m \quad (9)$$

and the equation in terms of t_2 can be found using the ratios of t_2/t_m in Figure 2.

Hence, using the equations 5 to 9 any wave based on crest and nominal steepness can be redesignated by crest and duration and calculations made as before.

Control of Impulse-Current Wave Shapes in General Testing

The calculating methods here presented are also applicable where nonlinear resistances, such as Thyrite, are used to control impulse-current wave shapes.[12,13] The use of such resistors permits higher crest currents without oscillation, and shorter wave tails, than can be obtained by use of constant resistance.

Description of Impulse Generators

It is evident from the foregoing material that lightning arrester impulse testing requires an extended range of circuit constants and unless the various circuits can be conveniently and quickly set up, much valuable time will be lost. In addition to the very high voltage and very high current impulse generators necessary for special tests on lightning arresters, there have been built during the last few years four generators at the continuous disposal of the lightning arrester department in Pittsfield.

Generator Number 1 for General Testing

Generator number 1 is shown in Figure 7 with part of the steel panels removed. The capacitors are all Pyranol-filled 75-kv units especially designed to have low inductance and to withstand repeated short-circuit currents. All units have mid-points tied to the cases. There are 28 capacitors rated 0.24 microfarad and 4 trimmers for fine adjustments rated 0.06 microfarad. The charge and discharge circuits are connected to two pairs of copper-tubing busses which may be operated in series for 150 kv or in parallel for 75 kv. The capacitors are mounted on two three-deck steel frameworks insulated from ground and each other. At 150 kv connection, the cases of capacitors in the front framework are at 112.5 kv and those in the back framework are at 37.5 kv. The handwheels shown in Figure 7 throw two or more capacitors on the lower busses or short circuit them to their respective frameworks. The capacitors in the two upper decks are permanently bussed in parallel but they can be connected either to the lower busses or short-circuited to the framework. The charging equipment is located on top of the steel housing, and the large cylinder contains a combination polarity reversing switch and ground switch which grounds all busses and frameworks except during the charging period.

Figure 8 shows the elementary circuit diagram for the 150-kv connection. For clarity none of the hand-operated switches H_1–H_7 are shown completely closed, but H_1 and H_2, when thrown to the indicated position, connect the two upper decks to the busses $ABCD$ while the capacitors in the lower deck are all removed from the busses and short-circuited by the switches H_3–H_7. By means of the switches any capacitance from 0.04 to 1.75 microfarads in steps of 0.04 microfarad can be instantly selected for 150-kv operation. For 75-kv operation switches (not shown in Figure 8) connect bus D to bus A and mid-point E to mid-point F. Also G is moved from D to BC and J from BC to EF. With these connections the capacitance can be varied from 0.16 to 7 microfarads in steps of 0.16 microfarad. For very long waves, all the capacitor bushings can be bussed together, using the cases for the return circuit, and then 28 microfarads can be obtained for charging voltages up to 37.5 kv.

Tests at moderate currents are made in the oscillograph room at the rear of the generator. High-current tests require short leads and are made inside the steel housing. Some of the tapped resistance and inductance control elements are shown hanging on the wall inside the door. The minimum discharge inductance is about two microhenrys and tests up to 100 kiloamperes can be made on low-voltage arresters. The oscillograms of Figure 6 were obtained using this generator.

The advantages of this impulse generator are:

1. *Safety.* No power can be applied until all safety gates are closed and all capacitance parts are grounded after every discharge.

2. *Convenience.* Capacitance and voltage are variable over wide ranges with little effort. The polarity can be changed by the flip of a switch. The three-electrode gap spacing is controlled by a wooden shaft extending into the oscillograph room, and the charging-voltage control is located on the oscillograph table.

3. *Reliability.* Several years of service without trouble have demonstrated its reliability.

4. *Compactness.* A minimum of floor space is used, the dimensions being $6^1/_2$ by 12 feet.

5. *Totally Enclosed.* The steel housing eliminates stray electrostatic fields, and the exterior is neat even when destructive tests are being made inside. It also reduces the noise when high-current tests are being made.

Generator Number 2 for General and High-Voltage Testing

Impulse generator number 2 has a 600-kv six-stage Marx circuit as shown in Figure 9. The Pyranol-filled capacitors are rated 2.2 microfarads at 25 kv and have but one bushing with the case serving as the other terminal. Each stage consists of two groups of four capacitors in series. The primary groups are shown on the left in Figure 9 and the secondary groups at the right can be connected in parallel or short-circuited and left with cases floating. The charging resistors and interstage sphere gaps are mounted on the vertical wooden box at the extreme left. By means of switches the generator can be connected conveniently to operate at reduced voltage and high capacitance, and, if desired, part of the capacitance can be omitted. The following combinations can be obtained with either polarity and any voltage up to the maximum listed:

Maximum Kv	Microfarads Available
50	1.1 to 26 in steps of 1.1
100	0.55 to 6.60 in steps of 0.55
200	0.28...0.55... 0.82...1.1...1.6
300	0.18...0.37... 0.73
400	0.14...0.28
500	0.11...0.22
600	0.09...0.18

The advantages of this generator over number 1 are its higher voltage and greater energy. Tests can be made on arresters up to 75-kv rating at 5,000 amperes, 10x20-microsecond waves, and at appreciably greater currents on lower ratings. Its minimum inductance is higher than for generator number 1 since the Marx circuit necessitates longer connections. Because the minimum inductance at 100 kv is about 3.5 microhenrys, generator number 2 will not produce as high currents as generator number 1 even though it contains nearly twice the energy.

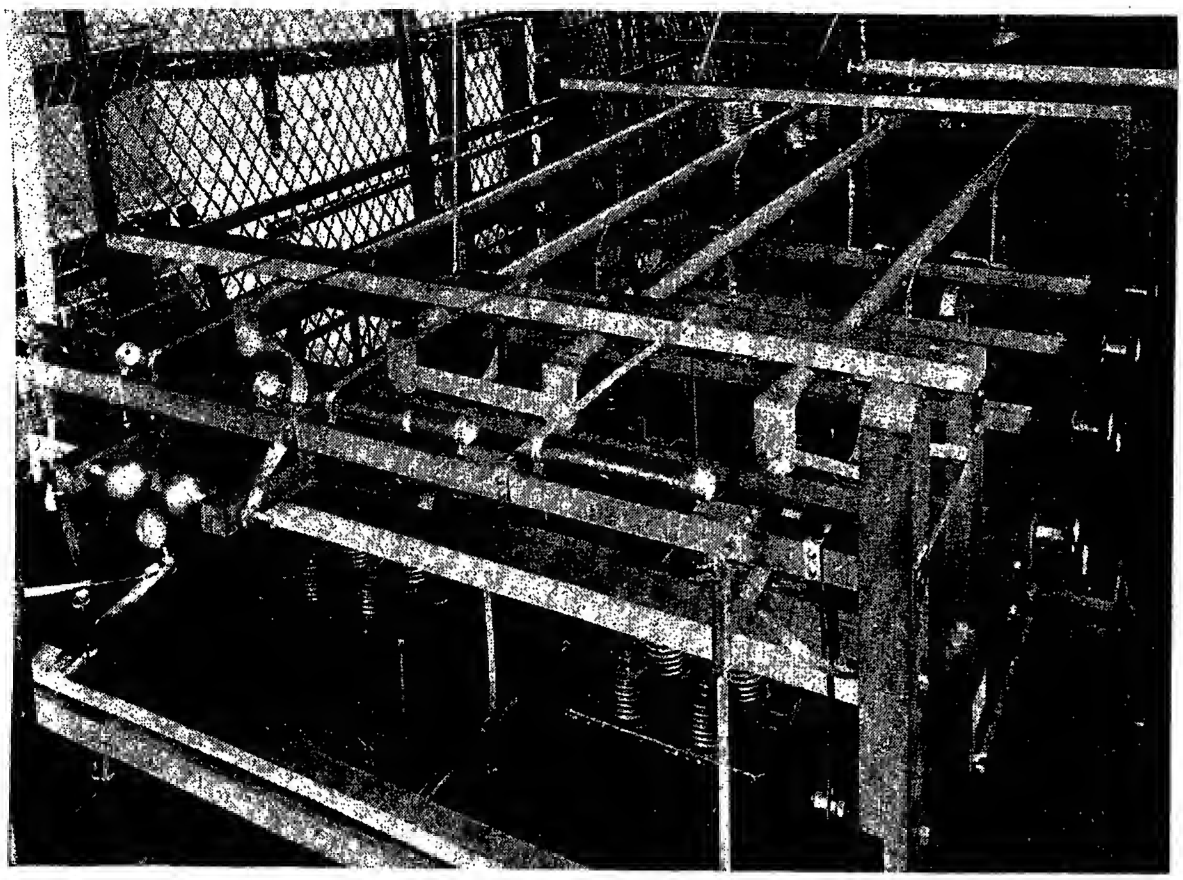

Figure 10. Adjustable-capacitance impulse generator number 3 used for operating-duty power tests

However, for a wide range of voltage and moderate currents of 50 kiloamperes or less, it supplements the other generator. The oscillograms in Figure 4 and all those in a contemporary paper[14] describing a new oscillograph were produced using this generator.

Generators Numbers 3 and 4 Used for Operating-Duty Tests

For convenience, two additional impulse generators are used for operating-duty power tests. Generator number 3, shown in Figure 10, consists of two rows of capacitors which can be connected in parallel or series for 50- or 100-kv operation. The usual connection is 100 kv, and by means of the handwheel-operated switches, the capacitance can be adjusted from 0.125 to 1.9 microfarads in steps of 0.125 microfarad. Units not in use are short-circuited by the switches, but the cases remain at the midtap potential of those in use. All live parts are automatically grounded except when the generator is on charge. The voltage and gap settings are easily adjustable, and the polarity can be reversed if desired.

Generator number 4 is similar in construction and rating to number 3. Either one is capable of sending a 10,000-ampere 10x20-microsecond wave through a 12.5-kv arrester. Number 3 is used for routine tests with a power supply of 500 kva at 3, 6, 12, or 24 kv at 60 cycles, while number 4 is used with a supply of 2,500 kva at 7.5 or 15 kv.

In addition to the four impulse generators described, there are available in the high-voltage engineering laboratory impulse generators rated up to 5,000 kv and a high-current generator[11] which can be connected for a maximum 6.2 microfarads at 150 kv, 14 microfarads at 100 kv, or 56 microfarads at 50 kv. This high-current generator has very low inductance and can produce currents up to 250 kiloamperes. It can be used for regular impulse tests or for operating-duty power tests with either of the power sources used with generators number 3 or 4.

Summary

1. Thorough testing of lightning arresters requires a wide variety of impulse-current waves.

2. The strictly mathematical calculation of circuit constants to produce such waves is limited to the few cases where the circuit resistance is constant.

3. Valve-type lightning arresters have a resistance that is intentionally a function of voltage or current and the determination of the constants of circuits containing valve elements must be done experimentally.

4. Impulse-current waves of the same shape but various durations and magnitudes have circuit constants where $R_T/\sqrt{4L/C}$ is fixed.

5. Once the circuit constants are determined for a particular wave, the constants for similar waves of other magnitudes and durations are easily calculated.

6. The curves of Figure 5 facilitate such calculations for the wide range of wave shapes shown in Figure 4.

7. The testing of various types and ratings of arresters with a number of different waves, requires extremely flexible impulse-generator circuits.

8. Ordinarily the impulse-generator capacitance is the most difficult circuit constant to adjust, but four special impulse generators are described having capacitance values easily adjustable over a wide range. Several years of experience with these generators, and the previously mentioned calculating methods, show that constants for any desired wave, within the capabilities of the equipment, can be computed and set up easily and quickly.

Analytical Treatment for Establishing Load-Cycle Ratings of Ignitrons

D. E. MARSHALL
MEMBER AIEE

E. G. F. ARNOTT
NONMEMBER AIEE

THE ignitron offers unique possibilities as a control element for high instantaneous alternating demand currents. The demand current is limited only by the capacity of the ionized vapor to conduct the current from the mercury pool to the anode and by probability of arc back, which increases as the peak current conducted by the tube increases. The design of ignitron tubes is a compromise between these two factors. Design for low arc-back rate usually results in anode baffles and shields which tend to increase the deionizing properties of the tube and thus decrease the peak current-carrying capacity.

The above consideration and not failure of the cathode to emit electrons limits the peak current that can be controlled by an ignitron. For various classes of control service, such as resistance welder control, the arc-back problem is minimized by the characteristics of the circuit, and the tubes are designed without baffles or other constrictions. Therefore, the peak to average current ratios can assume higher values than are customary in gas- or vapor-filled tubes in other classes of service.

Experience has indicated that the average current ratings within the above peak current limitation are limited mainly by thermal considerations. These limitations are relatively easy to determine under conditions of continuous operation. One operates the tube for a reasonable period of time with the circuit constants and the firing phase chosen so as to place the maximum arc-back stress on the tube at regularly increasing current steps until arc back or loss of control occurs and then backs off for a reasonable factor of safety to establish a point on the rating curve at 100 per cent duty.

By measuring the loss in the tube at this current the energy which can safely be dissipated by the tube can be determined for continuous duty.

Paper 42-94, recommended by the AIEE joint subcommittee on electronics and standards co-ordinating committee 4 for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942.* Manuscript submitted April 1, 1942; made available for printing May 18, 1942.

D. E. MARSHALL is section engineer, special products engineering department, Westinghouse Electric and Manufacturing Company, and E. G. F. ARNOTT is a research engineer, also with Westinghouse Electric and Manufacturing Company, both in Bloomfield, N. J.

However, tubes in general and welding tubes in particular are seldom operated at continuous duty. A large number of combinations of duty cycle and demand currents is possible for a given size ignitron and is used in commercial practice. It is, therefore, necessary to invent methods of determining rationally the rating of these tubes and presenting the data in a form which is capable of furnishing a definite figure for the permissible demand current at any conceivable combination of current and duty.

Obviously, the tube cannot be economically tested for all the various possible combinations. The present paper describes a method which can be used to interpolate or extrapolate to obtain ratings for any combination of intermittent duty. This method consists in operating the tube at a simple on- and off-duty cycle at a high current value and determining an intermittent rating point in addition to the continuous rating point determined as described above.

Curves of arc drop as a function of demand current are also determined. It will in general be found that the average loss in the tube for equal excellence of operation at high currents will be less than that at continuous duty. It is assumed that this difference in heat-dissipation quality is due to the intermittent production of heat in the tube and is a function of an equivalent "thermal time constant" similar to the equivalent electrical quantity. The accuracy of the method can be checked in practice by repeating the determination of the thermal constants using several different duty cycles. The authors realize that the variation of the temperature of the simple model treated in the following discussion does not completely describe the thermal cycle of an ignitron but believe that by its use a close enough approximation can be achieved for the degree of accuracy required.

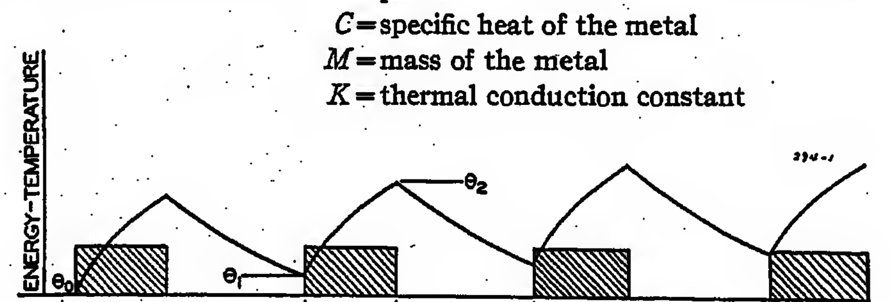

Figure 1. Temperature of model as function of time, with rectangular-waveform energy input

Similar methods are now in use employing the familiar concept of maximum averaging time and are satisfactory enough for most purposes but give results that seem artificial under certain conditions. It is hoped that the present paper will be regarded as a theoretical approach to a rating method based on more nearly correct physical principles.

Thermal Action of Equivalent Model

In approaching the problems of establishing ratings for ignitrons on intermittent duty, equations are developed for a model system. This system is one in which heat is lost by conduction, and the heat loss is therefore proportional to the first power of the temperature difference between the model and the cooling medium. The model is considered to be a small mass of metal in which the temperature at any time is uniform throughout. The mass of metal is surrounded by a cooling medium to which heat from the metal is lost by conduction.

The case to be considered is one where energy is put into the system in equal amounts at regularly spaced intervals. During the time that energy is being put into the system the temperature rises, although some heat is lost by conduction. During the off period when no energy is being supplied, the temperature falls.

To develop the general equation for intermittent loading it is necessary to set up relations between the temperature θ' and the energy input W and time t for both the heating and cooling portions of the cycle. The differential equation for the temperature, while energy is being supplied at the rate W, is

$$CMd\theta' = Wdt - K(\theta' - \theta_0)dt$$

If temperature rise $\theta' - \theta_0$ is replaced by θ, and consequently $d\theta'$ by $d\theta$, the equation will express the temperature θ referred to the temperature of the cooling medium as zero, giving

$$CMd\theta = Wdt - K\theta dt \tag{1}$$

where

θ = the temperature of the heated mass referred to the cooling medium temperature as zero
W = average watts input during the heating period
C = specific heat of the metal
M = mass of the metal
K = thermal conduction constant

Rearranging the terms in equation 1 and integrating:

$$\log_\epsilon (W-K\theta) = \text{constant} - \frac{K}{CM}t$$

and since at $t=0$, $\theta=\theta_1$, the constant $=\log_\epsilon (W-K\theta_1)$, where θ_1 is the temperature at the beginning of the heating period. Solving for θ, the temperature at any time during the heating period is given by

$$\theta = \left(\theta_1 - \frac{W}{K}\right)\epsilon^{-\frac{t}{T_c}} + \frac{W}{K} \quad \text{(heating period)} \qquad (2)$$

where

$$T_c = \frac{MC}{K} = \text{time constant}$$

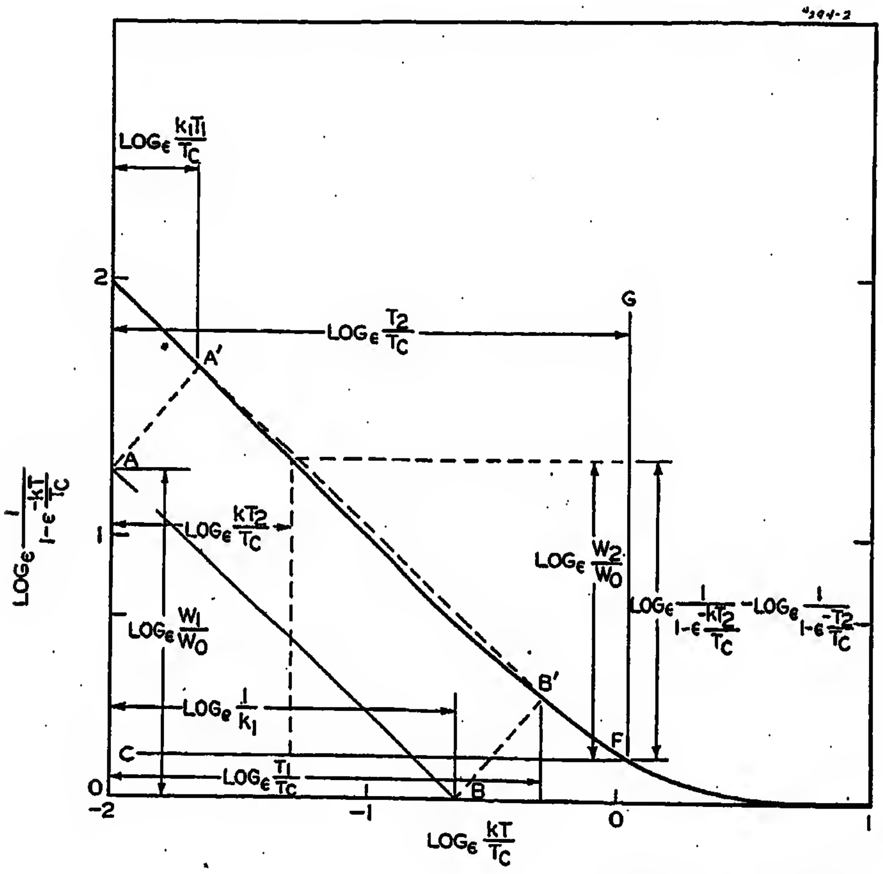

Figure 2 (left). Chart illustrating graphical method of determining rating of model as function of duty cycle and thermal time constant

The temperature during the cooling period can be found from equation 1 by letting $W=0$. This gives

$$\log_\epsilon \theta = \text{constant} - \frac{t}{T_c}$$

At $t=0$ that is, at the end of a heating period $\theta=\theta_2$ as given by equation 2 when t equals T_r, the length of the heating period. This makes the constant equal to $\log_\epsilon \theta_2$ and gives

$$\theta = \theta_2\epsilon^{-\frac{t}{T_c}} \quad \text{(cooling period)} \qquad (3)$$

Equations 2 and 3 are sufficient to determine the temperature θ at any time during load-cycle operation.

Regular Intermittent Duty

Figure 1 shows the temperature θ for a series of regularly spaced equal impulses supplied as shown by the shaded blocks. The time factor $k=T_r/(T_r+T_i)$ is the ratio of the time during which the load is on, to the period or length of the cycle. On the initial cycle θ_1 is equal to θ_0, and θ_2 is given by equation 2 where t is set equal to T_r. For each successive heating period a different value of θ_1 must be used, and this is of course the value of θ at the end of the previous cooling period. After a sufficient number of impulses equilibrium will be reached, and then all the successive values of θ_1 will be equal and the values of θ_2 will also be equal. This simply means that in each "off" period the system loses just the amount of heat which it gained in the previous "on" period.

The allowed value of the watts W during the on period is determined by the maximum temperature allowed. Therefore the value of θ_2 must be found after equilibrium has been reached. For this condition $\theta=\theta_1$ at $t=T_i$ in equation 3 and rearranging

$$\theta_2 = \theta_1\epsilon^{\frac{T_i}{T_c}} \qquad (4)$$

Also, θ_2 in equation 4 must equal θ from equation 2 when $t=T_r$ and therefore

$$\theta_2 = \theta_1\epsilon^{\frac{T_i}{T_c}} = \left(\theta_1 - \frac{W}{K}\right)\epsilon^{-\frac{T_r}{T_c}} + \frac{W}{K} \qquad (5)$$

Solving for θ_1

$$\theta_1 = \frac{W}{K}\left(\frac{1-\epsilon^{\frac{T_r}{T_c}}}{1-\epsilon^{\frac{T_r+T_i}{T_c}}}\right) \qquad (6)$$

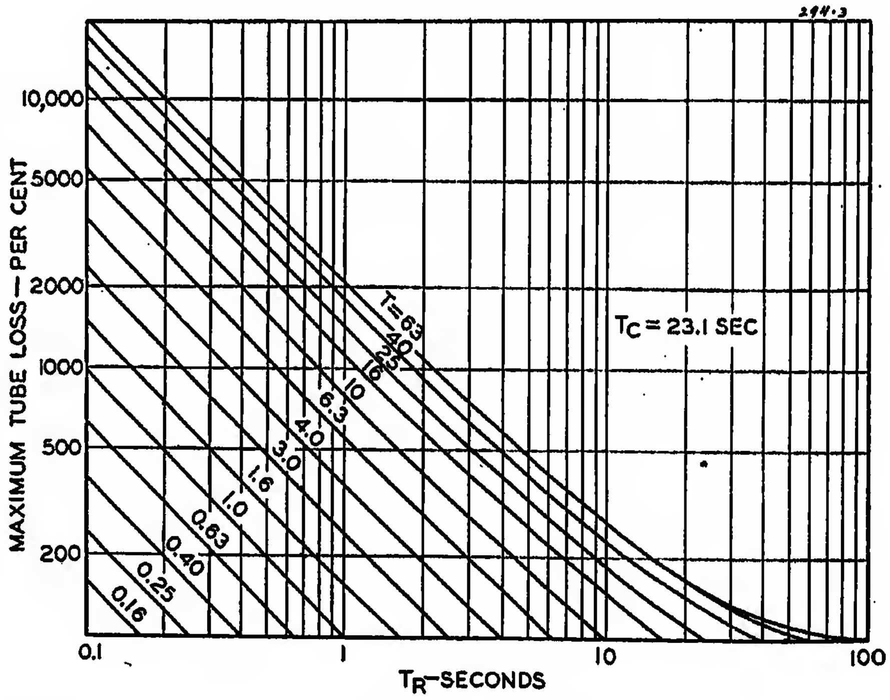

Figure 3 (right). Curve showing rating of model at a given thermal time constant equal to 23.1 seconds

Substituting this value of θ_1 in the second term of equation 5

$$\theta_2 = \frac{W}{K}\left(\frac{1-\epsilon^{\frac{T_r}{T_c}}}{1-\epsilon^{\frac{T_r+T_i}{T_c}}}\right)\epsilon^{\frac{T_i}{T_c}}$$

and simplifying

$$\theta_2 = \frac{W}{K}\left(\frac{1-\epsilon^{-\frac{T_r}{T_c}}}{1-\epsilon^{-\frac{T_r+T_i}{T_c}}}\right) \qquad (7)$$

We may now designate the period of the intermittent cycle, (T_r+T_i), by the symbol T as is customary. Then since the ratio of conducting time to the period $T_r/(T_r+T_i)=T_r/T=k$, equation 7 becomes

$$\theta_2 = \frac{W}{K}\left(\frac{1-\epsilon^{-\frac{kT}{T_c}}}{1-\epsilon^{-\frac{T}{T_c}}}\right) \qquad (8)$$

Equation 8 gives the value of the maximum temperature reached at equilibrium in terms of the watts input W, the period T, and the "on" time $kT=T_r$. The safe or allowed value of θ_2 can be obtained from the allowed watts, W_0, for continuous loading. In this case $k=1$ and equation 8 gives

$$\theta_{2\,\max} = \frac{W_0}{K} \qquad (9)$$

If the requirement for safe operation is that θ_2 shall never exceed W_0/K, it can be replaced by this value in equation 8, giving

$$\frac{W}{W_0} = \left(\frac{1-\epsilon^{-\frac{T}{T_c}}}{1-\epsilon^{-\frac{kT}{T_c}}}\right) \qquad (10)$$

This equation gives the allowed value of input watts W, which can be used for a time, $T_r=kT$ for a repeated loading cycle of period T.

In order to use a graphical construc-

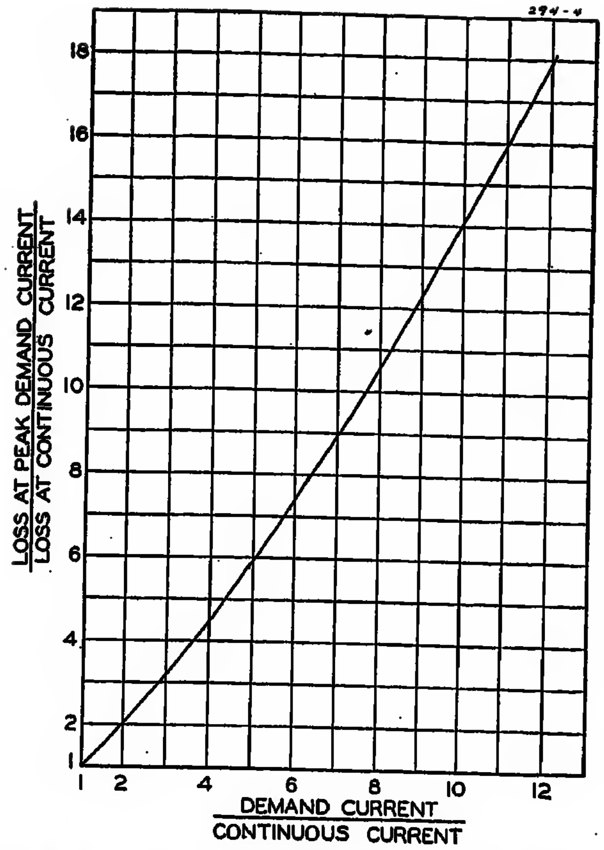

Figure 4. Curve showing increase in tube loss as function of increase in tube-demand current

tion from which the value of time constant can be determined, and rating curves can be laid out, it is convenient to consider equation 10 in the following manner. For two values of k, but the same period T

$$\frac{W_1}{W_0}=\frac{1-\epsilon^{-\frac{T}{T_c}}}{1-\epsilon^{-\frac{k_1T}{T_c}}} \tag{11}$$

and

$$\frac{W_2}{W_0}=\frac{1-\epsilon^{-\frac{T}{T_c}}}{1-\epsilon^{-\frac{k_2T}{T_c}}} \tag{12}$$

Dividing equation 11 by equation 12

$$\frac{W_1}{W_2}=\frac{1-\epsilon^{-\frac{k_2T}{T_c}}}{1-\epsilon^{-\frac{k_1T}{T_c}}} \tag{13}$$

This expression suggests the relations

$$W_1\propto\frac{1}{1-\epsilon^{-\frac{k_1T}{T_c}}} \tag{14}$$

and

$$W_2\propto\frac{1}{1-\epsilon^{-\frac{k_2T}{T_c}}} \tag{15}$$

Figure 2 shows $\dfrac{1}{1-\epsilon^{-\frac{kT}{T_c}}}$ plotted against kT/T_c. This curve will give the value of W/W_0 by dividing the value for k_1T/T_c by that for T/T_c. If the value of T_c is known, specific values of T_r and T can also be derived from this curve.

Application to Ignitron Ratings

As an illustration of the use of this method, rating curves will be obtained for a small water-cooled metal ignitron. Since all of the energy loss is eventually transferred to the cooling water, the problem will be regarded as one where heat is lost by conduction, as in the system covered by the preceding sections.

The test data were as follows:

1. Continuous duty
Tube loss at satisfactory operation $=W_0$
2. Intermittent duty
Tube loss at equally satisfactory operation $=W_1$
$T_r=$ 0.5 second
$T=$11.1 seconds
$k=$ 0.0448
3. $\dfrac{W_1}{W_0}=18.0$

To find T_c substitute in equation 10

$$\frac{W_1}{W_0}=18.0=\frac{1-\epsilon^{-\frac{11.1}{T_c}}}{1-\epsilon^{-0.0448\left(\frac{11.1}{T_c}\right)}}$$

This equation can be solved by trial for $11.1/T_c$. The solution is 0.48 ± 0.005

$$\text{or } T_c=\frac{11.1}{0.48\pm0.005}=23.1\pm0.3 \text{ seconds}$$

Since ignitrons are rectifiers the current conducted by them on a-c circuits is not continuous but consists of a series of half sine waves. The foregoing theory assumes that this intermittent power input can be represented by a continuous function of the time. The accuracy of this assumption can be checked by use of equation 4 where

$$\frac{\theta_2}{\theta_1}=\epsilon^{\frac{T_i}{T_c}}$$

Using the data of the above example and a line frequency of 60 cycles per second

$$\frac{T_i}{T_c}=\frac{\frac{1}{120}}{23.1}=0.00036$$

and therefore

$$\frac{\theta_2}{\theta_1}=1.0004$$

This result indicates that in this case the variation in temperature due to the rectified current pulsation in the tube can be neglected in comparison with the longer period load cycling.

Graphical Calculation and Presentation of Data

Assume that test data are available to establish a rating at a given T and T_r, and that the ratio of the loss in the tube at continuous duty to that at the given duty is known, then the above method will permit the calculation of a value for the thermal time constant, T_c.

The thermal time constant will allow a system of interpolation of the results of the rating tests to other load cycles in a systematic way which is mathematically continuous. The present method, wherein a "maximum averaging time" is used, has the effect of limiting the maximum time of impulse to values less than the maximum averaging time even for demand current loads of only a few per cent higher than continuous load rating. This new method goes over smoothly to the continuous rating.

Graphical Calculation of T_c

The function $\dfrac{1}{1-\epsilon^{-\frac{kT}{T_c}}}$ is plotted in Figure 2 on logarithmic co-ordinate scales. Our test data give us two values of tube loss (W_1 and W_0) at two values of T_r equal to kT_1 and T_1 respectively, where T_1 is the impulse period of the rating test. It is desired to determine the value of T_c which fixes the scale of the diagram, Figure 2, for the particular tube being rated.

From equation 11 we can write

$$\log_\epsilon\frac{W_1}{W_0}=\log_\epsilon\frac{1}{1-\epsilon^{-\frac{k_1T_1}{T_c}}}-\log_\epsilon\frac{1}{1-\epsilon^{-\frac{T_1}{T_c}}}$$

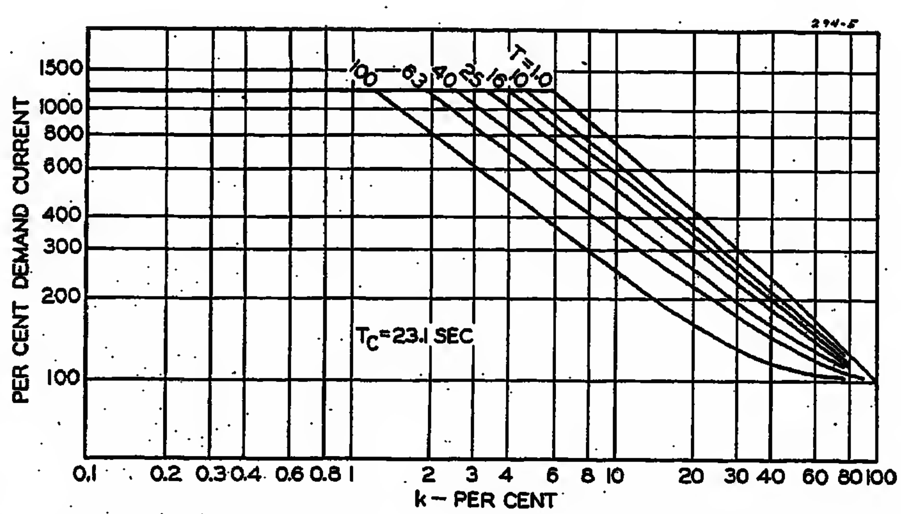

Figure 5. Example family of tube-rating curves as function of impulse time, T_r, and impulse period, T, for thermal time constant, T_c=23.1 seconds. Calculated from Figures 3 and 4

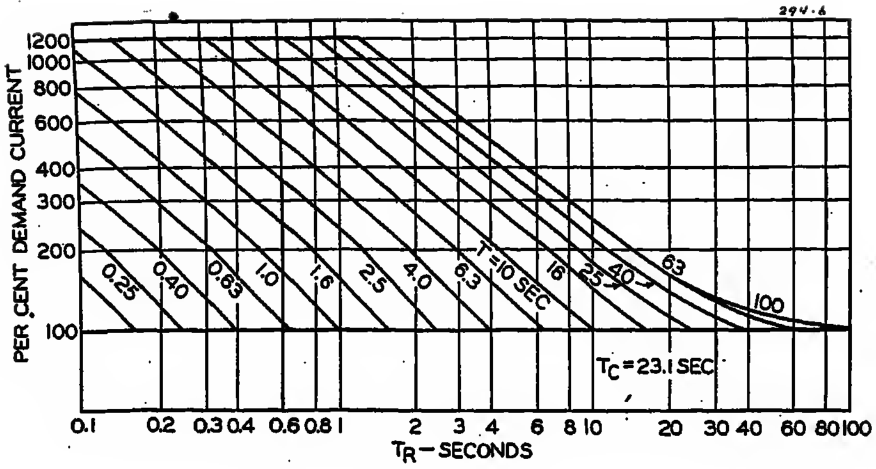

Figure 6. Example family of tube-rating curves as function of per cent duty and impulse period. Calculated from Figure 4

These curves are sharply cut off at the peak current value of 1,200 per cent.

The same information is given in curve Figure 6 in another form. Here, each of the abscissa is in values of k as per cent of the value of T used as parameter on the individual rating curves. This may be compared more directly with the present rating curves where the abscissa is plotted in per cent duty. T here compares with the present "maximum averaging time."

It is seen that the relationship existing between W_1/W_0 and k_1 for given values of T and T_c is in general given by the first term of the above equation, since when T and T_c are fixed, the second term is independent of k_1 and becomes of a constant value which can be subtracted graphically as is done in Figure 2. In order to determine T_c, it is necessary to determine the amount to be subtracted from the ordinate of the curve in Figure 2, in order to make the remainder of the curve fit the conditions as laid down by the test.

This can be done most easily in the following manner. Since the argument of the plotted function is kT/T_c and since the time difference of the test points is defined by k_1, the difference in the abscissa of the test points on the curve at A' and B', when found, must be equal to

$$\log_\epsilon \frac{T_1}{T_c} - \log_\epsilon \frac{k_1 T_1}{T_c} = -\log_\epsilon k_1 = \log_\epsilon \frac{1}{k_1}$$

Therefore, the slope of the chord at $A'B'$ will be

$$\frac{\log_\epsilon \dfrac{W_1}{W_0}}{\log_\epsilon \dfrac{1}{k_1}}$$

A convenient way to lay off this slope is to draw it in a corner of the diagram as shown at AB. In order to fix T_c, it is only necessary to find two points on the curve separated the same distance and at the same slope as the hypotenuse of the triangle AOB. This is done for the example case as shown dotted in the diagram. The lower point at B' thus found on the curve corresponds to $\log T_1/T_c$ and since T_1 is fixed by the test conditions T_c can be calculated. This value can be checked by substitution in formula 10.

Graphical Presentation of Rating Data

After T_c is determined, the rating curve for any other impulse period T_2 can be laid out. The point corresponding to $k=1$ will lie at F, distant $\log T_2/T_c$ from the vertical axis of the diagram. Lines CF and GF form the axes for a new curve whose abscissa is proportional to $\log kT_2$ and whose ordinates are proportional to $\log W_2/W_0$ as shown on the diagram.

By tracing these curves on Figure 3 the curves shown are obtained. This gives a family of curves showing the permissible ratio of tube heating loss to loss at continuous duty at a number of values as a function of $kT=T_r$. It will be noted that when $T=T_r$ the W/W_0 ratio$=1$. At low values of T the curves are nearly straight lines, but at large values they become curved and are not spaced as far apart as for corresponding lower values of T. A value of T is reached (63 in the curve) where no further advantage is gained by long cooling periods except for low values of demand ($T=100$ in the curve).

The above curve pertains only to actual energy loss in the tube. This can be translated into current values by plotting the corresponding current values as transformed by curve Figure 4, which gives the loss ratio between continuous rating and demand current as a function of the ratio of the corresponding currents.

Curve Figure 5 gives the rating ratio curves as a function of T_r and T for the example value of $T_c=23.1$ seconds.

Comparison of Thermal Action of Model and Ignitron

In comparing the model with the actual ignitron, the following considerations are worthy of note:

1. The temperature variation of the model finds no counterpart in any temperature assumed by any part of the ignitron which is susceptible to measurement. The nearest thing might conceivably be the equivalent temperature of the mercury vapor in the tube. Since this cannot be measured, the equations are set up so as not to make a numerical knowledge of any temperature necessary.

2. The criterion is assumed to be that no duty cycle shall impose a higher value of equivalent temperature on the tube than that determined to be safe at continuous operation. This assumption requires considerably more investigation than the authors have been able to do. However, since the action of ionic devices is very rapid, it would seem reasonable that any effect on arc back due to the equivalent temperature could act in such a short time that instantaneous values of this temperature would be critical.

Summary

The above theory suggests a method of defining the intermittent rating of an ignitron tube through the use of a so-called time constant. This method results in a smooth transition from intermittent to continuous duty ratings. It is possible to adapt the time-constant concept to the calculation of permissible ratings for more complicated duty cycles than are considered in the present paper.

The authors hope to be able, in the future, to check the actual performance of tubes against the above theory, especially at values approaching the continuous current rating.

Modern Cathode-Ray Oscillograph for Testing Lightning Arresters

E. J. WADE
ASSOCIATE AIEE

T. J. CARPENTER
ASSOCIATE AIEE

D. D. MacCARTHY
ASSOCIATE AIEE

THIS oscillograph was designed to meet the specialized needs of a group that uses the cathode-ray oscillograph as the principal tool in the study of transients in lightning-arrester development. The instrument is desirable for many purposes, especially those requiring very high writing speeds in connection with nonrepetitive transients where photographic records must be obtained. Other requirements of primary importance in the design were convenience of operation; accuracy of measurement of current, voltage, and time; accuracy of the timing; and linearity and rectilinearity of the plate pattern.

The cathode-ray oscillograph with the film in the vacuum was first described by Dufour,[1] and improvements have been described by numerous investigators such as Rogowski and his associates,[2] Burch and Whelpton,[3] Whipple,[4] Norinder,[5] to mention only a few.

General Description of the Oscillograph

The essential elements of any cathode-ray oscillograph include a cathode and anode operated in a vacuum to provide the electron beam; deflecting means; and a photographic film or fluorescent screen. The electrons from the cathode are accelerated to a high velocity by the cathode voltage, pass through an aperture in the anode, pass between the deflecting plates or coils, and impinge on the film or screen. The oscillograph described in this paper includes these elements and additional elements to make the instrument suitable for recording transients of extremely short duration. A focusing coil increases the intensity of the beam, trapping plates control its duration independently of the cathode voltage, and high-voltage circuits apply the cathode and beam-trapping voltages in the correct split-micro second sequence. An automatic regulator holds the oscillograph pressure at the desired value. The cathode voltage is held constant by a voltage regulator. These features that provide ease of control, fidelity of recording, and high writing speed are described more completely.

A view of the instrument is shown in Figure 1 and a diagram of the high-voltage circuits in Figure 6. The cold cathode is operated at 60 to 80 kv obtained from an impulse generator. The film chamber, deflection tube, and beam-trap tube are metal; both metal and glass cathode tubes have been satisfactory. The deflecting tube contains a pair of sweep plates to move the beam along the time axis and a pair of deflection plates to move the beam in a direction perpendicular to the sweep. The trap, consisting of three pairs of parallel plates, is placed between the anode and focusing coil.

Vacuum System

The vacuum system, Figure 2, was designed to maintain a pressure in the cathode tube sufficiently high to give a copious discharge, while the pressure in the remainder of the oscillograph is low enough to minimize scattering of the beam and fogging of the film.[6] This differential in pressure is provided by a controlled leak from the atmosphere to the cathode tube and by the restriction in flow of air from the cathode tube to the remainder of the oscillograph at the anode hole. The direction of air flow isolates the cathode tube from condensation-pump vapor without the necessity of a trap.

When the oscillograph is pumped down from atmospheric pressure, a rough vacuum is first obtained with the condensation pump by-passed through valve 5; valves 3 and 4 open, and valves 1 and 2 closed. To obtain a higher vacuum, valve 5 is then closed, and valves 6 and 7 are opened by a switch controlling the interlocked solenoids. The condensation-pump heater circuit and valve 5 will be opened and valves 6 and 7 closed by a flow switch if the cooling water for the condensation pump stops.

After the entire oscillograph has been evacuated to a low pressure, valve 3 is closed and valves 1 and 2 are manually adjusted to allow a gradual increase in the cathode-tube pressure. At this time, the vacuum system is switched to automatic operation with valves 3 and 4 controlled by a contact-making vacuum gauge to regulate the rate of leak to the discharge tube. Interlocked solenoids normally hold valve 3 closed and valve 4 open. When the pressure in the discharge tube has increased to the desired value because of the leak, the gauge causes the momentary opening of valve 3 and closing of valve 4, reducing the leak-chamber pressure. The ratio of expansion to leak-chamber volume is about two per cent, and the pressure in the leak chamber is much greater than in the expansion chamber so the rate of leak to the discharge tube is also reduced by about two per cent by the operation of valves 3 and 4. The vacuum gauge continues these automatic adjustments in rate of leak as frequently as is necessary, up to three times per minute, to maintain pressure in the cathode tube within a tolerance of 0.1 micron. Sudden changes in cathode-tube pressure are prevented by the smoothing action of the leak chamber.

Focusing Coil

The focusing coil has a steel shroud and pole pieces to give a short magnetic field of uniform intensity over the aperture to minimize aberration. The focusing current is held constant, independent of variation in line voltage, by a gas regulator tube. The effect of the focusing coil on the beam intensity is shown in Figure 3 by comparing the 5-millimeter width of the 1000-volt calibration line taken with the focusing coil unenergized, with the 0.5-millimeter width of the dense zero line taken with the proper focusing coil current. A fine trace can be obtained with no focusing coil provided the anode hole is very small, but this greatly reduces the writing speed.

Beam Trap

There are three pairs of cross-connected beam-trapping plates, as described by Burch and Whelpton.[3] With perfectly balanced plates, voltages insufficient to trap the beam will not deflect it. Actually it is impossible to adjust the plates perfectly; therefore, the trapping voltage is kept to a minimum during the sweeping time. Voltages in excess of about one kilovolt deflect the beam so that it cannot pass through an aperture located between the two upper pairs of trapping plates. The beam is cut off below the anode except during a relatively short interval adequate for sweeping it across the film, and conse-

E. J. WADE is research engineer, T. J. CARPENTER electrical engineer, and D. D. MACCARTHY engineer of the lightning arrester department, all of the General Electric Company, Pittsfield, Mass.

quently fogging of the film is reduced. With impulse excitation of the cathode, a beam trap is not a necessity as with continuous excitation, but it is advantageous to cut the beam off while the cathode discharge is stabilizing and after the beam has been swept across the film.

Cathode-Voltage Regulator

The charge on the capacitors of the impulse generator supplying the cathode voltage is made independent of the supplyline voltage by a regulator of the electronic type. If variation of cathode voltage is permitted, the deflection will vary as is shown in Figure 4 by the two 1,600-volt calibration lines differing by three per cent which were taken with the regulator disconnected. Two zero lines were also taken but coincide since variations in cathode voltage do not affect the position of the zero line.

Elimination of Spurious Deflection

Magnetic fields deflect the beam, but a constant field, such as that of the earth, merely affects the position of the zero axis and is not objectionable. The synchronous switch (see Figure 6) prevents random timing of the oscillograph operation with respect to the periodic variation in magnetic field from nearby 60-cycle apparatus. It prevents errors such as are shown in Figure 5 by the separation of 0.5 millimeters between two zero lines taken with the switch stopped.

The metal deflection tube in this oscillograph prevents errors such as may occur in oscillographs with glass deflection tubes due to charges transferred from the beam to the glass walls.

The deflection and sweep plates were designed and adjusted so that the deflection produced by the two sets is at right angles and is proportional to the voltage.

High-Voltage Circuits and Sequence of Operation

It would be impossible to obtain oscillograms of nonrecurrent transients of short duration without proper timing of the cathode-voltage and sweep circuits of the oscillograph, and synchronization with the transient to be studied.

A push-button control starts a sequence of operations in the high-voltage circuit of Figure 6. These operations include:

1. Charging the cathode generator.
2. Application of voltage to the cathode.
3. Trapping the beam while the cathode discharge stabilizes.
4. Sweeping the beam across the film.
5. Initiation of the impulse generator so that discharge occurs during the sweep.
6. Holding the beam off the film after the sweep is completed.
7. Grounding the high-voltage circuits.

In order to obtain constant sweeping speed, the sweep plates are operated at equal voltages of opposite polarity with respect to ground. For this reason, much of the high-voltage circuit is symmetrical with respect to ground. The operation of this circuit is best explained by considering each step in the order of occurrence.

Cathode-Generator Charging Period

Operation of the control button starts the charging of the cathode generator. The Marx circuit capacitors C_0 and the reservoir capacitor C_1 are charged to 20 kv, negative, and a positive charge of 20 kv is placed on the similar capacitors C_0' and C_1'. Simultaneously, the sweep-supply capacitors C_6 and C_6' in circuit 5 charge to equal voltages of opposite polarity through resistors R_{16} and R_{16}'. A fraction of this voltage, determined by the ratios of R_{14} to R_{15} and R_{14}' to R_{15}' in circuit 4 is applied to the sweep capacitors C_8 and C_8' to bias the cathode beam. Also a fraction of the voltage on the supply capacitor C_6 is applied to the beam-trap plates by the high-resistance potentiometer R_{22}, R_{23}, in circuit 8, compensated by capacitors C_{13}, C_{14} for fast response. Capacitor C_5 in circuit 3 is charged to 40 kv.

Application of Voltage to Cathode

When the capacitors of the cathode-voltage generator have been charged to the proper value of about 20 kv, the volt-

age regulator automatically opens the low-voltage charging circuit and releases the moving arms of the synchronous switch and the grounding contactor. The operating time of these switches is long compared with the longest sweeping time of the oscillograph. When the arms of the synchronous switch touch the middle pair of contacts, the cathode generator discharges as soon as the rotating arm reaches the closed position, which times the discharge with respect to the 60-cycle circuits. The gap G_1 discharges, and 80 kv negative is applied to the oscillograph cathode.

Gap G_2 discharges after an interval provided by the charging time of C_2 in circuit 1 for stabilization of the cathode discharge.

Initiation of the Impulse Generator

After G_2 sparks, gap G_3 is delayed by the time required to charge C_3 in circuit 2; the delay can be adjusted by the variable inductance. When G_3 sparks, an initiating impulse travels to the three-electrode gap of the generator[7] supplying the impulse to be measured. These circuits require careful adjustment to time the transient discharge to occur early in the period while the beam is crossing the film, which

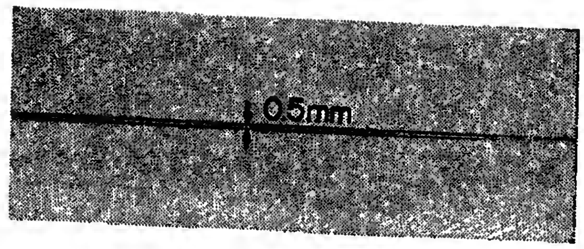

Figure 5. Effect of stray magnetic fields

Two zero lines taken with synchronous switch stopped; separation is caused by difference in instantaneous value of magnetic field from 60-cycle equipment

may be as short as 0.25 microsecond with a fast sweep.

Removal of Beam-Trap Voltage

The sparking of G_2 applies voltage to the line Z terminated by capacitor C_4 in circuit 3. This voltage disturbs the balance of voltage across the four-electrode gap S_1–S_2–S_3–S_4, which sparks and grounds electrodes S_1 and S_4 simultaneously. The capacitor C_5 discharges through R_{13} and the four-electrode gap, thus insuring low arc resistance and thorough grounding. A four-electrode switching gap, not previously used in such circuits, was necessary rather than the usual three-electrode gap. The two end gaps S_1 and S_4 must operate at equal voltages of opposite polarity to give the necessary symmetry of circuits; another electrode S_2 provides the connection to ground, and hence a fourth initiating electrode S_3 was introduced.

The points A and A' in circuit 5 are grounded by the four-electrode gap. As a result, the beam-trap voltage is removed by the compensated potentiometer in circuit 8, and the beam appears between the deflection plates, but is held at the edge of the film by the charges acquired by C_8 and C_8' during the charging period.

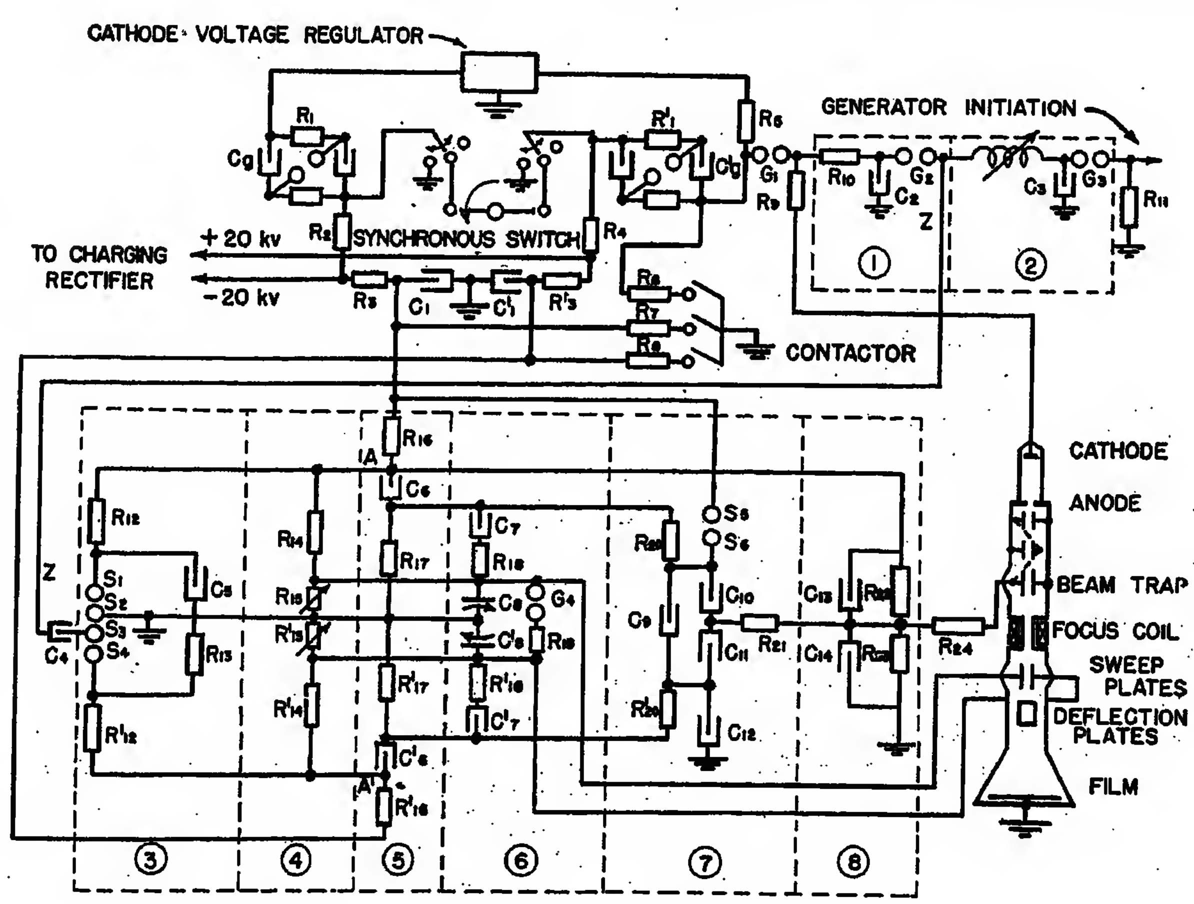

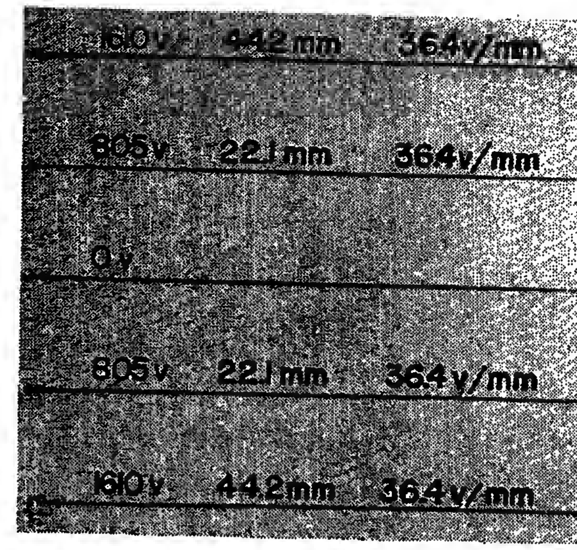

Figure 7. Consistency of deflection and absence of fogging

Five traces are superimposed on each of 5 lines. Superposition is possible because of the vacuum, cathode-voltage, and calibration-voltage regulators and the synchronous switch

Sweeping the Beam

Grounding of A and A' also puts 20 kv positive on R_{17} in circuit 5 and 20 kv negative on R_{17}' supplied from C_6 and C_6'. As a result, current flows through the blocking capacitors C_7 and C_7', resistors R_{18} and

R_{18}', and into sweep capacitors C_8 and C_8', which supply balanced positive and negative voltages to the deflection plates. This current reverses the sweep-plate bias voltage so that the beam is swept across the film. The plate voltage is limited by sparkover of G_4 after which R_{19} maintains sufficient voltage to hold the beam off the film.

Beam Cut-off

Voltage on R_{17} and R_{17}' also causes current to flow through R_{20}, C_9, R_{20}' in circuit 7 which builds up a positive voltage on S_6, while S_5 is held at 20 kv, negative, by the reservoir capacitor C_1. During the sweep when C_9 was charging, the voltage on the beam trap was unchanged, because circuit 7 is symmetrical and balanced to ground

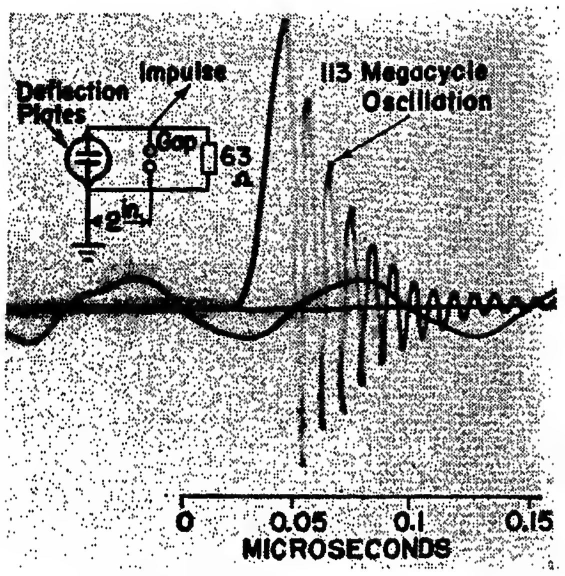

Figure 8. High writing speed

Voltage oscillation in a small circuit following gap breakdown. Timing wave is 10 megacycles; sweeping speed is 44 centimeters per microsecond and the maximum writing speed is 3,000 centimeters per microsecond

since C_{12} compensates for the capacitance of the gap S_5–S_6. After a time delay, the gap S_5–S_6 sparks, applying voltage from C_1 that unbalances the voltages on capacitors C_{10} and C_{11}. A fraction of this voltage appears on the beam trap through R_{21} and R_{24} and traps the beam.

High-Voltage Supply Grounded

The moving-contact arms of the synchronous switch have been falling continually since the holding contactor was tripped by the cathode-voltage regulator. When contact is made with the grounded stops, the cathode-generator capacitors C_g, C_g' are grounded. The grounding contactor was released also and when it closes, the other capacitors are grounded so that the operator can make adjustments in safety.

Operating Controls

Oscillator timing waves are provided by five pretuned circuits covering the range of 0.1 to 10 megacycles per second. Sweeping speeds which cross the film in 0.25 to 200 microseconds may be selected by means of a tap switch varying C_8 and C_8'. The maximum convenient sweeping speed is about 45 centimeters per microsecond. Special deflecting-plate switches change the circuits for recording the several functions such as the timing wave, calibration voltage, and impulse voltage or current. In operation, the desired conditions are set up by means of those switches, and the sequence of operations of the circuits to make the exposure is initiated by a single push button.

Performance of the Oscillograph

Several factors have been discussed that make the oscillograph free from spurious

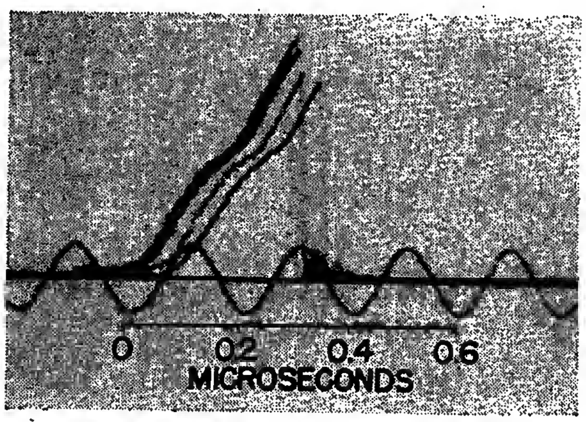

Figure 9. The consistent timing of oscillograph and generator is illustrated by 5 volt-time oscillograms of gap breakdown on one film. The variation in timing is 0.08 microsecond

deflection. Figure 7 shows a zero line and deflections due to positive and negative calibration voltages of 805 volts and 1,610 volts. This oscillogram demonstrates the accuracy and consistency of the instrument, since five separate traces were superimposed on each line without causing an appreciable increase in the width of the lines. The sensitivity was constant at 36.4 volts per millimeter for each calibration line. The 25 traces on the film have not caused fogging.

Figure 8 shows an oscillogram of a 113-megacycle oscillation in an extremely small local circuit following the breakdown of a gap. The beam crossed the film in 0.25 microsecond. The maximum writing speed on this oscillogram is about 3,000 centimeters per microsecond, which is ten per cent of the speed of light. To obtain this oscillogram, a rectangular circuit was connected directly to the deflecting plates, which provided most of the circuit capacity. The opposite side of the circuit contained a small gap that was sparked over by the impulse generator to start the oscillation. A resistor was connected in parallel with the gap to prevent deflection by voltage induced in the plate circuit previous to gap breakdown. Dividers are necessary for the measurement of high voltages and will limit the accuracy with which ultrafast transients can be recorded, rather than the writing or sweeping speeds of the oscillograph.

Comparison With Hot-Cathode Oscillograph Having Permanently Sealed Vacuum

The sealed-in high-speed oscillograph with the film outside the vacuum, on which improvements also have been reported[8,9] within recent years, occupies the position of an every-day general-purpose instrument for transient work. It is simpler in construction and operation and capably records all but the ultrafast transients for which the instrument described in this paper is especially valuable.

Conclusions

The oscillograph described should be regarded as a precision research tool capable of recording ultrafast phenomena. Due to the complexity of the circuits, the operator must use considerable care and skill to realize the best performance. The authors believe it represents marked progress in the design of ultrahigh-speed oscillographs for the measurements of transients and that several features add definitely to performance characteristics hitherto attained. During the two years in which this instrument has been in constant use, the accuracy, consistency, high writing speed, and convenience of operation have been of great benefit in the study of lightning arresters and problems of protecting insulation.

Application of Apparatus and Conductors Under Various Ambient-Temperature Conditions

R. E. HELLMUND
FELLOW AIEE (Deceased)

P. H. McAULEY
ASSOCIATE AIEE

Synopsis: Various electrical standards are reviewed from the viewpoint of the selection and interpretation of ambient temperature values. Equivalent aging temperatures for insulation have been calculated from recorded ambient temperature data for several typical outdoor and indoor locations. From these the suitability of ambient values now used for the establishment of temperature rises for rating purposes is discussed. These values seem to be well chosen, but some clarification in meaning and in methods of using them for rating and application purposes is desirable. For apparatus rated on a 40 degrees centigrade ambient basis, appreciable margins in permissible temperature rise exist under many conditions and for many places of application. Permissible increases in loading for certain motors without exceeding conservative hot-spot temperatures are suggested, subject to the limitations imposed by other operating considerations.

Standards for Electrical Apparatus

THE permissible temperature rises for rating purposes given in various commercial standards for apparatus and conductors were obtained by considering the maximum continuous temperatures for insulation and selecting certain values of ambient temperature. The ambient values most commonly used are:

40 degrees centigrade—For commercial standards for the majority of all electrical apparatus and for some cable-rating purposes.

30 degrees centigrade—For commercial standards for wires and cables and, with qualifying statements, for the newly proposed standard for transformers.

25 degrees centigrade—For standards for rotating apparatus on electrical vehicles and in some Underwriters' regulations.

50 degrees centigrade—For standards for marine apparatus for which 40 degrees centigrade is not considered adequate.

Generally speaking, these values are well chosen for the various cases indicated, but there is some inconsistency between the wording of the standards and the methods and generally accepted theory of applying apparatus. Some standards simply specify that apparatus will have the proper rating when the temperature of the cooling medium does not exceed 40 degrees centigrade. In at least one case the statement "at no time exceeds 40 degrees centigrade" is used. In others 40 degrees centigrade is specified as the limiting ambient temperature of the cooling air or other gases, with a supplementary statement that the ambient temperature in locations where electrical apparatus is operated in the United States rarely exceeds 40 degrees centigrade. There is a general impression that 40 degrees centigrade is exceeded in only a few locations, but this is not confirmed by actual records. Weather bureau statistics show that outdoor temperatures have at times exceeded 40 degrees centigrade in 30 out of 60 stations.[3] Thus, in indoor applications, where considerable heat is generated by losses in large electrical apparatus, heat engines, steam pipes, and industrial heating equipment, 40 degrees centigrade will at times be exceeded in a large number of applications. However, the total percentage of time during which 40 degrees centigrade is exceeded is as a rule very low, not more than 0.5 per cent for most outdoor locations and a somewhat higher percentage for some indoor locations. Nevertheless, with a strict interpretation of the statement that the cooling medium must not exceed 40 degrees centigrade, a large percentage of applications would have to be considered as special. In actual practice, standard apparatus having a temperature-rise rating based on a 40 degrees centigrade ambient is actually applied more or less indiscriminately with success in all but unusually hot locations. This is to be expected in the light of various investigations on the life of insulation, which have shown conclusively that life or rate of deterioration is dependent upon both time and temperature.

Since the temperature-rise rating presumes continuous operation at the standard ambient temperature, it may be expected that satisfactory life of insulation at rated load will be obtained when this ambient temperature is maintained continuously. If this is true, it follows directly from these investigations on the life of insulation that equal life will be obtained in spite of short periods at temperatures above 40 degrees centigrade, if values below 40 degrees prevail for the greater part of the time. This is the condition found nearly everywhere in practice; ambient temperatures usually vary over wide ranges and include values below 40 degrees centigrade for most of the time.

On the basis that a continuous ambient is used for rating purposes, it is merely necessary to make sure that the prevailing ambient temperatures, which vary continually in practice, are equivalent in their aging effects to this standard value. This will result in the most effective application of apparatus.. A method of determining the aging temperature equivalent to any given varying temperature is available in the eight degrees centigrade rule,[1,2] which states that the aging effect of temperature doubles for each eight degrees increase in temperature. This eight degrees centigrade rule is not a precise law and cannot be applied indiscriminately for all insulation, but it does serve as a useful guide for analytical purposes.

Equivalent Aging Temperatures

The use of the eight degrees centigrade rule is illustrated in Figure 1. Curve *A* was obtained from available outdoor temperature records for Dallas, Tex. It shows the percentage of time during which certain temperature values were exceeded. To obtain corresponding machine temperatures, the hot-spot temperature rise

of 65 degrees centigrade permissible for many forms of class-*A* insulation is added to curve *A*, giving curve *B*. By using the eight degrees centigrade rule, it is possible to calculate a constant temperature *D* (appendix II) which has the same effect in deteriorating insulation as curve *B*. By subtracting 65 degrees centigrade from *D*, the value *C* is obtained. This is a single value equivalent to the ambient temperature curve *A*. The validity of this operation depends, of course, on the empirical eight degrees centigrade rule, but its application is conservative. It is assumed that the insulation temperature follows changes in ambient temperature exactly. Actually, insulation temperatures lag and the effect of the higher ambient temperatures is somewhat less than curve *B* indicates.

Dallas is one of the hottest places in the country. Although the maximum temperature exceeds 40 degrees centigrade, the equivalent yearly outdoor temperature is only 22 degrees. Figure 2 shows

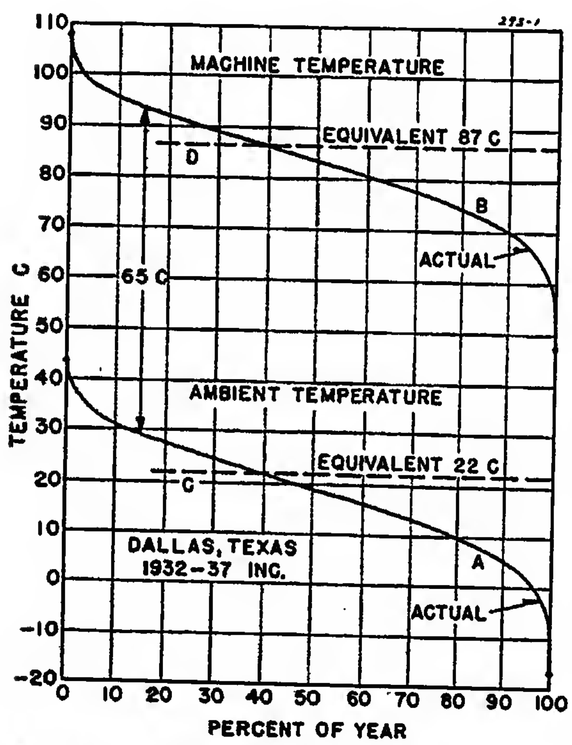

Figure 1. Actual and equivalent ambient and machine temperatures for outdoor locations in Dallas, Tex., 1932–37 inclusive

curves and values for other locations and the equivalent temperatures are from 12 to 22 degrees centigrade. Therefore, outdoor apparatus can be safely applied almost anywhere if the standard temperature rises are based on an ambient of 25 degrees centigrade. However, a further assumption that heat from sun radiation can be neglected is necessary. It has been shown that this assumption is correct in most cases, because wind velocities nearly always existing outdoors, though rather low, compensate for sun radiation. There are a few exceptions to this, such as meters or transformers mounted in well-protected corners of buildings and subject to considerable sun exposure, the influence of which may then at times be appreciable.

Most types of electrical apparatus are at times located indoors and the consideration of outdoor temperatures is in itself of restricted value. However, it is useful as a basis for the study of indoor temperatures for which no comprehensive statistics are available or likely to be available in the near future. Therefore, a logical method is to use outdoor statistics and make tests on the differences between outdoor and indoor temperatures for a limited number of typical indoor locations.

In buildings heated for human comfort, a more or less constant temperature is maintained during the cooler seasons of the year. A constant value of 25 degrees centigrade represents the higher limit of temperatures prevailing during the heating period. At other times it might be assumed that the indoor temperature can be maintained the same as the outdoor temperature in a substantial ideally ventilated building. In practice there are, however, a number of factors tending to increase indoor temperatures even when no appreciable amounts of heat are generated inside. These factors are: heat from occupants and lighting fixtures, the poor heat exchange generally given by open windows, the fact that windows are kept closed a part or all of the time, and, finally, heat caused by sun radiation.

Figure 3 shows simultaneous outdoor and indoor records taken in an office in a substantially built modern office building having northwestern exposure with sun radiation through the windows only after 5 p.m. At the end of the office hours, about 5 p.m., the windows are closed and night temperatures are appreciably higher indoors. During the second day shown it was cloudy after 5 o'clock, and the maximum temperature was only slightly higher indoors. In contrast, the marked influence of the late afternoon sun appeared during the third day, resulting in a difference of 5.6 degrees centigrade (ten degrees Fahrenheit) at 6:30 p.m. Similarly the influence of sun exposure with closed windows, as may be found in unoccupied storerooms and similar places with southern exposure, can be appreciable. The high peak on the first day indicated in Figure 3 was caused by the recording instrument being directly exposed to the sun. The effect is quite marked, although the instrument case is light in color and ventilated. If apparatus with dark heat-absorbing surfaces is subjected to sun radiation through windows, the effect may be quite marked because of the lack of compensating outdoor breezes.

Similar records have been obtained in a powerhouse basement and a factory building. The powerhouse basement was without windows and poorly ventilated, but the recorder was at least ten feet from direct heat sources such as steam pipes. The factory building was a single-story structure, with a covering of boards plus sheet iron on the walls and paper on the roof. Several small ovens operating at temperatures up to 175 degrees centigrade were located in the vicinity of the thermometer. It was placed near the south windows as well, which resulted in considerable influence from sun radiation.

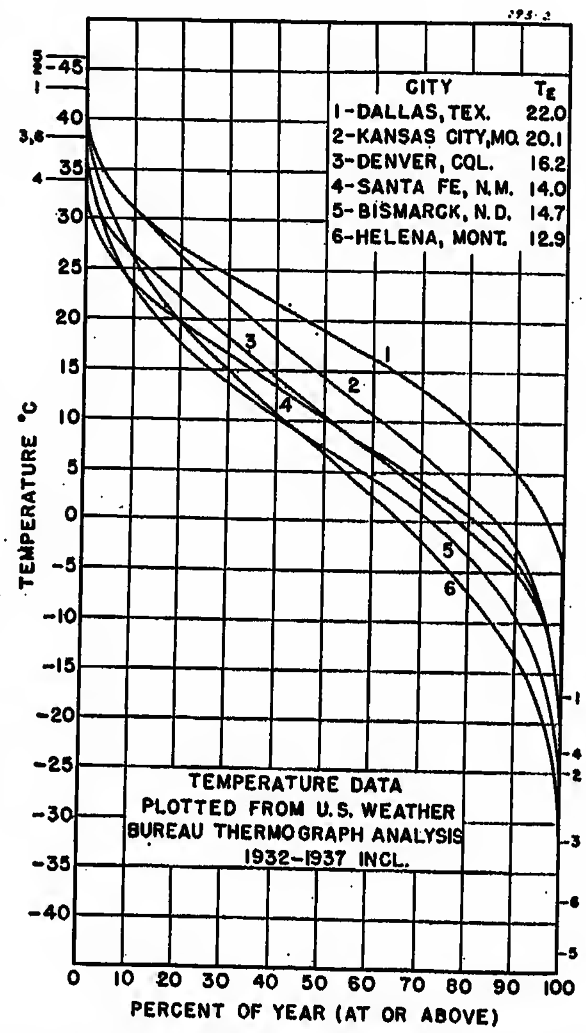

Figure 2. Actual and equivalent outdoor ambient temperatures for six cities of the United States

From these tests the curves of Figure 4 have been estimated for certain indoor conditions and the equivalent ambient temperatures calculated. The tests covered only a 100-day period in midsummer, but the data have been adjusted to an annual basis compared to the outdoor curve for the period of test and then applied to the Dallas outdoor curve. A constant indoor temperature of 25 degrees centigrade has been assumed when lower temperatures prevailed outdoors. Figure 5 shows the same procedure applied to the outdoor curve above 25 degrees centigrade for Bismarck, N. D. This is one of the hotter locations in the northern section of the United States, as divided in Figure 2 of AIEE Standard No. 1.[3] Although maximum temperatures are high, they do not persist as in more southern climates, and

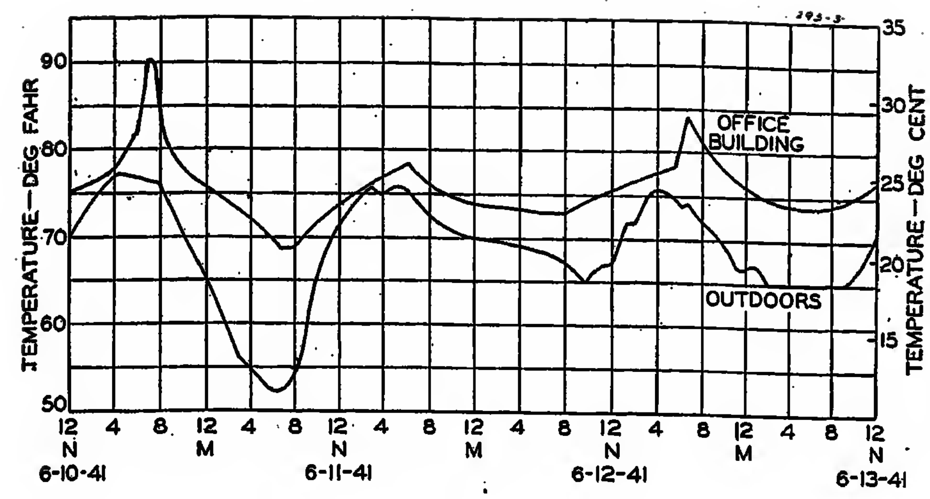

Figure 3. Recorded temperatures outdoors and in a modern office building at East Pittsburgh

equivalent aging temperatures are correspondingly lower than in Dallas. The equivalent aging temperatures for these selected locations in Dallas and Bismarck lie between 25 and 32 degrees centigrade for the most part, with the Dallas powerhouse 36.5 degrees centigrade. In the latter case, even with a 25 degrees centigrade minimum temperature, 30 degrees exceeded most of the time, and 40 degrees exceeded 20 per cent of the time, the equivalent temperature is still well within the 40-degree standard. In practice all sorts of variations will be encountered in individual applications, but for either locality it seems that, regardless of high maximum temperatures, equivalent aging temperatures as high as 40 degrees centigrade are likely to be found only under very unusual circumstances. Since Dallas is one of the hotter places in the country this statement may be applied to apparatus locations in buildings generally.

Figure 5 seems to indicate that, except with a great deal of heat generated and poor ventilation, the equivalent aging temperature will rarely exceed 27 degrees centigrade for large sections of the country. This applies particularly to many highly industrialized sections of the United States. Moreover, the 27 degrees centigrade value is based on the assumption that indoor winter temperatures are 25 degrees. Actually, the temperatures maintained in industrial establishments in winter are nearer 20 degrees centigrade, which results in equivalent aging temperatures for the year certainly no greater than 25 degrees.

Enclosures and Buildings

The inside temperatures of enclosures provided for the specific purpose of housing electrical apparatus are usually higher than the outside. In relatively small enclosures with restricted ventilation, such as steel cubicles for switch-gear, a distinction is made between inside and outside ambient temperatures. Extreme differences have of course been encountered when the enclosure had no ventilation. These conditions require special consideration in each case. On the other hand, when apparatus is enclosed in a regular building, the temperature in the building is considered the ambient temperature for the apparatus.

In this connection some interesting tests have been reported on an indoor transformer installation.[4] A ventilated building about 18 by 25 feet and 24 feet high housed three power transformers. In Figure 6 the heaviest lines represent the outline of the building, with cooling air flow indicated by the arrows. Figure 6a shows isothermal lines midway between two transformers, and Figure 6b shows the isothermal lines for a section through the center line of a transformer. The numbers given on the lines indicate the difference between outside and inside temperatures. The average temperature in the building is about eight degrees centigrade above the outdoor temperature. In the case of Dallas this would give an equivalent temperature of about 30 degrees centigrade. However, the lines above the transformer show an excess of 11 to 15 degrees centigrade over outside temperature. Applied to the Dallas equivalent temperature of 22 degrees centigrade, this gives ambient values of 33 to 37 degrees. If auxiliary apparatus were installed above the transformers, it would be operating under these ambient conditions. This conclusion is made under the assumption that the building is fully ventilated at all times; however, the ventilation may be restricted in cooler seasons of the year, resulting in equivalent ambient temperatures of 35 to 40 degrees centigrade at points above the transformers. It is believed that this general situation is frequently found in buildings housing electrical apparatus.

A somewhat different case is an industrial building subject to considerable sun radiation or other heat sources. Temperatures in the upper regions of the building, where some types of apparatus

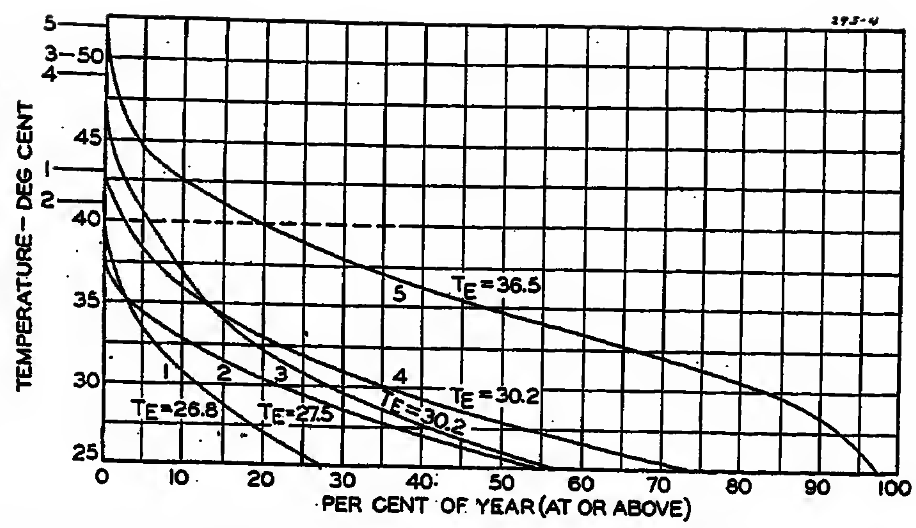

Figure 4. Estimated prevailing and equivalent ambient temperatures for typical locations in Dallas, Tex.

1. Outdoors 1932–37 inclusive—above 25 degrees centigrade

3. Office building—southern exposure—closed windows
4. Building with industrial heat sources—thin walls
5. Powerhouse—poorly ventilated area

may be installed, may be appreciably higher than in the lower parts where temperatures usually are measured. Although some of the previous cases derived from tests do not show equivalent ambient temperatures in excess of 35 degrees centigrade, equivalent temperatures close to 40 degrees may be expected in some parts of many buildings. The short-time maximum temperature in such locations is likely to be 50 to 60 degrees centigrade.

Preferred Standard Ambient Temperatures

From these studies, the suitability of the ambient temperature values used for temperature-rise standardization purposes can be considered. For maximum simplicity in the application of apparatus, the ambient temperature of 40 degrees centigrade has been well chosen. The temperature conditions for the very small percentage of cases where apparatus so standardized cannot be safely applied are so unusual that they will be readily recognized. (An equivalent temperature of 40 degrees centigrade usually permits occasional maximum values of 50 to 60 degrees; consequently, misapplications are easily avoided.)

On the other hand, it might be contended that 40 degrees centigrade is contrary to maximum economy, because in a large percentage of applications equivalent ambient values of 30 to 35 degrees are not exceeded. The question of what would be gained by using 35 degrees centigrade as a

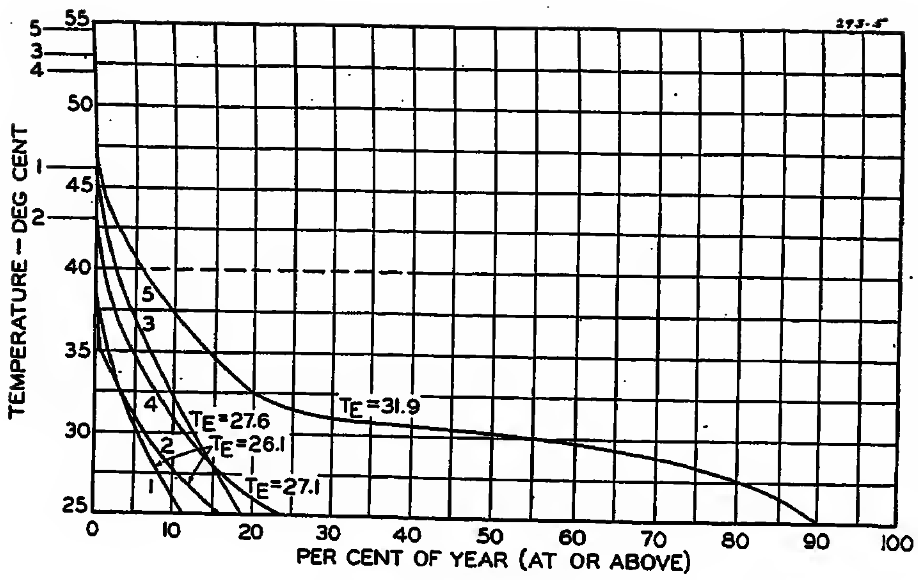

Figure 5. Estimated prevailing and equivalent ambient temperatures for typical locations in Bismarck, N. D.

4. Building with industrial heat sources—thin walls
5. Powerhouse—Poorly ventilated area

basic ambient value might therefore arise. It would permit hot-spot temperature rises[3] of 70 instead of 65 degrees centigrade for class-*A* insulation, and 95 instead of 90 degrees for class-*B* insulation, gains of 7.7 and 5.6 per cent respectively. With apparatus having chiefly copper losses, this means increases in rating of only 3.9 and 2.8 per cent respectively; with apparatus having both iron and copper losses, gains of 7 and 5 per cent might be realized.

For these gains it seems wrong to sacrifice the present satisfactory situation which permits almost indiscriminate application of standard apparatus drawn from storerooms all over the country. A great deal of this apparatus has line-voltage magnet coils, and adjustment of the load to suit special ambient temperature conditions is not possible; the same is true with motors permanently built into or connected to driven machines. In these cases special apparatus would be required, if the temperature rating of standard apparatus were not based on a sufficiently high and universally applicable ambient temperature. The cost probably would more than balance any economic gain from a lower ambient as a basis for standard apparatus. It is of course possible to load certain machines somewhat below their normal rating, if the ambient temperature is higher than that used as a basis for the rating; however, it is just as easy to apply a machine to a somewhat higher load, if its rating is based on 40 degrees centigrade, and it is used in a locality with a lower equivalent ambient value.

Considering further that there are certain inaccuracies in the eight degrees centigrade rule used as a basis for this study, and that there is usually not much known about the temperature conditions for many applications, it certainly seems advisable to retain the margin of safety and the simplicity afforded by the use of 40 degrees centigrade as an ambient value for general purposes. A further reason for adhering to this value is that frequently apparatus is installed under conditions which interfere with proper ventilation.

In Figure 7, curve *A* has been estimated to show the percentage of all apparatus that can be applied without special consideration for temperature-rise ratings based on different standard ambient temperatures. In the absence of extensive statistical data no claims can be made for the accuracy of the curve. It does illustrate the basic considerations involved and the greater applicability of stock apparatus, the higher the standard ambient temperature on which ratings are based.

In spite of the advantage of the 40 degrees centigrade value for general use, it must be admitted that the use of lower values such as 30, or even 25 degrees, is justified where some conditions of application or economic considerations apply. One such case is rubber-insulated wire, some varieties of which are suitable for a continuous maximum temperature of only 50 degrees centigrade. The permissible rise is 20 degrees centigrade with an ambient temperature of 30 degrees, and only 10 degrees with an ambient of 40 degrees; in other words, the increase of rating possible with 30 degrees is 41 per cent. The greater part of this wire is used in places where an equivalent temperature of 30 degrees centigrade is not exceeded. This is roughly illustrated by curve *B* of Figure 7. (The eight degree centigrade rule may not apply to rubber-insulated wire, and curve *B* may not be quantitatively correct.) It follows that the sacrifice in economy resulting from an ambient of 40 degrees centigrade for this wire is entirely too great for the advantages gained thereby. This is especially true, because in the few locations where higher temperatures prevail, standard wire can be used merely by reducing the rating. Hence, the storeroom problem, which would complicate the situation in connection with many other types of apparatus, is of no particular importance. On the whole, it seems that ratings for rubber-covered wire based on a standard ambient of 30 degrees centigrade are well justified.

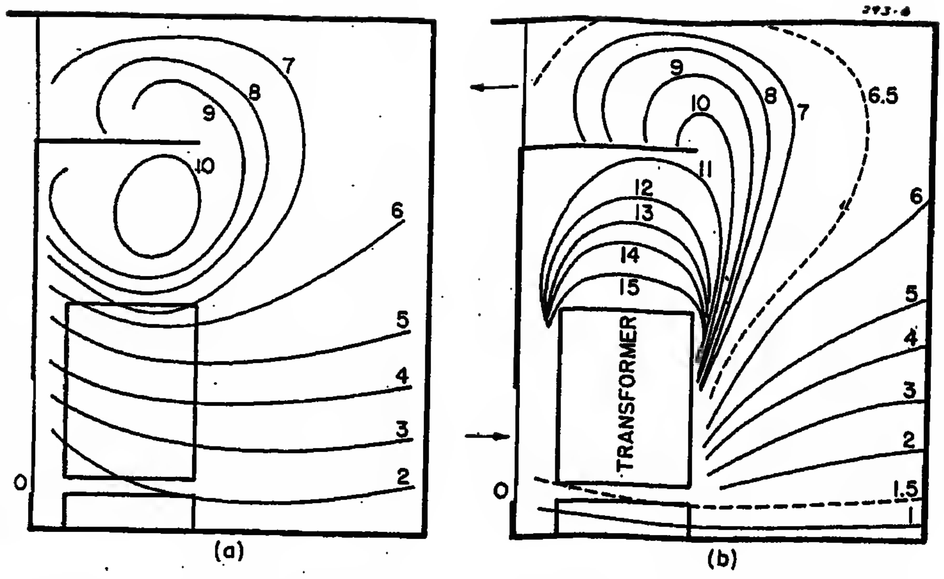

Figure 6. Isothermal lines around a large transformer in a ventilated enclosure

(*a*) Between two transformer units
(*b*) About the center line of one unit

Another case of interest is that of transformers. Curve *C* has been estimated as applying to transformers and shows approximately the percentage of transformers which can be applied on a 30-degree centigrade basis; this percentage is high because most transformers are located outside. A rather small percentage of 30 degrees centigrade transformers require special consideration in their application. Also, since transformers are nearly always applied by engineers fully familiar with all the problems involved, ratings based on a 30 degrees centigrade ambient seem well justified. (The proposed transformer standards specify that nominal rating can be used if the average temperature during any 24 hours does not exceed 30 degrees centigrade, with a maximum of 40 degrees, which gives a continuous hot-spot temperature of 95 degrees. This provision in itself will result in an equivalent value somewhat in excess of 30 degrees centigrade for the 24-hour period, as here developed. However, since there will be only a few days during the year with such high temperatures, it is estimated that the provisions in the transformer standards are about the same as an equivalent temperature of 30 degrees centigrade or less.)

Curve *D* applies to rotating apparatus for electric vehicles. In view of the necessity to keep weight to a minimum, and because such apparatus is nearly always outdoors, the present practice of a 25 degree centigrade standard ambient is justified. For the sake of maximum simplicity in the standard structure, a value of 30 degrees centigrade for railway work seems preferable and would hardly interfere with maximum economy. The five degree centigrade difference represents a very small percentage of the customary temperature rises in this type of apparatus.

There are other cases where a standard ambient temperature of 30 degrees centigrade would be justified. For example, some domestic or office appliances are used almost exclusively in locations where an equivalent temperature of 30 degrees centigrade is not exceeded while the devices are in use. There are practically no homes or offices in which the equivalent temperature exceeds 30 degrees centigrade while occupied. Even if higher temperatures prevail when windows are closed, this is of no particular importance because the devices are not then loaded and will not overheat.

Therefore, considering both simplicity and economy, it seems well to retain the 40 degrees centigrade value but to recognize that a 30-degree value is justified for some apparatus and applications. It will of course also be necessary to use the 50 degree centigrade value for those few locations, such as holds of ships, where 40 degrees is not sufficient. An even higher standard ambient value may be necessary in special cases.

The previous considerations all are based on the deterioration of the conventional insulating materials, with the idea of assuring satisfactory life of apparatus from that point of view. The influence of temperature conditions on the oxidation and operation of contact surfaces or upon the operation of electronic devices and other types of apparatus may, of course, be subject to different laws and thus require separate consideration. Very few quantitative data seem to be available for such studies, but AIEE standards co-ordinating committee 7 is working on these problems. Regardless of the results, it would seem best to use the same basic ambient values for standardization purposes, with the understanding that satisfactory results are obtained if these ambient temperatures are maintained continuously. Any difference between the characteristics of other types of apparatus and ordinary electromagnetic apparatus can be taken care of in the methods of application.

Conclusions

Ambient temperature values equivalent to the continually changing temperatures encountered in practice have been derived for various localities. From these data it is concluded that the standard ambient temperature values selected for use in establishing temperature rises for rating purposes in the various standards are, in general, sound. It is suggested, however, that some clarification in meaning and in methods of using these selected values for rating purposes is desirable.

The data also show that for apparatus rated on a continuous 40 degree centigrade ambient basis, certain margins in temperature rise exist under many conditions and for many places of application. Recognition of this situation is particularly valuable at this time, when it is often necessary to increase loads on industrial equipment. Under these rating conditions an equivalent ambient temperature of 25 degrees centigrade may permit overloads which increase operating temperature-rises by 15 degrees without exceeding permissible hot-spot temperatures, when this is compatible with other operating considerations.

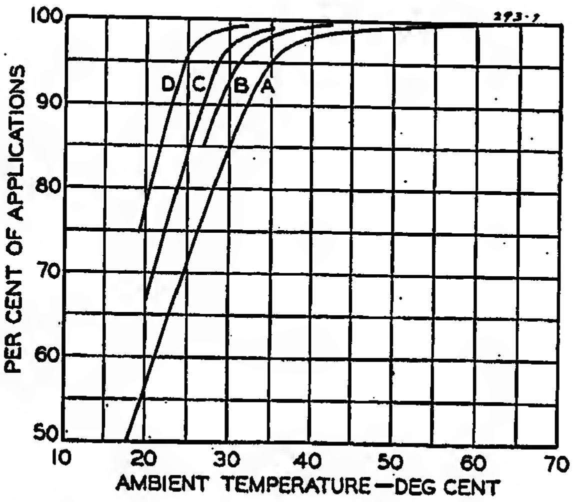

Figure 7. Estimated curves for different apparatus applications, showing the percentage of applications for which standard apparatus based on different ambient temperatures is suitable

A. General
B. Cables
C. Transformers
D. Railway apparatus

Apparatus ratings primarily are based on a continuous hot-spot temperature of 105 degrees centigrade for class-*A* insulation, although transformer standards specify 95 degrees. At times doubt has been expressed that the 105 degrees centigrade temperature will give satisfactory life of insulation, since laboratory tests have demonstrated loss in mechanical strength of materials continuously subjected to 105 degrees. On the other hand, hot spots in many machines occur in slots where the insulation is well supported and where some loss of mechanical strength can be tolerated. Extensive trials on actual machines at 105 degrees centigrade for long periods have shown very satisfactory life.

To eliminate this doubtful point, it can be assumed that the equivalent hot-spot temperature should not exceed 100 degrees centigrade. This takes advantage of only ten of the 15-degree margin and gives a permissible temperature-rise of 75 instead of 65 degrees, or an increase of 15.4 per cent. For general-purpose motors based on a 40 degree centigrade temperature-rise by thermometer, an extra ten degrees is available, permitting an increase in this case of 36.5 per cent. (Actually, the service factor for these machines requires the ability to carry a 15 per-cent overload with a 40 degree centigrade ambient maintained continuously.) Table I shows permissible increases in loads for motors, considering temperature only and taking advantage of these temperature-rise increases of 36.5 and 15.4 per cent. With the total losses increased by these percentages, permissible increases in copper losses are given in columns 3 and 5. Columns 4 and 6 show the increases in currents corresponding to these copper losses.

Table I. Permissible Per-Cent Increases in Motor Losses and Currents for 100C Hot-Spot Temperatures at 25C Ambient

Assumed Loss Distribution		General Purpose 40C Rise by Thermometer		Ratings Based on 50C Rise by Thermometer	
Iron	Copper	Copper Loss	Current	Copper Loss	Current
0.25	0.75	49	22	20.5	10
0.35	0.65	56	25	25.5	12
0.50	0.50	73	31.5	31	14.5

Since hot-spot temperatures are not directly proportional to total losses but depend also upon distribution of losses between copper and iron, these figures may be somewhat optimistic. It does appear reasonably safe, however, to increase currents on 50-degree-rise machines by 8 to 13 per cent and on general-purpose 40-degree-rise machines by 20 to 30 per cent under the conditions stated. For induction motors torque usually increases somewhat faster than the current. It is assumed, of course, that operation is at rated voltage. If operation is not at rated voltage, part of the margin indicated may not be available for increased loads.

Furthermore, this paper deals only with the effect of temperature on the aging of electrical insulation. There are other factors that should be considered when con-

templating placing an overload upon a rotating machine.[5] Mechanical strength of shafts, bearings and couplings, commutators, lubrication, and so forth, must be recognized as limiting factors also and should receive due consideration. Furthermore, utilizing these temperature margins may reduce insulation life from that commonly obtained under operation at substandard temperatures.

Unfortunately, simple conclusions covering all conditions encountered in practice are not possible, but it is hoped the data presented will be of assistance in determining increased loads for existing machines and apparatus in this time of emergency. Also, the statistical data of AIEE Standard No. 1 should be helpful in determining the localities where prevailing ambient temperatures might make increased loading of equipment possible.

Although the data given here are primarily intended to be helpful under present emergency conditions, it is also hoped that the views presented will be convincing evidence of the futility of suggestions for the use of a great variety of ambient temperature values and departures from standard temperature-rises in commercial transactions. Certain variations in ambient temperatures always will occur but wide confusion would result from attempts to reflect these into the system of rating apparatus.

Appendix I. Ambient Temperature Specifications in Standards

(The wording referring to ambient temperature in the different standards is far from uniform. The letters in these data indicate certain general classifications but do not cover all the variations in wording even where no distinctions in meaning are intended. Furthermore, where apparatus may be water-cooled, supplementary statements are given.)

General Classification

A. Equipment conforming with these standards shall be suitable for carrying the rated load when and where the ambient air temperature at the equipment does not exceed ——C.

B. Apparatus conforming with these standards shall be suitable for operation at the standard rating when and where the temperature of the cooling medium does not exceed ——C.

C. Apparatus bushings conforming to these standards shall be suitable for operation at their standard ratings when and where the temperature of the external cooling medium does not exceed 40C maximum or 30C average for any 24-hour period.

D. Apparatus conforming to these standards shall be suitable for operation at rated load with rated secondary voltage, provided the temperature of the cooling air at no time exceeds 40C, and the average temperature of the cooling air during any 24-hour period does not exceed 30C.

E. The standard ambient temperature of reference when the cooling medium is air shall be 40C.

F. The standard ambient temperature shall be 24C.

G. It is assumed that the ambient temperature will be ordinarily about ——C.

H. The temperatures given in these requirements are based on a room temperature of 25C.

I. The tests shall be conducted with the switch at room temperature, preferably 24C.

J. Capacities are based on room temperature of 30C.

Appendix II. Calculation of Equivalent Aging Temperature by Eight Degree Centigrade Rule

The continuous temperature equivalent to a given temperature distribution curve for a period of time is calculated by dividing the curve into convenient trapezoids or rectangles and applying equations 1 and 2.

$$A = t_0 \frac{(e^{KT_2} - e^{KT_1})}{K(T_2 - T_1)} \text{ for a trapezoid} \tag{1}$$

$$A = t_0 e^{KT} \text{ for a rectangle} \tag{2}$$

A = aging units

t_0 = time in convenient units (hours or per cent)

$e = 2.718 \qquad K = 0.0865$

T_2 = maximum temperature of trapezoid in degrees centigrade

T_1 = minimum temperature of trapezoid in degrees centigrade

T = constant temperature of rectangle in degrees centigrade

The aging units for all the sections of the curve are added, and equation 2 is applied to this sum for the total time involved. Solving for T gives the equivalent aging temperature for the curve.

With $K = 0.0865$ the aging units are doubled for an eight degrees centigrade increase in temperature.

Effect of Lightning on Thin Metal Surfaces

K. B. McEACHRON

Synopsis: In the search for means for measuring the properties of natural lightning much can be learned from the evidence left at points struck by lightning. This paper deals principally with such evidence and the process of evaluating the characteristics of the lightning strokes responsible for the evidence.

For six years a nickel-plated, 18-inch copper sphere, 878 feet above the ground atop the WSM radiator at Nashville, had been collecting data in the form of holes and pits due to lightning strokes to the sphere. A total of 150 holes of varying sizes were found together with 300 pits. A laboratory setup was made consisting of the high-capacity impulse generator together with a d-c generator so arranged that the known characteristics of lightning with respect to the so-called continuing current could be duplicated. With this equipment holes having the same appearance could be produced in copper sheets, and from the results of the test a calibration curve was produced. At the same time calibration curves were obtained for other metals in addition to copper. From these data an expectancy curve was obtained between coulombs and per cent of holes. The average hole corresponded to 15 coulombs while the maximum size hole corresponded to 240 coulombs.

No satisfactory calibration was obtained for the pits, many of which no doubt were the result of high current peaks having a low coulomb content.

It is interesting to learn that of the 150 holes in the sphere 89 were found in the upper half and 61 in the lower half, with the great majority appearing in a six-inch belt around the seam at the sphere's equator.

The results of some laboratory high-current impulses on metal sheets are also shown, indicating pressure effects without appreciable burning.

A lightning stroke to a metal-roofed rural home is described, the largest hole in the roof indicating a charge of 210 coulombs. The home was not wired, but a part of the lightning discharge traveled a distance of 162 feet to the wired house next door to puncture the cellar wall and contact the neutral ground rod driven in the cellar. Another channel was found extending to the base of the service pole where two ground rods were driven. It was estimated that the discharge removed approximately 250 cubic feet of earth in its travel. Available data indicate the stroke was negative and had a total charge of more than 240 coulombs with a suggested peak current of the order of 200,000 amperes. Although the struck home was quite badly damaged, there was no fire, nor was there any trouble with the electric equipment in the wired home.

The results of this work indicate that sheet metal may be made to yield certain data of value with reference to lightning.

LIGHTNING strokes to objects on the earth have been characterized by two major effects[1–4] one causing explosive effects[5,6] and the other often resulting in fire. In many cases both effects have been present. The explosive effects are now known to be due to sudden increases in current which may reach a crest of several thousand or even a hundred thousand amperes or more in a few millionths of a second, decaying to half of the crest value in a time of the order of 40 microseconds. It is the expansion effects in the air resulting from these rapid current changes which cause the thunder which we hear. The burning effects are the result of the flow of current of relatively low magnitude of the general order of 200 or 300 amperes[7] for times which may be as long as 1.5 seconds, but on the average, persist for about 0.3 second or about 7,000 times as long as the average time to half value of the current peak. Correlating photographic and oscillographic data for strokes to the Empire State building having a height of 1,275 feet, strokes began at the building in about 80 per cent of the cases. As the height of the earth object becomes less, the percentage of cloud-initiated strokes increases. It is believed that for transmission-line heights the contacting strokes are always cloud initiated. Currents in earth-initiated strokes measured at the earth end begin with a relatively small value of current—a few hundred amperes—which develop into a continuing current when contact is made with the cloud. Superimposed current peaks may develop later, with varying time intervals and magnitudes, all of these peaks being cloud-initiated just as in the case of the stroke to objects of ordinary height on the earth's surface.

Laboratory Lightning

The impulsive nature of lightning strokes has been known for a long time, and it was natural to consider the cloud as one pole of a condenser and the earth as the other. Thus the laboratory lightning maker noted the similarity between the discharge of a charged laboratory capacitor and natural lightning. It looked the same, and the sound effects were there also. Furthermore, wood could be blown apart as in nature, and many of the distance–time–voltage or current phenomena found in connection with the operation of outdoor circuits could be reproduced. And so with the development of the Marx-circuit impulse generator and the cathode-ray oscillograph, data became available proving the similitude of the laboratory and the natural lightning as to the nature of the phenomena involved.

The continuing part of the natural lightning stroke was not simulated, as its existence was not shown oscillographically until 1937. The lack of knowledge of this component explains the inability of investigators to make the lightning fulgurites found in nature when discharging a lightning generator into wet sand. The impulsive nature of the current blew the

Paper 42-104, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 10, 1942; made available for printing April 11, 1942.

K. B. McEachron is research engineer, high-voltage practice and designing engineer, power transformer engineering department, and J. H. Hagenguth is electrical engineer, both with General Electric Company, Pittsfield, Mass.

The authors acknowledge the assistance of A. F. Rohlfs, C. R. Craig, and W. C. Lasher, and the personnel of the high-voltage engineering laboratory for obtaining the test data.

Figure 2. Side view of lightning-damaged 18-inch nickel-plated copper sphere installed for six years at top of WSM vertical radiator 878 feet above ground

sand out of the container, and it was not until currents of a few amperes were used, continuing for a second or so, that fulgurites could be formed.

The charge represented by the current peak is very small indeed. The average measured in natural lightning is only a fraction of a coulomb, whereas the charge represented by the continuing current may be of the order of 200 coulombs or more. Even very large impulse generators with voltages suitable for general testing work will have a charge of considerably less than ten coulombs. It is clear, therefore, that to simulate the complete lightning stroke a generator of more than 20 times the present capacity is needed, and therefore it is necessary as an economic expedient to make use of generators such as illustrated in Figure 1, where the discharge is initiated by a high capacitance generator, with a follow current supplied by a 500-volt d-c generator. Such an arrangement, though not suitable for long arcs, was quite satisfactory for the tests on metal sheets described in this paper. Modifications of this circuit have been used during other long-duration lightning current tests. More than one high current impulse may be superimposed using a circuit of this general character.

Lightning Strokes to Sphere at WSM

Our interest in the use of thin metal as a means of collecting lightning data was aroused when William Montgomery, Jr., engineer for WSM radio station of the National Life and Accident Insurance Company at Nashville, Tenn., sent us the sphere illustrated in Figure 2. This nickel-plated, 18-inch diameter sphere made of 19-mil copper had been in service at the top of WSM's vertical radiator, 878 feet in height, for a period of six years. During that time it was struck frequently by lightning and in the summer of 1937 was thrown to the ground during a lightning storm which damaged the tuning coil at the base of the tower as shown in Figure 3. The sphere was damaged in its fall on the reverse side but had been mounted in the position shown in Figure 2.

The large number and varying size of holes and pits found indicated that the sphere could be made to tell a story about lightning strokes if a proper calibration for the holes could be found. The globules of copper found around many of the holes indicated clearly that the holes were produced by continuing currents rather than by current peaks, which would have produced sufficient pressure in many cases to have blown the molten metal away.

Tests were begun, therefore, with the circuit shown in Figure 1, using a variety of current and time values until the appearance of the holes produced corresponded closely to those found on the WSM sphere. A few of the test holes are reproduced in Figure 4. A calibration curve is shown in Figure 5 together with a similar curve for galvanized iron. All tests were made with the sheet positive, electrode negative.

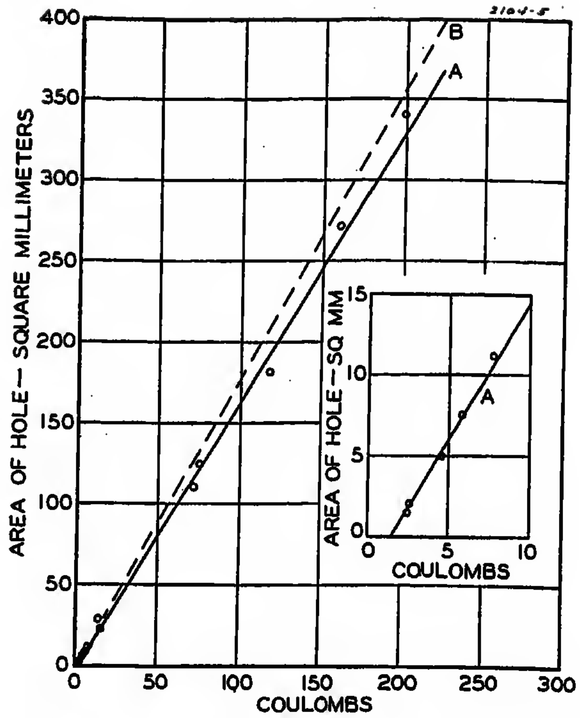

Figure 5. Relation between coulombs in the arc and resultant area of holes burned in (*A*) 15-mil galvanized iron sheets, (*B*) 20-mil copper sheets

Sheet positive, electrode negative polarity

Using the calibration curve of Figure 5 for nickel-plated copper sheets, the experience curve for the entire sphere in terms of coulombs versus holes was obtained and is compared, in Figure 6, with the curve of strokes versus coulombs as obtained for the Empire State building. Considering the fact that the number of holes per stroke is not known in the case of the WSM sphere, the agreement seems quite good when it is remembered that in many cases there may be more than one hole per stroke. The Empire State building data come from measurements of oscillograms and are known to represent the complete stroke. Of course, the difference in height and location no doubt has also had some effect on the recorded results.

It is a matter of considerable interest to note the number of holes in the sphere below its equator compared with those above. A curve similar to that of Figure

A—Oscillographic measurement Empire State building
B—Hole calibration for WSM sphere

6 for the upper and lower halves shows ten coulombs at the 80 per cent point for the upper half and five coulombs for the lower, while for values below 50 per cent the curve for the upper and lower halves is about equal to and practically coincides with that shown in Figure 5 for the whole sphere. The total number of holes in the upper half is 89 and in the lower is 61. Within a three-inch belt above the equator, 44 holes were found, while in a similar zone below the equator, 41 holes were counted, with five holes in the seam around the equator. Thus, 60 per cent of the holes were located on 32 per cent of the total surface of the sphere. In view of the distance to the cloud, the field surrounding the sphere is quite uniform except for the effect of its support which would lead one to expect a shielded zone near the point of attachment, and this is just what was found. If the strokes represented by the holes were all initiated by the tower, one would expect streamers to be formed as the cloud field became more intense from all over the sphere's surface except close to the point of support. Chance conditions of ionization in the atmosphere probably have considerable effect in determining which of the streamers from the sphere will develop into the stroke.

It is quite likely also that the seam around the equator had a considerable effect in promoting the formation of streamers at the time of a stroke. Drops of rain water, particularly at the seam may have added to this effect. The top of the sphere was apparently shielded to some extent by a probable extension of the sphere support above the top of the sphere. The details of the attachment are not known.

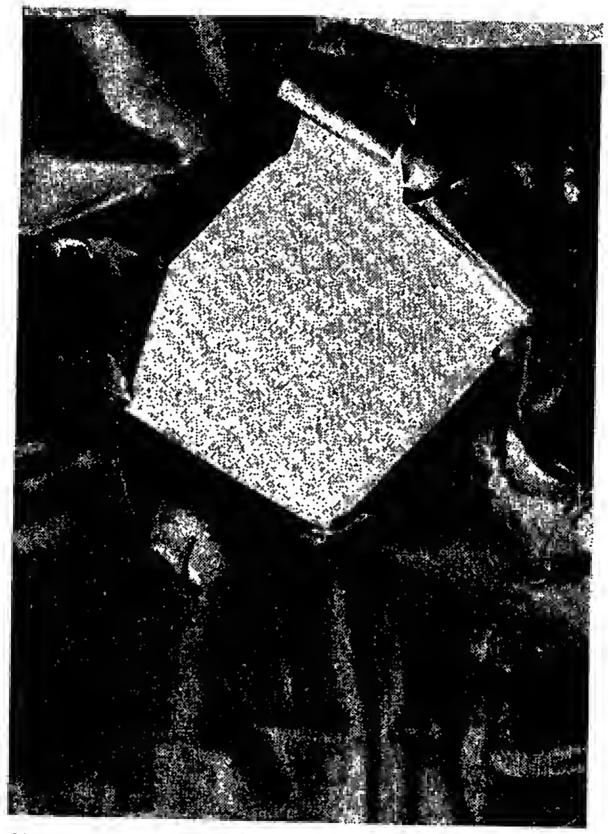

Figure 8. 265,000-ampere negative-polarity discharge through 10-mil plain copper sheet

Side away from arc. Sheet used as one electrode

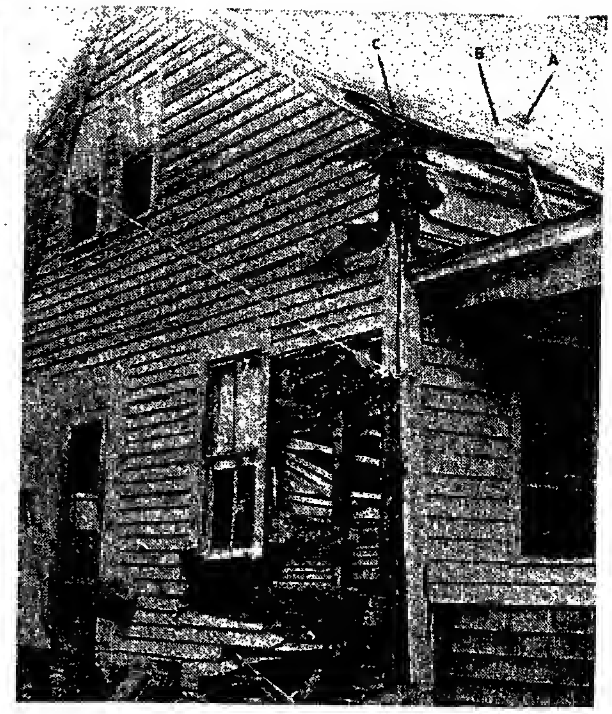

Figure 10. Exterior view of Amherst house struck by lightning

(*A*) Position of chimney. (*B*) Location of large hole. (*C*) Location of several small holes

Three hundred pits were found, many of these being accounted for as direct strokes having relatively high current magnitude, but having a low coulomb content (two coulombs or less). It does not appear to be possible to draw any definite conclusion concerning these pits in terms of current magnitude. It is possible, of course, that some of them are part of strokes which burned holes, and, if so, the effect on the calibration of holes in terms of strokes would be small on account of the small coulomb content.

In considering the interpretation to be put upon the results obtained by this sphere, it should be recorded that the number of separate strokes is not known, although Mr. Montgomery believes, based

Pelham Road near Amherst, Mass.

on his records, that 24 direct hits is a reasonable number to use. It is probable that this number is too low. With 150 holes, and assuming equal distribution of holes for all strokes, one arrives at seven holes per stroke which, from Figure 6, would indicate an average coulomb value of $7 \times 14 = 98$ coulombs, which is probably much too high, although the maximum hole indicates 240 coulombs. It must also be recognized that more than one stroke could contribute to the same hole as well as the same stroke making several holes.

At WSM, magnetic links had been installed on the antenna lead-in and guy wires at the time the sphere came down and the tuning coil of Figure 3 was damaged, which indicated a current of +66,000 amperes in the antenna lead-in and +6,400 amperes in two of the guy wires and a total of −73,000 amperes in six other guy wires. This record may cover more than one stroke, but it does indicate the highest currents recorded. It is interesting to point out that the most severe current peak measured with the cathode-ray oscillograph at the Empire State building[7] had a crest current of 58,000 amperes, contained 4.9 coulombs to half current value, and was positive.

Tests made in the laboratory on tubing similar to that of the tuning coil shown in Figure 3 indicate that the turns of the coil begin to pull together at a current crest of 75,000 amperes. The copper tubing itself begins to flatten at around 118,000 amperes. The difference between the effects of laboratory current amplitudes and the 66,000 amperes measured in the actual stroke is probably due to different wave shape, as well as the fact that two concentric coils were involved in the actual stroke. Furthermore, the heavy discharge current may have been preceded by a high coulomb–long duration discharge heating the copper tubing sufficiently to produce crushing at much lower crest currents. The laboratory current waves were oscillatory waves of 86 microseconds period with the initial peak of negative polarity. The tuning coil consisted of $^5/_8$-inch outside diameter tubing with 40-mil wall thickness.

Lightning Strokes to WGY

In 1938 a 20-mil chromium-plated copper cylinder was mounted on top of the then new WGY 635-foot radiator at Schenectady. The top of the cylinder was closed with a hemisphere of the same metal and thickness. When this was removed for examination in 1941, seven holes and several hundred small pits were found. The radiator was known to have been struck three times, the magnetic links showing −3,000, −7,800, and −30,000 amperes.

Of the seven holes, six were located in the 12-inch diameter hemisphere, mostly in the upper part, but none at the highest point of the sphere as installed. The cylindrical portion had a height of 14 inches, and one hole was found six inches from its lower edge. The pits were most numerous in the area above a line nine inches from the bottom of the cylinder. Twenty-nine of the pits had an appearance similar to that obtained from high-current laboratory discharges of one or two coulombs.

Concerning the Holes Burned

With reference to the appearance and size of holes some comment is desirable. While the WSM sphere showed some very small holes—as small as three square millimeters—such small holes could not be produced in the laboratory in copper sheets. The smallest hole obtained had an area of 28 square millimeters. However, in galvanized iron sheets, holes as small as 1.5 square millimeters could be produced.

This effect has been attributed to the close proximity ($^1/_4$ to $^1/_2$ inch) of electrode to the sheets under test. A tapered carbon electrode was used to avoid the effect of the metal of the electrode on the calibration. Although the electrode begins to glow at 60 coulombs, very little gas is given off. Brass electrodes were tried but consistent results were not obtained.

It is expected that the only difference to be obtained from a longer arc would be the possibility of forming smaller holes in copper sheets. Within the range investigated—spacing $^1/_4$ inch to $^1/_2$ inch—the character of the holes is not changed, indicating that the electrode effect is not appreciable. The close proximity of the electrode possibly has the effect of spreading the core of the arc wider than would be the case in a lightning stroke. However, the holes produced showed the same characteristics as those produced by natural lightning as evidenced on the WSM sphere.

The tests on metal sheets up to 100-

mil thickness indicate the following relations:

$$C=\frac{A}{25}\times t^{0.9} \quad (t=0 \text{ to } 35 \text{ mils})$$

$$C=\frac{A}{245}\times t^{1.54} \quad (t=35 \text{ to } 150 \text{ mils})$$

where

C = coulombs
A = area of hole in square millimeters
t = thickness of sheet in mils

Such equations are reasonably accurate for copper and galvanized iron and may be used to estimate the coulombs in a given lightning stroke. The use of the curves of Figure 5 for the individual metal is more accurate, but tests of this nature do not permit close calibration, the variation from the curves shown in Figure 5 being as much as 40 per cent for some individual points.

That the hole burning is a function of coulombs rather than i^2t has been verified by the fact that equal holes are burned when equal coulombs in the arc are produced with widely different current amplitudes. The test currents ranged from 50 amperes to 600 amperes, which is in the range of natural lightning continuing discharges. Tests at high currents with high coulomb values have not been made, but the calibration data given in Figure 5 should not be used for high currents. Bellaschi[2] similarly showed that burning of solid heavy electrodes is dependent upon coulombs.

In Figure 7 are shown holes burned in a five-mil, nickel-plated copper sheet with discharge currents of 40,000 amperes crest. The small holes and burns numbered 1–5 were produced with the sheet grounded. The larger holes 6–9 were obtained with the sheet midway between the line electrode and the ground electrode. The jagged character of the holes is apparent, especially in number 9 where the electrode distance was increased from $^5/_{16}$ to $2^3/_4$ inches. There is no evidence of the copper beads lining the hole as is observed on the sphere and the corresponding test sheets. As the current amplitude is increased, the explosive effect is increased as shown in Figure 8, which gives the effect of a 265,000 ampere 30-coulomb discharge to a grounded copper sheet of ten-mil thickness. The same impulse applied to a 25-mil copper sheet did not rupture it but did produce a large dent in its surface. On the other hand, a 25,000-ampere one- to two-coulomb discharge will form a bright bead on a 20-mil copper sheet but will not puncture the sheet. In the explosive type or high current discharge many factors have to be weighed besides current amplitude, while the charge in the long-duration low-current continuous discharge can be computed with fair accuracy.

The tests indicate a possible source of fire with thin metal-roofed buildings, if inflammable material is close to the metal or in such position that molten metal may drop on combustible materials. If thin metals are to be used for covering, then elevated air terminals should be used to keep the arc away from the building and a suitable path to ground provided to prevent damage at joints in the metal structure.

Tests on Steel Plate

In view of possible lightning strokes to metal containers of explosive gases of liquids, tests were made with the equipment shown in Figure 1 with the following result. A $^3/_8$-inch steel plate was tested with 430 coulombs in the arc. Results of such tests are shown in Figure 9. The plate could not be punctured but a crater-like hole was formed of $^3/_{16}$-inch depth and 180 square millimeters area. To puncture such a plate several thousand coulombs would be required.

Lightning Stroke to Home

Of the many lightning damage cases which the authors have investigated, that which occurred near Amherst, Mass., during the summer of 1939 is perhaps one of the most interesting. Lightning struck the home shown in Figure 10, resulting in the external damage shown. The upper portion of the chimney had been eliminated, and the chimney was cracked throughout its length. A hole having an area of 345 square millimeters was found in the 15-mil galvanized-iron shingle roof at a point about three feet from the chimney and in the direction of the damaged corner of the building shown in Figure 10. Several small holes were found in a shingle, which apparently had been located at the corner of the roof above the damaged corner. No evidence of fire could be found anywhere, although in the kitchen there was a considerable burn between a sink and a nearby pipe, which had a combined effective resistance to ground of 47 ohms. This was the only ground in this house. There was also considerable burning between the cover of an ice box and the zinc lining. Nearly all of the windows on the ground floor were blown outward, showing the high pressure developed within the house. Two persons were in the house, one upstairs to the right of the chimney, and the other in the kitchen to the left of the door shown in Figure 10. Neither was hurt.

There was no wiring of any sort in this home. In Figure 11 is shown another home, 155 feet away, which had a three-wire service with the usual appliances connected. In the cellar was a driven ground of 430 ohms. In addition, two grounds having a combined resistance of 215 ohms were driven at the service pole located 110 feet from the house of Figure 10, and 80 feet from the house of Figure 11. A portion of the path of the lightning discharge is shown in Figure 12. At the point illustrated the channel in the earth was about three feet in width and about 15 inches in depth. It continued with two-foot width and about the same depth for a distance of 74 feet where it split into two parts, one to continue 88 feet to the ground rod in the cellar of the house of Figure 11, and the other to travel 81 feet to the ground rods driven at the base of the service pole. The electric equipment in the wired house was in operating condition after the storm, although the cellar windows were blown out as the result of the pressure developed in the spark to the driven ground rod inside close to the cellar wall.

From magnetic effects observed, it was concluded that the current in the neutral wire was of the order of 30,000 amperes of a slow rate of rise and indicated a negative-polarity stroke to the unwired house of Figure 10. A calibration of the shingle burns indicates a coulomb value of 210 for the larger burn and 30 coulombs for the smaller burns.

In reconstructing what happened, it is probable that the stroke was negative, beginning with a current peak of the order of 200,000 amperes, followed by a continuing current having a coulomb value of 240. The physical damage seen in Figures 10 and 12 resulted from the high current peak. After the chimney exploded; apparently the path shifted to the burned points found on the roof. With the high coulomb value of the continuing current, one would have expected a fire to ensue, but no evidence of this could be found, indicating that the inflammability of the various paths was such as not to cause fire.

This case is given here, because some knowledge exists as to the magnitude of the lightning current which caused the damage observed. This again illustrates what may happen when good grounds are not available when lightning strikes.

The pine tree shown in Figure 13 is mute evidence of the same type of lightning discharge just described. This tree struck by lightning exploded a few feet

Abnormal Currents in Distribution Transformers Due to Lightning

J. M. BRYANT
MEMBER AIEE

M. NEWMAN
ASSOCIATE AIEE

Synopsis: Abnormal currents in distribution transformers due to lightning are analyzed both theoretically and from field experiences. Under certain conditions of direct stroke transferred through the arrester to the neutral of the secondary winding, excessive currents may wreck the secondary windings by electromagnetic forces. Long-duration surges, or shorter repeated surges, saturate the transformer cores producing greatly increased surge currents in the primary windings which influence fuse failures. The saturation of the cores by unidirectional lightning surges also brings about increased power-frequency magnetizing currents influencing sectionalizing-fuse and circuit-breaker operations.

A GREAT deal of research has been done and many papers have been written dealing with the problems of overvoltages under lightning conditions. It has been assumed generally that, because of the relatively high inductance of transformer windings, very little lightning current builds up within them. There are, however, certain conditions under which the lightning current may enter the secondary windings of grounded-neutral distribution transformers and rise to such magnitudes as to develop electromagnetic forces sufficient to destroy that winding by mechanical stress. Also, for long-duration single or multiple lightning surges enough current builds up through the primary winding to saturate the core; and the consequent rate of increase of current in the winding becomes more rapid, and the current is finally limited only by the d-c resistance of the primary winding. These latter currents are generally insufficient to damage the winding, but they are important in the determination of fuse failures[1] and sectionalizing operation under lightning conditions.

Paper 42-109, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 9, 1942; made available for printing May 4, 1942.

J. M. BRYANT is professor and head of the electrical engineering department, and M. NEWMAN is associate research engineer in the electrical engineering department, University of Minnesota, Minneapolis, Minn.

The authors acknowledge the co-operation of J. H. Willox and E. H. Yonkers of the Joslyn Manufacturing and Supply Company, both in the investigations and in the development of special methods of protection related to the new factors brought out in this paper.

Another source of abnormal transformer currents is that of large magnetizing inrush currents brought about by surge conditions, which will be primarily important in the operation of fuses or breakers. These various phenomena of abnormal transformer currents are discussed further in this paper, with special reference to distribution transformers on rural lines.

Direct-Stroke Lightning Currents in the Secondary Windings

Under certain circumstances of direct lightning strokes to the primary line, very large currents may go through the secondary winding when the lightning arrester functions to protect the primary. Occasionally the effect of such currents is completely to disrupt the windings, as shown in Figure 1. There is no present protection scheme in use which protects against such conditions. The transformer was connected as shown in Figure 2. The lightning arrester effectively by-passed to the ground lead the resulting current from a direct stroke to the line, and the primary winding was perfectly protected, as determined by subsequent test. The voltage of the secondary wires rose, together with that of the transformer case, to the value of the surge-impedance drop of the grounding wire impedance and ground resistance, and another flashover to ground occurred, this time on the customer's premises. Current in the two wires on each side of the grounded neutral to the customer ground fault went through the secondary winding. Since the current went from the transformer case at raised potential into the neutral connection of the transformer coil, and from there into the winding halves in opposite directions, the magnetic fields of the two halves of the secondary winding canceled out to a high degree, because of the close coupling. The leakage-reactance drop and also the resistance drop were not sufficient to flash over the bushing or the normal shunt safety gaps in use. Thus the current continued to go into the secondary coil sections in opposing directions; the extreme resulting mechanical forces due to electromagnetic reaction distended the secondary winding, as shown at X in Figure 1, and actually cut several turns in two by jamming them against the core laminations.

Such conditions to a greater or lesser extent, must occur in almost every case of a direct stroke to line near a transformer installation. The paths for the lightning current through the transformer secondaries are indicated by arrows in Figure 2. The relative amount of current going into the windings varies with the relative ground resistances; in this case it was probably of the order of 20,000 amperes

---

above the ground. Examination of the upper portion of the tree and the debris scattered over a considerable area showed no signs of burning; yet the stump was on fire when the owner of the land ran to the point where he saw the lightning strike. Evidently this stroke also began with a high current peak blowing the tree apart. The stroke persisted as a continuing current to the stump of the tree, which was still grounded, setting it afire. This was going on while the tree and the debris were in the air.

The data which have been collected thus far seem to indicate that the use of thin metal surfaces makes a fairly satisfactory means for collecting data with respect to the number of coulombs contained in natural lightning strokes, excluding the effects of the high current peaks which may be present.

in each transformer section, but in most cases the current is apparently low enough to be harmless.

Insufficient field data are available on the frequency of such failures, and therefore it is uncertain whether protection against such faults is economically feasible. Also, it is beyond the scope of this paper to consider protective means beyond mentioning a few obvious measures such as:

1. Reduction of arrester ground resistance to a value considerably less than the customer's ground, although the customer's ground must also be kept low for his safety.

2. Application of very low breakdown-value protectors across the secondary bushings.

3. Placing of small reactors in the transformer secondary leads inside the tank, which will cause the bushing gaps to flash over and protect the secondary winding.

4. Placing the two secondary leads inside a waterproof metallic cable, the metallic covering of the cable serving as the neutral lead grounded to the case, and also serving as a supplement to the arrester ground when the cable is run underground to the customer.

Primary Winding Currents Under Long-Duration Surge Conditions

Very little surge current is built up in the primary winding until the transformer core reaches saturation, when the effective primary-winding inductance drops sharply; short-duration surges do not produce saturation. Long-duration or repeated surges equivalent to long surges can build up considerable currents, often sufficient to blow the usual primary protective fuse. The determining factors in this saturation phenomenon can be more readily analyzed by taking a specific field example of a 7,200-volt rural distribution system feeding a network of three-kva transformers, shown in Figure 3.

There are two possible conditions under which long surge waves may be present on the system. The arresters on the system may be functioning and, if they are of the conventional type, they will limit the peak voltage to about 55 kv, but this will drop at a slower rate than the incident wave; thus, in effect, producing a lengthened surge. On the other hand, especially in the case of repeated discharges, long surges may be present on the system without any arresters functioning on some of the later of the repeated discharges which may have dropped to below the breakdown point of the arrester. In the latter case the duration of the surge is influenced by the discharge path both from cloud to ground and within the cloud itself. Recent investigations[2,3] show such waves may be from 1,000 to 20,000 microseconds duration. A border-line case which would fit the above conditions of the arresters functioning or not functioning could be represented on the particular 7,200-volt line by a surge expressed as

$$e=E_s\epsilon^{-at}=55{,}000\epsilon^{-0.0003t}$$

This expression corresponds to a wave having a crest value of 55 kv and dropping exponentially to half value in about 2,500 microseconds. It will be noted that the second term of the more general expression for a surge, $e=kE(\epsilon^{-at}-\epsilon^{-bt})$, which is omitted, represents the rate of rise of the front of the wave. The duration of the "front" of the wave is so short in relation to the very long duration of the "tail" of the wave that it plays little importance in the determination of the final current through the winding; and therefore, the corresponding term is left off to simplify the mathematical presentation.

This surge wave is so long relative to the time of travel along the entire transmission line that the same potential can be considered applied at all the transformer installations, and the surge impedance of the line can be considered a negligible factor. This becomes clear when it is considered that the length of the wave of 2,500 microseconds corresponds to a time such a wave could travel 475 miles, or would travel back and forth in successive reflections on an average 50-mile rural system about ten times while dropping to half value. Hence the conditions can be considered essentially the same at each of the distribution transformers and may be schematically represented as shown in Figure 4.

The curves C and F, Figure 4, show the resulting current rise in the primary winding with the surge occurring at different points C' and F' on the normal 60-cycle wave, shown in Figure 5. The current begins to be appreciable only as the transformer core saturates. The hysteresis loop A-B-C-D-E-F-G in Figure 5 gives the normal variation of B-H as the transformer core changes its values of B to produce the equal but opposite sinusoidal electromotive force, $iR+N(d\Phi/dt)\cdot 10^{-8}$,

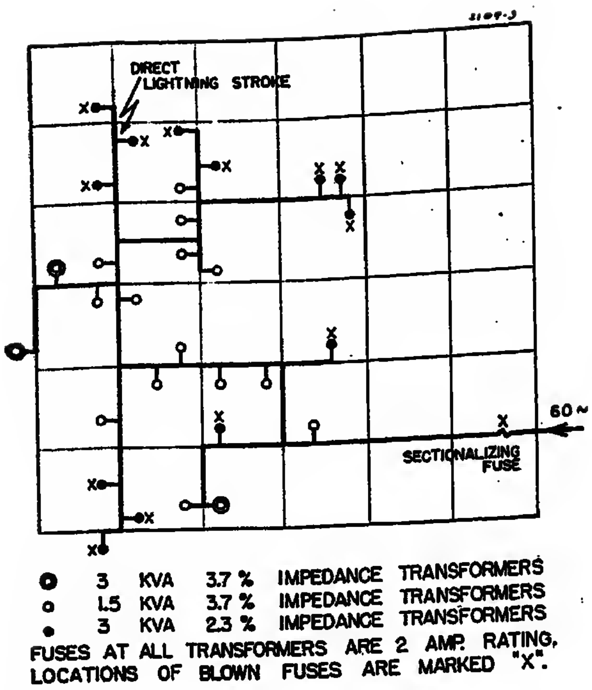

Figure 3. Typical 7,200-volt rural single-phase section in which fuse failures were caused by lightning current penetrating the primary windings of the distribution transformers

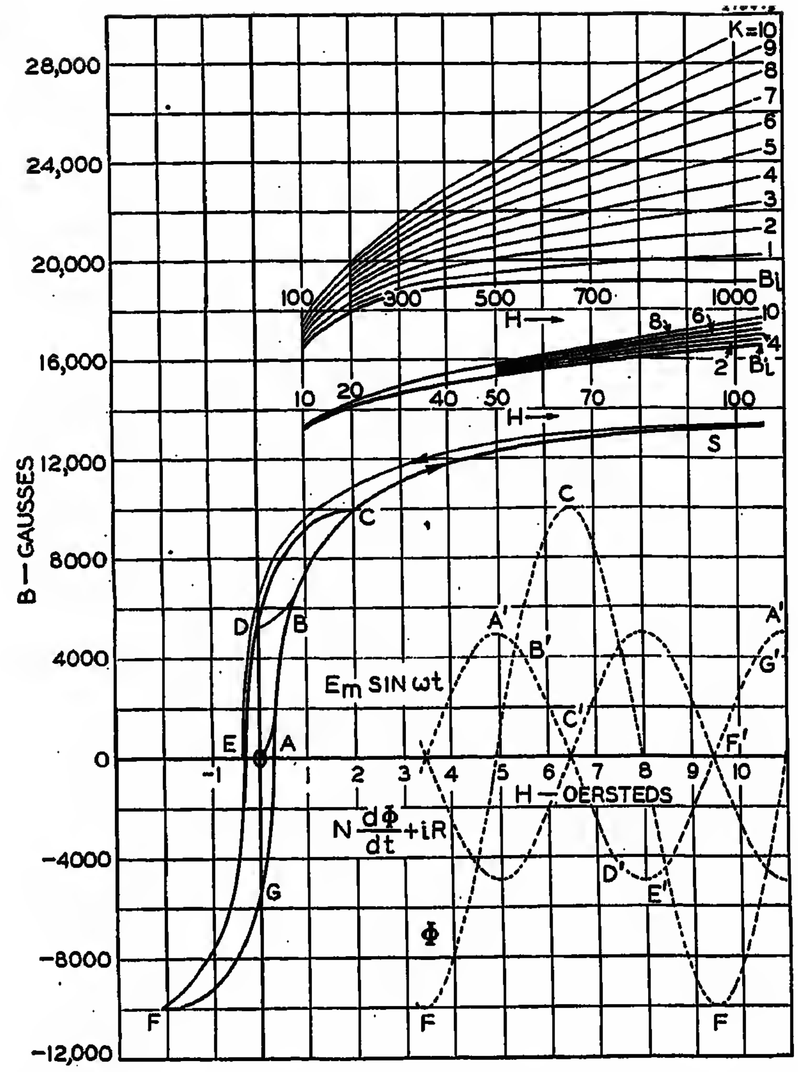
Figure 5. Magnetization curve for the core of the typical distribution transformer

The dashed lines indicate relative flux-voltage relations under normal operation



which balances the applied electromotive force, $E_m \sin \omega t$. The B and electromotive force relationships are indicated in dashed lines on Figure 5, from which it is clear that a surge impressed at C' on the 60-cycle voltage wave conforms to C or maximum flux value, on the hysteresis loop, will cause a maximum flux increase along S; and, therefore, will result in the shortest time to core saturation. Similarly a surge at point F' on the 60-cycle wave would result in the longest time to saturation. The calculation of the growth of current must take into account these various states of magnetization of the core; and because the B-H curves cannot be expressed mathematically by a simple equation, the fundamental equations must be solved graphically or in a step-by-step manner, as given in the appendix. From these calculations and the resulting

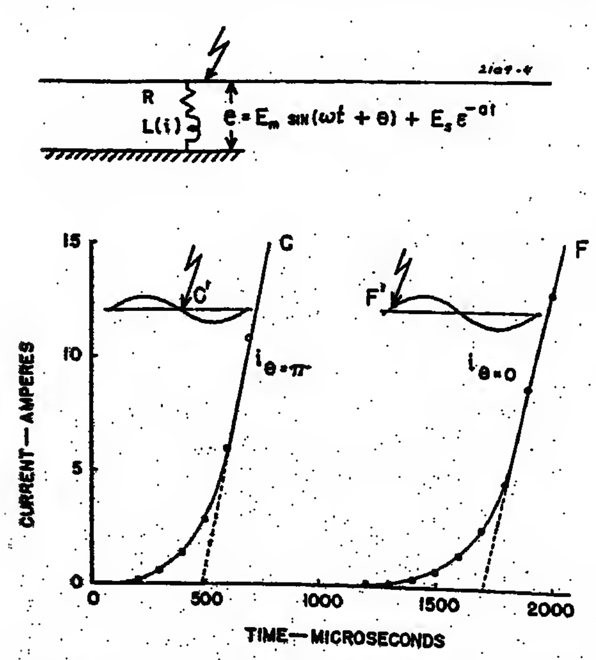


Figure 4. Initial current rise in a distribution-transformer primary due to lightning surges incident at different points on the normal power-frequency cycle

curves of Figure 4, it is clear that the time denoted by t_o elapsing before the core saturates and appreciable currents can develop varies with the point of surge incidence on the 60-cycle wave and lies in the range $t_o = 1,100 \pm 600$ microseconds.

The above range of t_o was determined for one specific 7,200-volt transformer of three-kilovolt-ampere rating. It follows, however, from the calculations (see appendix) that the time t_o is independent of the transformer kilovolt-ampere rating and of the voltage rating of the transformer, so long as the ratio of its voltage to the surge voltage remains the same. It also follows, from the calculations and the curves of Figure 5, that for the larger values of current as the core saturates, the relation of B to H increments or $\Delta B/\Delta H$ becomes a constant, and the problem may be solved as with constant parameters. The relation for the current due to a surge potential $e = E_s\epsilon^{-at}$, may be written as

$$i = \frac{E_s}{R - aL}[\epsilon^{-at} - \epsilon^{R/L(t-t_o)}]$$

where L is the inductance of the circuit with the core saturated, t_o is $1,100 \pm 600$ microseconds, depending on the point of surge incidence on the power frequency cycle; the values of i up to $t = t_o$ being relatively small and considered zero.

The derived simplified equation lends itself readily to the examination of possible currents flowing into various transformers having different impedance characteristics. Thus, Figure 6 shows possible currents due to the surge alone flowing into two transformers of different impedances but of the same kilovolt-ampere and kilovolt ratings. These currents are of sufficient magnitude to cause the protective fuses in the transformer-primary-circuit leads to fail, as was proven by instances of fuse failures on *unenergized* lines under lightning conditions. Conclusive evidence that the relative currents are as calculated is given by the field case summarized in Figure 3, where every fuse failed at a 2.3 per cent impedance transformer but where none failed at any of the higher impedance transformers. The greater current associated with the lower impedance transformer, as shown

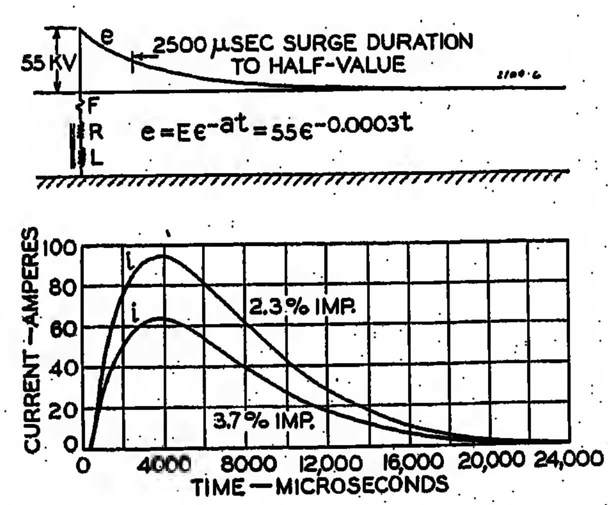

Figure 6. Incident surge wave and resulting current in the primary windings of three-kilovolt-ampere, 7,200-volt distribution transformers having per cent impedance values as marked on the curves

in Figure 6, accounts for the selective action noted. The solution of the fuse-failure problem is definitely not, however, the use of high-impedance transformers. In this particular case all of the fuses were of the same rating; and none failed on the high-impedance transformers, because these transformers were overfused relative to their impedance and, therefore, were actually unprotected against normal overloads.

Conclusion

Direct lightning strokes may cause very large currents to penetrate the secondary windings of distribution transformers with destructive effects, even though the primaries are perfectly protected. It is important, therefore, to determine the actual extent and frequency of occurrence of this type of failure in practice.

Long-duration surges cause relatively large currents to build up also in the primary windings of distribution transformers, as analyzed in this paper. Field experience with fuse failures and laboratory research by the writers with simulated surge conditions, have checked the validity of the analytical approach. Oscillographic records obtained in this research agree closely with Figure 6. Conclusions on the effect of variations of incidence of a surge on the 60-cycle wave follow readily and accurately from the detailed analysis in the appendix and elsewhere in this paper. Published experiments by Bergvall and Beck[4] with direct currents equivalent to long-duration surges applied to transformers are also in reasonable agreement.

The calculations of Table I in the appendix, extended over a number of cycles, show that even after the surge voltage has completely disappeared a high magnetizing current transient results, due to the high degree of saturation in the core. Reference to equation 5 in the appendix shows that the flux increment, due to a small surge incident on the transformer 60-cycle wave at a point corresponding to low core flux value, may be written

$$\sum \Delta B = \sum \frac{\omega B_m}{E_m} E_s \epsilon^{-at} \Delta t$$

since iR would then be negligible during the surge-incidence time. The total flux increment due to a surge $E_s\epsilon^{-at}$ would be

$$\int_0^\infty \frac{\omega B_m}{E_m} E_s \epsilon^{-at} dt = \frac{\omega B_m E_s}{aE_m}$$

It follows, therefore, that every surge, no matter how small, would cause a certain shift in flux and would produce a magnetizing transient. These transients, although usually more severe, are of the same character as the magnetizing inrush currents experienced when energizing a transformer at certain points on a 60-cycle wave. This fact is of importance in examining possible faulty operation of fuses and breakers. An interesting proof that such "induced" magnetizing inrush currents may cause faulty fuse and breaker operation is given by cases of recent outages during periods of severe sun-spot activity which resulted in long-duration relatively constant voltages across the transformers, which although quite different in magnitude were comparable in effect to long-duration repeated lightning surges.

Although complete protection methods have been developed, further researches and field studies are necessary to determine the frequency of occurrence of these problems in actual practice.

Appendix. Solution for Current in Transformer Due to Lightning Surge Superposed on the Normal Power Cycle

The fundamental relationship for the transformer with a total voltage e across it, composed of the normal operating voltage $E_m \sin \omega t$ and a superposed surge voltage $E_s\epsilon^{-at}$ may be written as

$$\begin{aligned} e &= E_m \sin(\omega t+\theta) + E_s\epsilon^{-at} \\ &= N(d\phi/dt)\times 10^{-8} + iR \\ &= A(dB/dt) + iR \end{aligned} \tag{1}$$

where ϕ represents the total value of the flux linking the primary winding, including the air space around the core, that is, the leakage inductance $L(di/dt)$ drop. This leakage inductance is introduced in the calculation by choosing the graph corresponding to the proper value of K in Figure 5, the value of K being equal to the ratio of total leakage flux (excluding the contribution of the core) to the leakage flux which would be obtained in the space occupied by the core. External inductance of transmission lines, and so forth, can also be included in determining the value of K, as suggested by Steinmetz[5] in solving the somewhat similar problem of determining magnetizing inrush current. The value of the constant A can be determined from the physical characteristics of the winding or from the known maximum flux density under normal operating voltage conditions. Neglecting the iR term for normal magnetizing currents, and for normal steady-state conditions

$$E_m \sin \omega t = A(dB/dt)$$

from which

$$dB = (E_m/A) \sin \omega t dt \tag{2}$$

$$B = (E_m/A)\int \sin \omega t dt = (-E_m/A) \cos \omega t$$
$$B_m = E_m/\omega A$$

and hence,

$$A = E_m/\omega B_m \tag{3}$$

Thus, substituting this value of A in equation 1 for surge conditions

$$\begin{aligned} e &= E_m \sin(\omega t+\theta) + E_s\epsilon^{-at} \\ &= (E_m/\omega B_m)(dB/dt) + iR \end{aligned} \tag{4}$$

For a solution of equation 4, dB/dt may be written in finite increment form $\Delta B/\Delta t$, giving

$$\Delta B = (\omega B_m/E_m)(e - iR)\,\Delta t \tag{5}$$

The values of the total potential e composed of $E_m \sin(\omega t+\theta)$ and $E_s\epsilon^{-at}$ in equation 5 must be the average values over the interval Δt. To avoid the approximation of finding the average, $E_m \sin(\omega t+\theta)dt$ may be written as $-d[(E_m/\omega)\cos(\omega t+\theta)]$, and $E_s\epsilon^{-at}dt$ as $-d\left[\frac{E_s\epsilon^{-at}}{a}\right]$ so that, in substitut-

ing increments for the differentials, equation 5 may be written as

$$\Delta B = -B_m \Delta \cos(\omega t + \theta) - \frac{\omega E_s B_m}{a E_m} \Delta \epsilon^{-at} - \frac{\bar{i} R \omega B_m \Delta t}{E_m} \quad (6)$$

The values of i remain to be averaged over the interval Δt, so that, where variations of i are rapid, it may be necessary to use shorter intervals of t. The values of ΔB are added to the preceding values to give the total B, and the corresponding values of i are determined from the B-H curve of Figure 5 in the step-by-step manner indicated in Table I. The relation of i to H depends upon the number of turns in the winding, N, and the mean length of the magnetic path, l;

$$H = \frac{0.4\pi N i}{l} \text{ or } i = \frac{Hl}{0.4\pi N} \quad (7)$$

For a typical three-kilovolt-ampere, 7,200-volt distribution transformer it was found that for $E_s = 55$ kv, as shown for the surge $e = E_s \epsilon^{-at}$, and for the actual constants as determined from the transformer of $B_m = 10{,}000$ and $E_m = 7{,}200\sqrt{2}$ or 10,200 volts, and $R = 280$ ohms, equation 6 for ΔB could be expressed with convenient coefficients for step-by-step calculations, to within two to three per cent probable error, as

$$\Delta B = -10{,}000 \Delta \cos(0.000377t + \theta) - 67{,}700 \Delta \epsilon^{-0.0003t} - 0.1\bar{i} \Delta t \quad (8)$$

with t and Δt expressed in microseconds, and where, for the particular transformer $l = 32$ inches and $N = 6{,}240$ turns, the values of i are given by

$$i \approx 0.01H \quad (9)$$

with H corresponding to the various values of B determined for the proper value of K (in this case $K = 3$) from Figure 5.

The initial value of B in Table I is taken as that corresponding to the point on the normal 60-cycle voltage wave at which the surge is incident. The particular value taken in the given tabulation is that value nearest saturation, or with an initial value of $B = B_m = 10{,}000$, corresponding to the incidence of the surge at the zero point C' on the 60-cycle wave, or where $\theta = \pi$ in equation 6. It is clear from the tabulation and from the corresponding plotted curve in Figure 4, that the values of current are relatively small until the time when the core is very near the saturation point, or until $t_o = 500$ microseconds in this case. Similar calculations for a point of incidence of the surge corresponding to $\theta = 0$ in equation 6 and to F' in Figure 5 gives, for the equivalent time to saturation t_o, the value of 1,700 microseconds. Thus the time elapsing before the core saturates and appreciable currents can develop varies with the point of surge incidence on the normal voltage wave, and for the given ratio of

$$(E_s/E_m) = \frac{55{,}000}{10{,}200} \text{ lies in the range}$$

$$t_o = 1{,}100 \pm 600 \text{ microseconds} \quad (10)$$

The above value of t_o was determined for one specific 7,200-volt transformer of three-kva rating. It is of interest to refer back to equation 6 from which it will be noted that while i is still small, that is, before $t = t_o$, the values of ΔB due to the surge voltage are proportional to (E_s/E_m). This proportionality means that for the same ratio of surge voltage to line voltage the values of $t_o = 1{,}100 \pm 600$ microseconds will hold closely, irrespective of the transformer rating, and will vary only in response to (E_s/E_m). Thus, since there is a fairly well-established ratio of allowable surge voltage to 60-cycle voltage on distribution lines the values for t_o are valid for all distribution transformers, irrespective of kilovolt and kilovolt-ampere ratings.

Another interesting development which follows upon examination of Table I and Figure 5 is that, as the core saturates the relation $(\Delta B/\Delta H)$ becomes a constant and the problem may be solved approximately with equivalent parameters. If one neglects the much smaller component of the 60-cycle voltage effective under the surge conditions of saturation, the current due to a surge potential $e = E_s^{-at}$ may then be found from,

$$i = \frac{E_s}{R - aL}[\epsilon^{-at} - \epsilon^{-(R/L)(t - t_o)}] \quad (11)$$

where L is the inductance of the circuit with the core saturated, t_o is $1{,}100 \pm 600$ microseconds dependent on the point of surge incidence on the 60-cycle wave, and the values of i up to $t = t_o$, being small, may be neglected.

Current Ratings of Electronic Devices for Intermittent Service

R. E. HELLMUND
FELLOW AIEE (Deceased)

Synopsis: Electronic devices are used extensively for switching, relaying, welding, and similar service resulting in intermittent loads. In the paper methods for assigning standard ratings suitable for such intermittent loads are investigated, both for single-anode tubes and tube circuit combinations. Vapor-filled tubes with oxide-coated filaments are treated somewhat in detail in order to develop the basic considerations. Other types of tubes, such as the pool-type and cold-cathode, are only briefly discussed. A method of rating which seems generally applicable is proposed, with the suggestion that its suitability for the great variety of conditions encountered be further investigated.

THE assignment of ratings especially suited for intermittent service is desirable, if it results in more economic use of devices than the present practice of assigning continuous ratings. The subject is of particular importance in connection with tubes, because they are used so extensively for intermittent operations such as switching, relaying, signaling, spot-welding, and so forth. It is intended in this paper to examine the possibilities of assigning intermittent service ratings to electronic devices, giving due consideration to the methods proposed in the recent AIEE report No. 1-A on "General Principles for Rating of Electrical Apparatus for Short-Time, Intermittent, or Varying Duty," by standards co-ordinating committee 4.[1]

In any analysis of the rating of electronic devices the following must be kept in mind:

1. The flow of current through each anode, and consequently through a single-anode tube, is intermittent in nearly all applications. This is shown in Figure 1, case A_1, which illustrates the current flowing with a single-anode rectifier. The same condition applies with a single-phase full-wave rectifier for each anode. Case C_1 shows the current in each single-anode tube for three-phase rectification; similarly E_1 applies to six-phase arrangements. In some applications the time of current-flow is even less, as in the ignitor circuit tubes of ignitrons, illustrated by case G_1. If the application is such that the current-flow periods repeat continuously, it is customary to consider it continuous service, which for each anode means continuously repeating pulsations of the current. Regardless of this continuous feature, it must be realized that dependent upon the duration of each pulsation and the amount of idle time between pulsations, different current rating values may have to be assigned for the different cases of Figure 1 and similar variations, in order to bring about economical use of the electronic devices.

2. In all electronic arrangements consisting of two or more single-anode tubes, careful distinction must be made between the rating of individual tubes and that of the complete tube combination. Cases B_1, D_1, and F_1 show the output of two-, three-, and six-tube arrangements corresponding to the single-anode currents of cases A_1, C_1, and E_1, respectively.

3. The output of the tube combination may be continuous as discussed so far, or intermittent as illustrated for equal time on and off in B_2, D_2, and F_2 of Figure 1. The currents in the individual single-anode tubes for these cases are shown in A_2, C_2, and E_2 respectively. The current here is intermittently pulsating. G_2 shows an intermittent load for short-time individual pulsation as might be found in the individual ignitor circuit tubes used in seam-welding. Ratings for such intermittent tube loads may be different from those of the previously described continuously pulsating loads.

Rating of Single-Anode Tubes

Depending upon the type of tube and type of load, the permissible rating of a single-anode tube may be limited by any one of the following factors:

(*a*). *Heating of the Tube as a Whole.* With the usual assumption of constant voltage-drop in gas-filled tubes, it is customary to consider the average current as the principal factor in this respect. Investigations by Knowles and McNall[2] indicate, however, that with short-time pulsations in a hot-cathode tube the assumption of constant voltage-drop does not hold true, and this may have to be considered under some conditions. (In the case of rectification of frequencies of hundreds or thousands of cycles, there is considerable additional anode heating due to positive ion bombardment of the anode during the inverse part of the cycle, a fact which, of course, must receive due consideration.)

(*b*). *Heating at the Lead-in Conductors and Seals.* This is influenced largely by the rms current, and if it is too high difficulties may develop. (Unfortunately the heating of the lead-in conductors and of the tube as a whole are interdependent, making a clear-cut distinction between the limits imposed by the average current and the effective current difficult.)

(*c*). *Values of the Individual Current Pulsations and Their Duration and Frequency.* These may be important factors in limiting tube ratings for a number of reasons dependent on the physical phenomena entering into the operation of various types of tubes. (The sparking tendency of oxide-coated filament tubes and the back-fire phenomena in pool-type tubes are examples of this.)

(*d*). *Requirements for Satisfactory Life of the Tubes.* Even though the limitations imposed by items a, b, and c have been taken into account to assure satisfactory operation, rating values may have to be made the subject of further adjustments to assure satisfactory life of the tube. (The life of oxide-coated filaments or the life of the covering of cold cathodes are examples of this. The electron emission in a hot-cathode tube decreases during life, and in many cases the end of life is determined by lack of cathode emission. Therefore, tests or ratings involving peak-current-carrying capacity, as well as any other current rating, of the tube must take this into account.)

Separate consideration will have to be given to each type of tube for various service conditions before any plan toward a reasonably uniform method of rating can be devised. As a contribution toward a satisfactory system of rating a number of typical cases will be considered in the following.

Vapor-filled tubes with oxide-coated filaments will be considered first. Rating data for those tubes usually give the continuous average current rating and a limiting peak or crest value for the current. The latter ranges in some tubes from four to six times the continuous average current value, or conversely, the continuous average is 25 to 16.6 per cent of the specified peak value. In Figure 1 the rms and average current values are indicated in per cent of the crest values for each of the cases shown. It will be noted that in all cases of the single-anode tube currents except A_1 and C_1 the average current is less than 16.6 per cent. This in turn means that with the data indicated above, which are those usually given, the average current is the limiting factor in cases A_1 and C_1, while in all other cases the specified peak current limits the permissible load, regardless of the duration and frequency of the current impulses. A question therefore arises as to whether better utilization of these devices might not be brought about by some other method of specifying ratings more suitable for loads with short-time pulsations. Knowles and McNall have made an investigation on the sparking point of

Paper 42-87, recommended by the AIEE joint subcommittee on electronics for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted March 2, 1942; made available for printing April 14, 1942.

R. E. HELLMUND was chief engineer of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa., at the time of his death, May 1942.

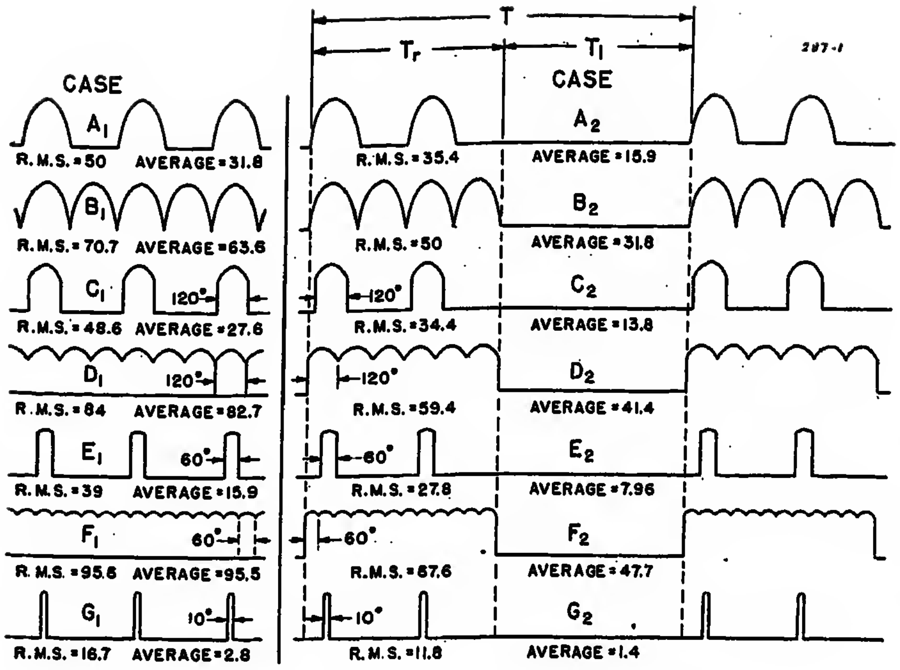

Figure 1. Typical load current for tubes and tube combinations

A_2 to F_2—Intermittent loads

Rms and average current values in per cent of crest values are indicated in each case

the filament as depending upon current and time. Some of their results are rearranged in Figure 2. It will be noted that with the minimum filament voltage of 2.25 volts, peak currents of 2.75 amperes for long durations of the pulsation are indicated. The curve also shows that the permissible peak loads can be increased by 2 per cent, 11 per cent, 32 per cent, and 80 per cent, for 180, 120, 60, and 10 degrees of the 60-cycle wave respectively; especially in the last two cases the gain is appreciable and seems to make it worth-while to standardize on several ratings suitable for service with various short-time pulsations.

The underlying physical phenomena make it necessary to specify for each of such ratings:

1. The wave shape of the impulse.
2. The crest value of the impulse.
3. The duration of the individual impulse.
4. The frequency at which the impulses can be safely repeated.

1. *Wave shape.* The tests by Knowles and McNall were made with a rectangular impulse wave. In actual practice a variety of waves is likely to be found, some of which are shown in Figure 3. Although all of these waves have the same crest value and the same total time of current-flow, it is obvious that the effect of wave *A*, for instance, upon the sparking tendency and other characteristics of the tube is likely to be considerably different from that of wave *F*. Since it is obviously impracticable to establish a multitude of standards for all these wave shapes, a few typical ones will have to be selected as a basis for standardization; the choice will be determined largely by the wave shapes encountered in practical applications. A near rectangular or a sinusoidal wave, or both, may at times be selected for this purpose. In the application of tubes waves approaching a rectangular wave shape (see cases *C* to *G* of Figure 1) are at least as frequent as sine waves (*A* and *B*). The ease with which tests, especially life tests, can be made with a given type of wave should probably also have an important influence upon the final choice. Multiphase arrangements of single-anode tubes on 60-cycle circuits with at least six phases (six tubes) give a wave shape approximating a rectangular wave (Figure 1, case E_1), and thus seem to be very convenient for test purposes. Therefore, standardization with such a wave shape of the impulse as a basis seems advisable in addition to standardization with a sinusoidal wave shape. Tests for standards with shorter impulses can be made either by increasing the number of phases (tubes) or by using basic frequencies above 60 cycles, depending upon the case. (In case of rectangular waves the steepness of the wave front may have to be specified, as destructive cathode bombardment may result if full anode current is drawn in time less than ionizing time of tube.)

2. *The crest value of the impulse* has the advantage of simplicity over the use of rms or average values, since it obviates in many instances the necessity for calculating these latter values.

3. *The time of the individual impulse* may be expressed in units of time such as milliseconds or microseconds; this practice has the advantage of being most generally applicable to all conditions found in actual practice. However, in some applications it may be convenient to express the time in degrees of some standard frequency, such as 60 cycles. (If a near-rectangular wave with a peak value and time specified is used as a basis for standardization, a question naturally arises as to how a tube so rated can be applied to pulsations having different wave shapes, such as shown in Figure 3. A practical and safe method can be based on the assumption that current values below a certain percentage (possibly below 50 per cent) of the peak value will have but negligible effect upon either the sparking tendency or the life of the tube. If this is true, the time *t* during which the current exceeds such percentage can be safely considered the effective time of the impulse, as illustrated in Figure 3. For example, an application with a wave shape as in case *F* would use a tube standardized on a much shorter rectangular impulse duration than would be used in *D*, although the total time of the current flow is the same in both cases.)

4. *The frequency at which the impulses can be safely repeated*, either continuously or for a limited period, must be given with the rating data. The tests on sparking tendency by Knowles and McNall were carried on with single impulses. If several such impulses were to follow each other at very close intervals, their effect might approach that of one longer interval, and sparking might result. If on the other hand the impulses are repeated at not too frequent intervals, the only result is likely to be a slight increase of the temperature of the filament, which in general will have a favorable effect on the operation at the lower filament voltages and no particularly harmful effect at the higher filament voltages. If the impulses are repeated too frequently for extended periods, limitations may also be reached, because of exceeding the safe average or rms currents of the tube, or because the life of the tube is decreased below satisfactory values. Various other limitations may have to be considered in this connection. The maximum frequency of impulses at which any of the limitations are reached can be readily determined by test, so that usually it is not difficult to establish a maximum frequency that is safe. In many arrangements connected to commercial circuits with a definite frequency, such as 60 cycles, a pulsating frequency in each single-anode tube in excess of the circuit frequency cannot be readily obtained and therefore is not of any practical value.

Since this paper deals essentially with current ratings, little mention has been made of the voltage conditions in the tube. It is of course appreciated that the various factors relating to current ratings

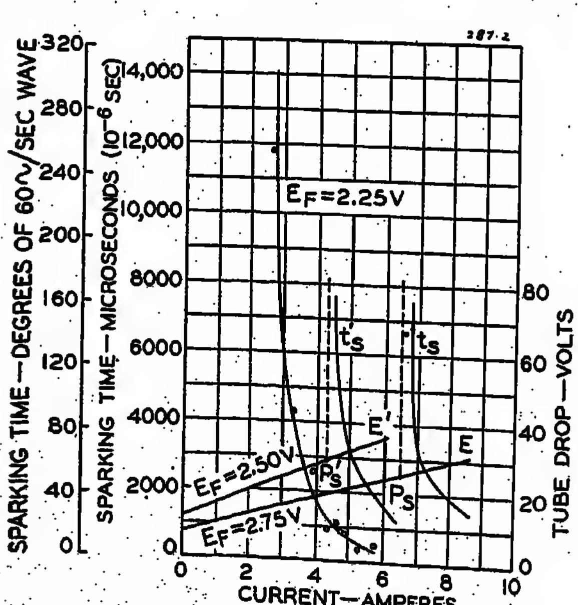

Figure 2. Current values dependent upon time above which cathode sparking may occur in a vapor-filled oxide-coated-filament tube

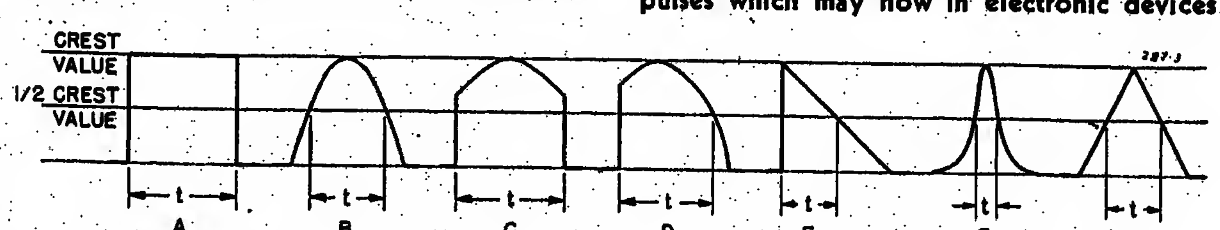
Figure 3. Typical wave shapes of current impulses which may flow in electronic devices



may be appreciably influenced by the operating voltage, the inverse voltage, the rate of rise of the inverse voltage, and so forth. This simply means that the complete rating structure must take such influences into account where they are of importance.

If pulsations as defined by the quantities previously discussed can be repeated continuously and without overheating the tube or any of its parts, no further information on the current rating is required. Practical applications of this kind are illustrated in E_1 and G_1 of Figure 1, as in these cases the average or rms values indicated are not likely to give unsafe temperatures. On the other hand, for applications A_1 and C_1 the average currents are likely to be in excess of safe values with continuously pulsating service. However, the current values of cases A_1 and C_1 can be safely applied for intermittent pulsating service, such as illustrated by cases A_2 and C_2. In rating tubes for such service, some additional rating information must be given. The most convenient method of rating to be applied here seems to be the duty-cycle method described in AIEE report No. 1-A. However, in applying this method to the case at hand, it requires some modification. The method calls for the specification of the maximum load time per duty cycle and a time factor k indicating the maximum ratio of load time or "on" time to the total time per load cycle. Due to pulsating nature of the load current, adherence to the exact wording of report 1-A would be confusing. In Figure 1 the time T_r indicates the time of the cycles during which pulsations occur, and T indicates the time of the total number of system cycles for one duty cycle. It is obvious that confusion can be avoided by giving the maximum permissible number of pulsations per load cycle and the ratio k of these pulsations to the total number of cycles of the system frequency per load cycle. These two values must be so chosen that satisfactory operation and life of the tube is assured. (Consideration has been given to the use of the service-factor method described in report 1-A, but it was found that the use of this method would unnecessarily complicate matters for the specific case without giving any compensating advantage. This really is to be expected, because the tube ratings under discussion depend upon many factors other than the rms current, which is one of the basic values of the service-factor method.)

In some respects the considerations up to this point have been specific to vapor-filled tubes with oxide-coated filaments. However, many of the conditions are the same as for most other types of tubes, at least qualitatively. Quantitatively, there may be marked differences, because the limitations are imposed by different physical phenomena. In an ignitron, for example, tendencies toward back-fire or the possibility of losing control of the tube by the ignitor will govern the amplitude and time of the current impulses and the permissible number of impulses per load cycle; the ratio of the permissible peak currents to the average and rms values is, however, many times larger than that with oxide-coated filament tubes; again various voltage conditions may influence some of the current ratings to a considerable degree. (While some of the restricting factors for the ignitron have been mentioned merely to point out certain differences, it should not be inferred that the ignitron involves more factors for satisfactory operation than a hot-cathode tube. A complete analysis is likely to indicate that on the whole the hot-cathode tube has more restrictions and complicating factors.)

Conditions with the cold-cathode tube are somewhat peculiar, as pointed out by G. H. Rockwood.[3] He gives a curve showing that with every load current of these tubes there is a certain total life in hours of current flow. He also indicates how the life of these tubes can be calculated from his curve for other than rectangular wave shapes. With this information it is possible to calculate for any required type and amplitude of load current the percentage of idle time which must be allowed for to assure a desired total life of the tube. In this manner the time factor k can be determined. There is no need in this case to specify the maximum number of impulses per load cycle, because the "on" time can be distributed in any desirable manner over the entire life of the tube. It will thus be seen that even the cold-cathode tube, although very different from the mercury-pool or the hot-cathode tube may be fitted into the general pattern of rating structure previously described.

The method of rating single-anode tubes suggested here should enable the designer of tube circuits to apply the tubes to best advantage. It unfortunately means the assignment of a number of different ratings corresponding to a variety of practical applications encountered. However, there seems to be no way of avoiding this with the many different phenomena and considerations entering into the operation of tubes. Any attempt to pattern tube ratings after the familiar type of ratings of most electromagnetic apparatus is contrary to the basic principles involved and therefore bound to result in misapplications or uneconomical use of the devices. If single-anode tubes are used by themselves, as may be the case with half-wave rectification, it may be advisable to give in addition to the rating structure described, the rms current and possibly the average current for the various ratings to assist in the selection of conductors, protecting devices, and so forth, connected in the tube circuit.

Rating of Tube Combinations and Circuits

For many practical applications, several single-anode tubes are used in combination, and in addition other apparatus such as transformers, reactors, capacitors, resistors, and so forth, are often employed in the combination, which has either a certain output as in the case of rectifiers or inverters, or a certain carrying-capacity as in applications involving control functions. The heating of most of the additional apparatus is determined by rms current values and usually the output or carrying-capacity of the entire combination in rms values is of principal interest to the user. (There are some exceptions to this, for instance, battery chargers, where the average current value is of importance.) For these reasons, and also because most users are accustomed to rms ratings, it is usually desirable to base the ratings of the combination arrangements wherever possible on rms values unless the load is of a type requiring pulsations, such as the ignitor circuit of an ignitron. (See G_2 of Figure 1.) For cases B_1, D_1, and F_1 of Figure 1, a continuous rms rating can readily be given, and for cases B_2, D_2, and F_2 the assignment of an intermittent or load-cycle rms current rating seems to be desirable. In most applications similar to D_1 and F_1 the difference between the rms and average ratings is of little practical importance, and in cases like B_1 filters are often used and minimize the difference. In B_2, D_2, and F_2 it is necessary on account of the tube characteristics previously discussed to specify the maximum duration of the "on" period per load cycle. It thus seems simplest to complete the rating structure by merely adding the time factor k, which is also limited by the tube characteristics as previously outlined.

Whenever additional apparatus is used in the circuit combination, certain rating limitations may be imposed by this apparatus. This may at times result in the

assignment of a time factor k smaller than that called for by the tubes. For the purpose of selecting certain standard devices such as fuses, switches, and so forth, connected in series with the tube device, the rms currents corresponding to the various load-cycle ratings should be known. Although with the factor k specified, the service factor can be readily calculated, it may nevertheless be desirable to give in the rating structure the service factor in addition to the time factor k. However, the service factor here cannot, as in most other apparatus, be construed as meaning that the "on" current and the "on" time can be varied at will as long as the service factor rms value is not exceeded. (Careful study of individual types of tubes and tube combinations may disclose some cases where this interpretation can be used. For the sake of flexibility in application, it is of course desirable to at least explore in many cases the possibilities of service-factor ratings which permit variation of current and time values at least below the rated current, and preferably also above this value, within the limit of an rms rating indicated by the service factor.)

Unfortunately the load-cycle method proposed is not very flexible in its application. It restricts the application of each load-cycle rating to but a limited variety of load-cycle conditions. The time $T = T_r/k$ (in which T_r is the specified maximum "on" time per load cycle) corresponds in some ways to the so-called "averaging" time used to some extent in tube specifications. Satisfactory results will be obtained with the rated current, if there are several load cycles instead of one during the time T, as long as the ratio of the total "on" time T_r to T does not exceed the value k. Additional load-cycle ratings have to be given for applications with different current values.

It may be advisable to illustrate briefly here the rating and application method for cold-cathode tubes. Assuming, for instance, a current of 50 milliamperes in the tube described by Rockwood, the life is found to be about 42 hours a tube. Therefore, if six such tubes are used in a six-phase arrangement, giving approximately rectangular wave shapes for the impulses of each tube, the combination would have a life of about 250 hours at 50 milliamperes. This, then, simply means that if a tube combination of this type is applied in service where a life of 10,000 hours is required, the factor k should not exceed the value of 0.025, which may be entirely practical for the relay service mentioned by Mr. Rockwood. For this case the maximum "on" time per load cycle could be given as 250 hours, although this would be of no practical significance in the usual relay application having a large number of short operating periods. The principal condition is that during the 10,000-hour life the total load time does not exceed 250 hours. (This is merely given as an illustration. With the relay service under consideration by Rockwood, an arrangement of one or two tubes is more likely to be used, and in such cases the impulses will be sinusoidal.)

The examples in Figure 1 all deal with rectification. Another function of tubes is that of switching or controlling alternating current for such purposes as spot welding, for instance. The individual single-anode tube here again carries pulsations which are either sinusoidal half waves as in Figure 3B, or sinusoidal waves with delayed starts as in Figure 3D. The current handled by the usual 2-tube combination is alternating instead of direct current as in cases B_2, D_2, and F_2 of Figure 1, and the load is as a rule intermittent. The operation of the individual anodes is the same as previously discussed; the conditions with regard to multianode arrangements are different only in so far as the current ratings for the combination should be expressed in rms values of alternating current, with all other factors handled as previously indicated.

Summarizing, the rating structure suggested here comprises:

The above rating structure for continuous loads of single-anode tubes is not proposed to the exclusion of the present method of giving the average current for continuous ratings of tubes. It is intended essentially for cases where it results in more economical application of tubes than the conventional method, or where it is found more convenient. The use of the rating structure on the left side of the table is not necessarily limited to single anodes. It may also be found convenient for multianode arrangements primarily intended for supplying pulsations. If it should happen with cases G_1 and G_2 of Figure 1, for instance, that a single tube does not permit a frequency of pulsations high enough for a given application, a two-tube arrangement can be used to good advantage and may then be rated as indicated on the left side of the table. The rating structure on the right side is intended for all cases where direct or alternating currents are desired, and where pulsations or harmonics may or may not be present as an undesirable by-product of the circuits employed.

For load-cycle ratings the nominal rating is the value of the current during the load or "on" period of the load cycle. The service factor S is the ratio of the rms current for the entire time of the load cycle to the nominal rms current value during the "on" period.

Whenever tubes have a limited life, the

5. Maximum number of impulses per load cycle (or equivalent time)	2. Maximum active time per load cycle
6. Time factor k	3. Time factor k
	4. Service factors in addition to k

In devising a system of ratings, it must be considered that under many conditions the maximum "on" time T_r per load cycle and the time factor k are interdependent. Usually k has to be decreased with an increasing value of T_r. This is always the case when heating considerations are the determining factor. (See references 4 and 5 which demonstrate this in connection with machines and other apparatus. For tubes this is more fully discussed in a companion paper by Marshall and Arnott.[6]) For this reason T_r should not be chosen any larger than necessary for practical applications. By keeping T_r low, the value of k is favorably affected.

expected life in hours must necessarily enter into the rating structure somehow, because the choice of the quantities given in the table may be materially affected by the assumed life. A typical example of this is the cold-cathode tube previously described.

As a rule, all of the quantities of the table except the service factor S, which may be given for convenience, are essential to definitely limit the application of the device to service it can handle satisfactorily. (There are a few exceptions to this, such as the cold-cathode tube where the indication of the maximum active time per load cycle is of no practical im-

portance.) However, the importance of the different quantities may vary appreciably with different tubes and applications, as may the reasons why the factors must be limited to the values given. In hot cathode tubes, for instance, the crest value of the impulses is quite a decisive value, while in many other types of tubes the maximum crest value is not such an important limitation. The maximum active time per load cycle may be primarily limited by heating considerations of various structural parts in hot-cathode tubes, while back-fire considerations or loss of proper control (also largely influenced by heating) may be most essential in some pool-type tubes. The time factor k, which determines the minimum idle periods, may be chiefly determined by heating consideration in a hot-cathode tube, while in a cold-cathode tube its value is determined essentially by the expected life of the tube. However, regardless of what these numerous variations may be, it seems that the suggested rating structure satisfies almost every conceivable condition that could be encountered in practice with continuous or intermittent service, although some exceptions to this can undoubtedly be found. It is fully realized that many factors (especially various voltage conditions) not discussed here in detail will have to be given careful consideration in the setting of current ratings. It is obvious that in the brief review of rating structures given here it would be impractical to attempt a comprehensive treatment of all phenomena involved. Some of the more important considerations not covered here will undoubtedly be pointed out in the discussion.

With the load-cycle current ratings so far discussed it has been assumed that they are intended for typical intermittent loads with definite requirements, as, for instance, the operation of relays designed for such current. Many applications like this are found in practice and can be taken care of by a single load-cycle rating. However, with many other tube arrangements, it may be desirable to give sufficient rating information to facilitate their application for a variety of intermittent service conditions. In Figure 4 the curve shown is intended to indicate the maximum "on" time permissible for a specific tube arrangement for various nominal load currents. Since it seems undesirable to list a great number of different current ratings, only a few, such as Pn_1, Pn_2, Pn_3, and Pn_4, are indicated in the figure. For each of these the maximum "on" time per load cycle can be given, as indicated by the values T_1, T_2, T_3, and T_4. In addition the value k would have to be given for each case. This then would make possible the application of the arrangement within its range of satisfactory performance for different applications, as intermediate values could be readily interpolated. A question arises, however, as to how a single nominal commercial rating should be selected for such a condition, especially for service where any of the loads are at times applied for considerable periods, as may occur with spot-welding arrangements for instance. There is not much choice between the different ratings in selecting one as a nominal commercial rating under these circumstances. The continuous rating P is so far from representing actual service conditions that it would not be a very satisfactory nominal rating. The maximum rating P_m is not very well defined because the time T_5 in Figure 4 may range from one cycle in the case of spot welding to the conventional period of one minute used in connection with the larger rectifier equipment.

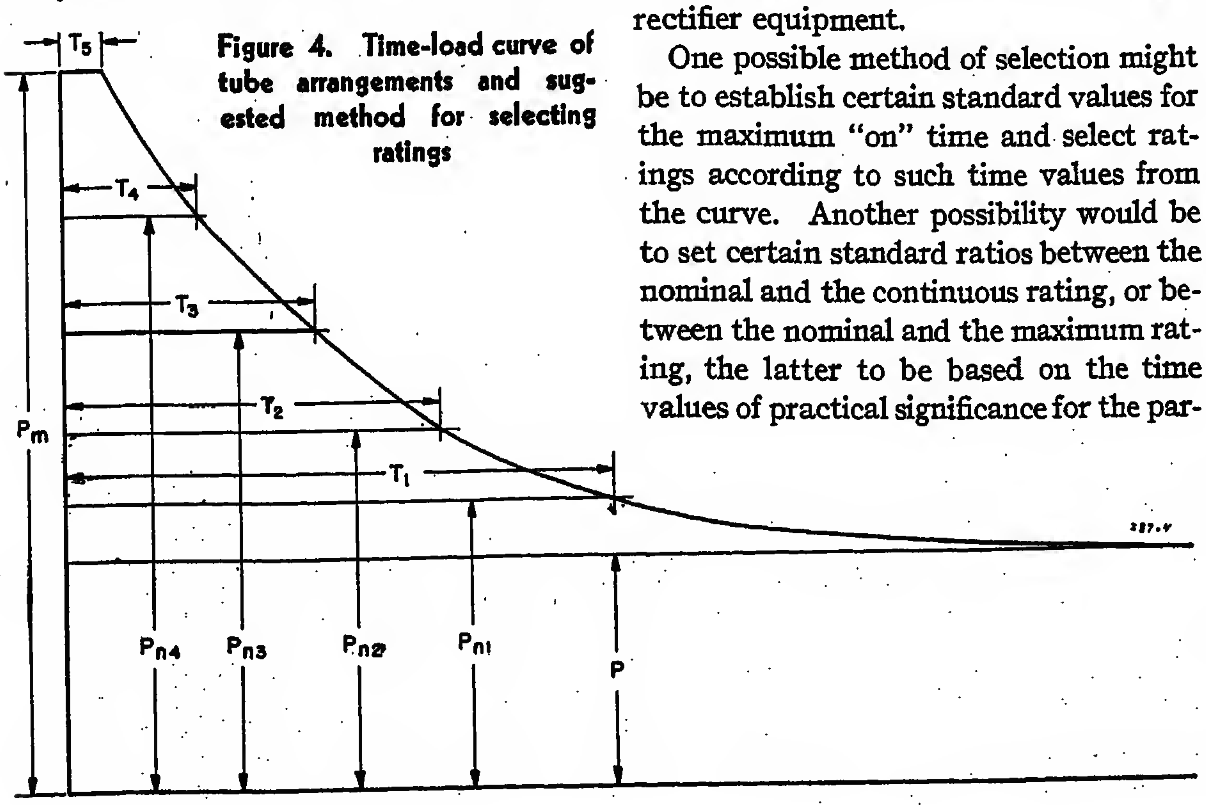

Figure 4. Time-load curve of tube arrangements and suggested method for selecting ratings

One possible method of selection might be to establish certain standard values for the maximum "on" time and select ratings according to such time values from the curve. Another possibility would be to set certain standard ratios between the nominal and the continuous rating, or between the nominal and the maximum rating, the latter to be based on the time values of practical significance for the particular type of tube or service, such as one cycle for spot-welding arrangements and one minute for large rectifying equipment. Some measure of uniformity could be accomplished by always using preferred numbers for these ratios, as indicated in Figure 4, where all the steps between the different ratings have been selected to be 25 per cent, corresponding to the coefficient of the ten series of preferred numbers. In this case the load Pn_3, which is about halfway between the continuous and short-time maximum rating, has been indicated by a heavy line to serve as the nominal commercial rating. It would seem highly desirable to devise some standard method for settling some of these questions, as it would greatly assist in the gradual evolution of a reasonably uniform method for electronic devices.

As previously stated, the suggestions given here are merely preliminary; final recommendations should not be given until considerably more work has been done in analyzing the various conditions. However, it is hoped that the brief outline will stimulate others to investigate various practical arrangements and applications for the purpose of determining whether the suggestions made here can be used, or whether they can be altered in some way to make them even more generally applicable. It is obvious that no system of rating applicable to all conditions can be devised; however, it seems entirely possible to develop a system capable of broad application and requiring only slight modifications for specific cases. At any rate, it should be possible to at least establish a nomenclature defining such terms as time factor, service factor, and so forth, which will be generally applicable and definite in its interpretation in all applications.

Ignitor Excitation Circuits and Misfire Indication Circuits

Synopsis: Several circuits are available for excitation of ignitron rectifiers. Static magnetic-impulse circuits are used for most applications. Several such circuits are discussed in some detail. Ignitor requirements are given, and circuit requirements affecting the choice of excitation circuits are indicated.

While ignitor failures are rare, they should be detected promptly to utilize all apparatus to the best advantage. Two conditions may arise

1. When two anodes operate in parallel from a single transformer winding.
2. When a single anode is connected to each transformer winding.

Means for detecting ignitor misfiring are described for both conditions.

An ignitron is an electric valve in which the cathode spot or electric arc is established every cycle at the beginning of the conduction period of the main anode and is allowed to extinguish

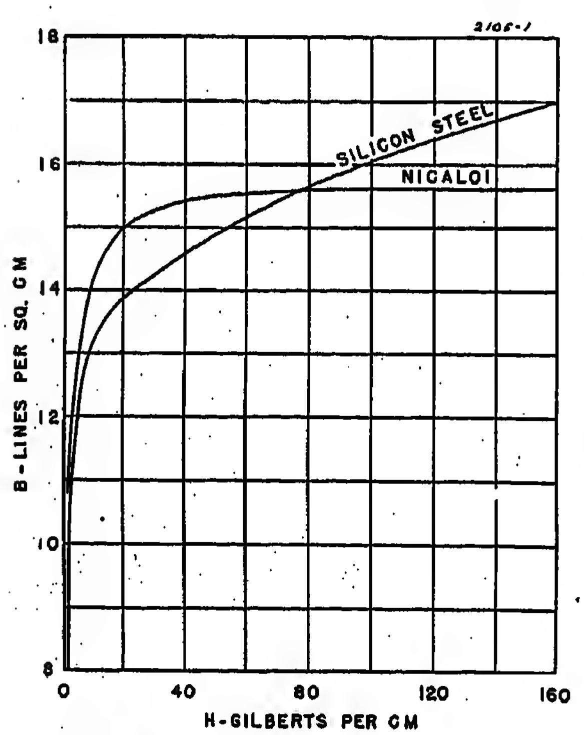

Figure 1. D-c magnetization curves

at the end of the conduction period. The arc is established by means of an ignitor, which is an element made of a high-resistance material and partly submerged in the cathode mercury pool. The ignitor is excited or fired by passing an electric current of sufficient strength through it into the cathode to establish a cathode spot or arc. Static magnetic-impulse excitation circuits have certain definite advantages over other ignitor excitation circuits.[1,2] The circuits here described satisfy certain operating conditions.

As current is built up in the ignitor to the firing value, power is consumed by the ignitor. At the instant the cathode spot appears most of the ignitor current transfers to the electric arc instead of passing through the whole length of the ignitor to the cathode, and the voltage across the ignitor suddenly collapses to arc-drop value. It is therefore desirable to build up the ignitor current rapidly to the firing point to limit the losses and the heating of the ignitor. Further, since the ignition current varies considerably from cycle to cycle, a rapid build-up of ignitor current will result in a more uniform firing angle.

Magnetic-Impulse Excitation Circuits

To obtain a rapid build-up of current or peaked current wave, a nonlinear reactor is used.

In the high impedance region of such a reactor, that is, below its saturation point, there is substantially no ignitor current. As the impedance decreases, the rate of change of ignitor current increases. An abrupt transition to a peaked current wave requires a sharp knee in the magnetization curve of the reactor; a rapid rise of current requires a low saturated reactance. The use of an alloy such as Nicaloi (see Figure 1) and a well-interleaved core construction result in

1. Sudden initiation of impulse current.
2. A maximum ratio of unsaturated to saturated reactance values. A capacitor may be used as a storage reservoir so that other circuit reactance will not reduce the rate of rise of the firing impulse current.

In Figure 2 is shown a magnetic-impulse ignitor excitation circuit. Here a nonlinear reactor X_{NL} is used for each ignitor. This is necessary, because the reactor is biased with d-c ampere-turns to obtain a high peak current in the a-c winding in one direction but not in the other. The high peak current is allowed to pass through the ignitor in the positive direction, that is, from ignitor to cathode, while the low negative current is blocked by a dry-plate rectifier in series with the ignitor and instead flows through the linear reactor X_L. This circuit gives a peaked current wave having a base 60 electrical degrees long, that is, the arc is maintained for 60 electrical degrees of the fundamental frequency. In order to relieve the ignitor and the rectifier in series with the ignitor of this current after the arc has been established, a relieving anode and transfer resistor R_3 are used. The resistance R_4 reduces the inverse voltage impressed on the rectifier. The resistance R_2 limits the current in the circuit. Voltage control of the d-c output of an ignitron rectifier can be obtained by retarding the firing of the ignitors. The capacitors and resistance connected between the power supply and the primary of the transformer T, together with the amount of d-c saturation of the nonlinear reactors X_{NL}, permit voltage control by shifting of the ignitor firing.

The vector diagram shows how this shifting of phase is accomplished. Vector 1-4 is the voltage impressed on the primary of the transformer, and vector 4-3 the voltage impressed across the condenser C_1, and triangle 1, 2, and 3 represents the three-phase supply voltage. As the saturating current in the nonlinear reactors is increased, the point 4 travels

on the locus, 4, 4′, and 4″. Thus the voltage impressed on the transformer advances as the saturating current is increased, and therefore the angle of ignitor firing advances with increasing saturating current. The purpose of resistance R_1 is to hold the amplitude of the voltage E_3 more nearly constant. The advantage of this firing circuit is the long period over which the arc is maintained.

Figure 3 shows an excitation circuit in which one nonlinear reactor X_{NL} is used to fire two ignitors. The nonlinear reactor is allowed to saturate in both directions, thus giving peak currents in both directions. An autotransformer T_2 is used to provide a return path for the ignitor current from the cathodes of the ignitrons. In case the cathodes must be insulated from each other, this can be done by making the autotransformer an insulating transformer as shown in Figure 3b. The shifting of the angle of ignitor firing in this case is accomplished by a saturable reactor X_s, together with a capacitor C_1. The resistances R_1 and R_2 keep the voltage wave across the transformer T_1 symmetrical and in this way insure that the two ignitors will fire 180 electrical degrees apart. Capacitor C_2 helps to increase the peak volt-amperes delivered to the ignitors.

In the vector diagram, E_3 is the voltage impressed on the transformer T_1 with low saturating current in the saturable reactor, E_2 is the voltage across the capacitor C_1, E_4 is the voltage across the a-c winding on the saturable reactor, and E_1 is the line or supply voltage. As saturating current in the saturable reactor is increased, the a-c voltage across the saturable reactor decreases, and the voltage across the capacitor C_1 increases as shown by the dotted vectors. The voltage E_3 on the transformer advances from E_3 to E_3' and consequently the ignitor firing advances. The voltage drops across the resistances R_1 and R_2 are neglected to simplify the diagram. In this firing circuit the arc is maintained for about 25 degrees. The advantages of this circuit over the one shown in Figure 2 are that the power consumed is less and the apparatus is smaller.

Figure 4 shows still another type of excitation circuit which shortens up the period over which the arc is maintained to about 18 degrees. This reduces the power drawn by the circuit still further, being only about 200 watts per ignitor. A modification of the autotransformer similar to Figure 3b will provide for insulated cathodes. The phase-shifting network consists of a saturable reactor X_S, a linear reactor X_1, and a capacitor C_1.

The vector diagram shows how the voltage E_3 varies in phase, with substantially constant amplitude as the voltage vector E_2, which is the a-c voltage across the saturable reactor, is changed in amplitude by means of the d-c saturating winding. The angle of firing of the ignitors shifts with the angle of the vector E_3.

Figure 4c shows the current in the nonlinear reactor, the voltage impressed on the ignitor, and the supply voltage.

Sometimes it is desirable to operate the main anodes of two ignitrons in parallel, and in that case the ignitors must be fired simultaneously in order that the main anodes will divide the current equally. This is best accomplished by firing four ignitors from one ignitor excitation circuit as shown in Figure 5. The current dividing autotransformer T_3 causes the two ignitors connected to the ends of the same transformer to be fired practically simultaneously. If the other transformers, reactors, resistors, and capacitors in the excitation circuit are built for the same voltage, but twice the current rating, we will have a circuit that is twice the size in kilovolt-ampere rating and will draw twice as much current and power from the line to fire twice as many ignitors. However, it has been found that the peak volt-amperes that this circuit is capable of delivering to a hard firing ignitor have been practically doubled. There is therefore a distinct advantage when operating ignitrons in parallel in firing their ignitors by this arrangement.

In order that various kinds of ignitor excitation circuits can be compared, it is necessary to have some way of measuring the peak voltage and current that the circuit is capable of delivering to the ignitor. In a circuit designed to use relieving anodes a variable resistance is connected in series with one ignitor between the ignitor and the blocking rectifier. In case the circuit is designed to operate without relieving anodes, a relieving anode should be used during this test connected as shown in Figure 6. This variable resistance can then be considered as being part of the ignitor, and the two together represent a high-resistance ignitor. The amount of current required to fire the ignitor can be varied by changing the depth of immersion of the ignitor in the cathode. With deep immersion a high current is required, and with shallow immersion a low current. For each different ignitor immersion depth, the resistance R is increased to such a value

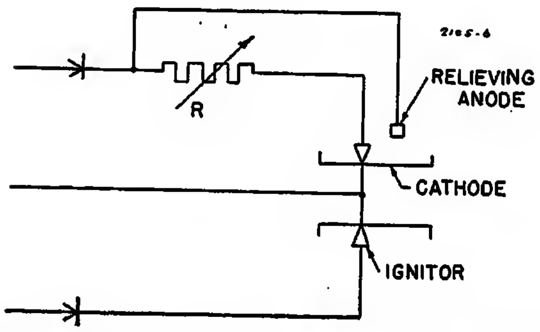

Figure 6. Circuit for measuring output of excitation circuit

that the ignitor misfires occasionally. With this setting the peak voltage across the resistance and ignitor is measured during a misfire. This is the peak voltage the circuit is capable of delivering simultaneously with the peak current. The peak current is determined from the voltage across R. A curve can then be plotted showing the peak current and the peak voltage the circuit is capable of delivering to the ignitor. Such curves are shown in Figure 7. A circuit test made by substituting a resistance for the ignitors can give misleading results, because a resistance does not have the nonlinear characteristic of an ignitor at the instant of firing.

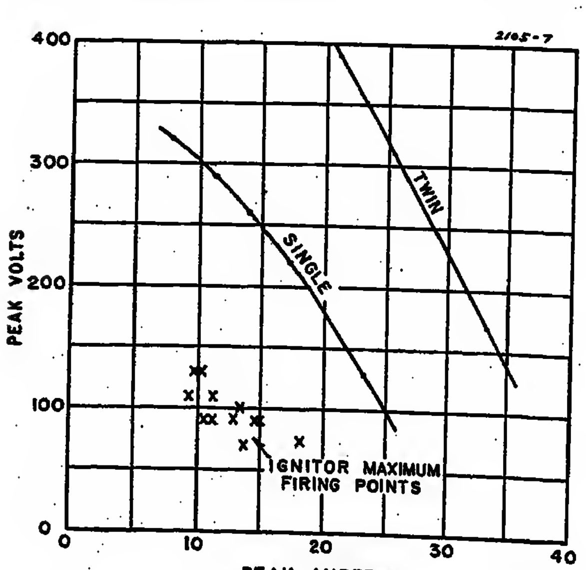

Figure 7. Volt-ampere output curves of excitation circuit Figure 4 and modification as in Figure 5, with maximum firing points of typical ignitors

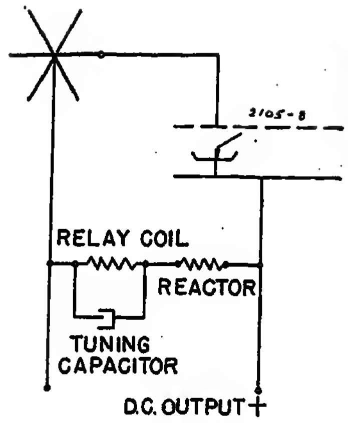

Figure 8 (left). Detection of ignitor misfire by fundamental - frequency component in d-c ripple

Figure 7 shows the peak volts and amperes that a typical circuit as in Figure 4 is capable of delivering to the ignitors. The curve labelled "single" is for the circuit as shown in Figure 4 and the curve labelled "twin" is for the circuit in Figure 4 when modified according to Figure 5 and using apparatus with twice the current rating. The points indicated by crosses in Figure 7 represent maximum peak voltage and current to fire typical ignitors. This shows that the circuit is putting ample power into the ignitors.

Detection of Excitation Failure

During operation of an ignitron rectifier one or more anodes may fail to conduct, due to a fault in the ignitor firing circuit or in one of the ignitors. Failure may be occasional or persistent.

Persistent misfire of one anode in a rectifier where two anodes are operating in parallel results in increased load being carried by the companion anode with a corresponding increase in arcback probability. In other circuits misfire of an anode may result in increased duty on one or more of the other anodes, with

1. Corresponding greater arcback probability.
2. Increase in transformer heating.

In any case, an indication of faulty operation is desirable, so that the fault may be remedied and normal operation continue.

Excitation failure may be detected by:

1. Action of the power circuit.
2. Action of the excitation circuit.
3. Action of auxiliary electrodes in the rectifier.

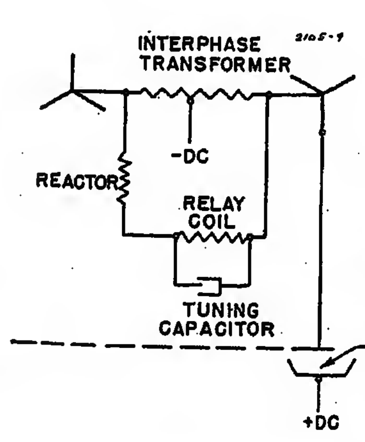

Figure 9 (left). Detection of ignitor misfire by fundamental - frequency component in interphase transformer voltage

I. Detection of Excitation Failure by Action of the Power Circuit

1. If one anode of a rectifier fails to fire, there will be a component of supply frequency in the d-c voltage ripple. The magnitude of this component will depend on the number of phases of the rectifier and the nature of the load. A relay connected to the d-c output voltage and having its coil tuned to the supply frequency will indicate misfire. This circuit is shown in Figure 8. A variation of this arrangement is to connect the tuned relay across a d-c reactor in series with the load. Either arrangement is most effective when the number of phases is small, and the d-c load is fairly reactive.

2. When an interphase transformer is included in the rectifier circuit, a voltage component of supply frequency occurs across the interphase transformer during misfire. A relay or other indicating device tuned to the supply frequency and connected across the interphase transformer will indicate the presence of a missing anode. The connections are shown in Figure 9. In a quadruple-wye circuit, an induction relay with two tuned coils may be used, each coil being connected to one of the 180-cycle interphase transformers.

3. Figure 10 shows a circuit which utilizes the increased positive voltage between anode and cathode, when the anode does not fire. This arrangement is most suitable for rectifiers operating without phase retard.

4. Figure 11 shows a circuit where unbalance between the neutral currents of a double-wye rectifier saturates a reactor and decreases its impedance.

5. Missing of an anode in one wye of a double-wye rectifier generally results in a disproportionate decrease of current in the other anodes of that wye. This is the basis of the circuit in Figure 12, which is affected by the difference between anode currents in the two wyes.

6. The missing of one anode will result in unequal currents in the supply line. This

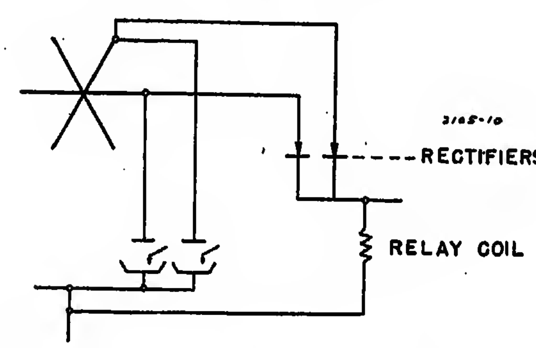

Figure 10. Detection of ignitor misfire by positive voltage of missing anode

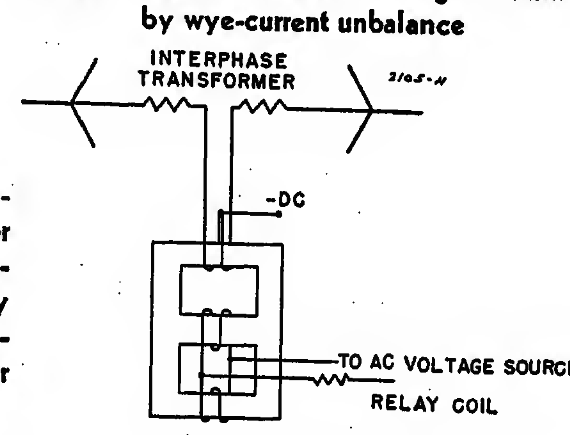
Figure 11 (below). Detection of ignitor misfire by wye-current unbalance



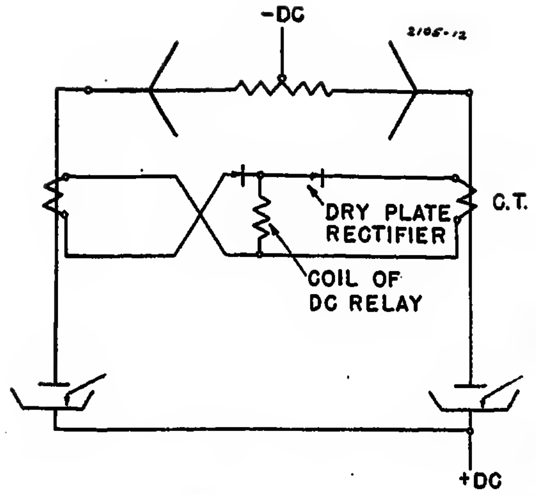


Figure 12. Detection of ignitor misfire by anode-current unbalance

may be recognized by visual observation of line ammeters or by a negative-phase-sequence relay. Operation of a double-wye rectifier circuit on five anodes results in a large negative-phase-sequence second harmonic component, due to the unbalance between the two secondary wyes. A negative-phase-sequence relay is less useful for misfire detection as the number of phases is increased.

7. When two anodes are operated in parallel from the same transformer winding, it is possible to utilize the current-dividing reactor, if one be used, as an indicator of misfire. Failure of an anode to fire would result in a much higher voltage than normal across the current-dividing reactor. This voltage may be utilized to operate an indicating device. Another method of using the current-dividing reactor is to design the reactor so that the core acts as the magnet of a relay and design the relay structure so that there will be sufficient flux to attract the armature only when the unbalance between the anode currents corresponds to misfire of one anode at 50 per cent or more load on the rectifier. Figure 13 is a photograph of such a reactor.

8. Another method of detecting misfire in the case of parallel anodes is to connect in each anode lead a current transformer designed to permit open circuit operation. If the secondaries are connected in opposition, there will be no voltage when both anodes fire, but a resultant voltage if one is missing. This may be used to operate a suitable relay. The resultant voltage will be present if all the pairs of oppositely connected secondaries are joined in series.

It should be noted that the above schemes for detecting missing of one of a pair of parallel anodes will not detect simultaneous missing of both anodes. Such missing will require one of the previously described circuits.

9. When a rectifier is carrying a steady load, as in electrolytic processes, and anodes are not operated in parallel, missing of an ignitor may be detected by observation of the d-c ammeter in the output circuit of the rectifier. This will show a distinct flicker each time misfire occurs. The anode transformer also gives an audible indication of misfire.

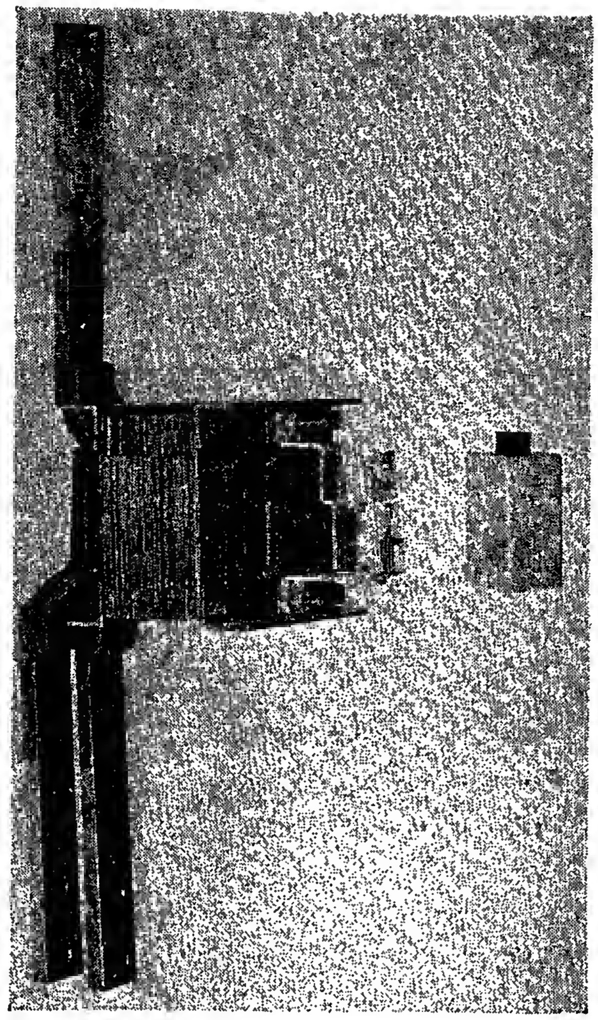

Figure 13. Combined current-dividing reactor and misfire-detection relay

II. Detection of Excitation Failure by Action of the Excitation Circuit

Failure of an element of the excitation circuit may result in one of a number of conditions, depending upon the nature of the failure. Since the ultimate purpose of failure detection is to determine if an ignitor is missing, the preferred location of a misfire device is in the circuit of the ignitor itself. Such a device becomes involved as it must function during

1. Ignitor short circuit.
2. Ignitor open circuit.
3. Insufficient power to fire ignitor.

Moreover, there must be one such device for each ignitor. Action of some other circuit than the excitation circuit appears desirable for misfire detection.

III. Detection of Excitation Failure by Action of Auxiliary Electrodes in the Rectifiers

The ignitron rectifier cell usually has an anode baffle which is excited from a different source than the other electrodes. Since current cannot flow in the baffle circuit unless a cathode spot is formed, current indicating means in series with the baffle or voltage indicating means across the baffle resistor will detect misfire.

Location of Missing Ignitor

With the exception of the scheme just described for indicating the presence of baffle current, the above misfire indication circuits do not indicate the specific ignitor which is misfiring. If an oscilloscope is at hand, missing may be located by observation of ignitor voltage. A clampon or tong ammeter may be used to detect current in the main anode. If a low-reading tong ammeter is available, it may be used to measure the current in the baffle. A compass held near an anode bus will show when an anode is not firing.

Conclusion

Static magnetic-impulse excitation circuits have definite advantages in many applications of ignitron rectifiers. Three circuits which have been described have different modes of operation, and their choice is determined by operating requirements. Excitation circuits are generally designed with an ample margin of power over ignitor requirements and in twin circuits for parallel operation. This margin is automatically increased for hard-firing ignitors.

An ignitor may stop firing even with ample excitation power. This condition may be detected in a number of ways. A choice of methods is available for specific applications.

Formulas for Calculating Short-Circuit Stresses for Bus Supports for Rectangular Tubular Conductors

THOMAS JAMES HIGGINS
ASSOCIATE AIEE

THE mechanical forces acting on bus-bar supports during short circuit are determined in some measure by all of the following:

The magnitude and decrement factor of the short-circuit current.

The mutual electromagnetic forces exerted among the individual conductors.

The natural frequencies, motional resistance, and physical arrangement of the bus-bar structures.

A theoretical treatment, substantiated by experimental data, of the individual and collective effects of these factors on the magnitude of bus-bar support stresses and a method of calculating numerically these effects are to be found in a comprehensive paper by Schurig and Sayre.[1] In shorter articles based on the just mentioned paper Schurig, Frick and Sayre,[2] Tanberg,[3] and Specht[4] have presented certain charts, nomograms, and short-cut methods facilitating the numerical calculations involved in an actual problem. However, regardless of the method of calculation adopted, a determination of bus-bar support stress yet requires calculation of the electromagnetic forces exerted on the conductors carried on the support.

The mutual electromagnetic force exerted between two isolated, long nonpermeable conductors, spaced D inches between their parallel axes and carrying direct currents of I and I' amperes, is commonly calculated from the formula

$$f = (5.4kII'/D)10^{-7} \text{ pounds per foot of bus length} \quad (1)$$

or, if absolute units are used, from

$$f = 2kII'/D \text{ dynes per centimeter of bus length} \quad (2)$$

Herein k is a parameter, a variously named constant, of magnitude determined by the geometry and relative position of the two conductor cross sections. In a group of conductors the force acting on any one conductor is calculated by using equation 1 to compute in turn the force exerted on the conductor by each of the remaining conductors and then adding these forces vectorially. If alternating instead of direct currents flow in the conductors, then providing f, I, and I' are taken as instantaneous values, and providing skin and proximity effects are negligible—this latter condition is commonly satisfied if rectangular tubular conductors are used and is sufficiently satisfied for strap conductors if, as is usual, the bus bar considered is either a single nonlaminated strap or is constructed of properly transposed laminated conductors—equation 1 is yet used, and k is the same as for direct currents. Accordingly, simple arithmetic aside, determination of the *electromagnetic* force acting on a given support reduces, in essence, to determination of the needed values of k.

Of essential interest to the designer of polyphase bus structures are the values of k for a group of identical conductors of solid or tubular rectangular cross section with axes in a plane. The formula for k for conductors of *solid* rectangular cross section was derived a quarter of a century ago; as regards rectangular tubular conductors, no formula for k seems to have been published hitherto. Yet as the mechanical and electrical advantages stemming from use of this cross section have resulted in an extensive and currently increasing use of it for feeding heavy current loads—to be noted in particular is its use in new bus installations supplying batteries of welders (in airplane, tank, and automobile factories) and banks of electric furnaces (for alloy and tool steels, aluminum, and various other metals) necessitated by the defense program—it is most desirable to have formulas with which one can quickly calculate the value of k for any conductor spacing or rectangular cross section. Such formulas are derived in this paper.

It is assumed that the conductors are nonmagnetic, right-cornered, and of such length that end effects are negligible, and that they carry currents uniformly distributed over the cross sections of the individual conductors. Of these assumptions all but that of right-corneredness are consistent with or are closely approximated in current practice. But although rounded corners are found on rectangular tubular conductors—to minimize "edge effect"—treating them as right-cornered introduces error negligible with reference to the accuracy required in calculating bus-bar stresses and enables solution of an otherwise intractable problem.

As regards values of k for strap conductors (which usually have right corners), the formulas derived in this paper—a strap conductor is a special case of a rectangular tubular conductor—offer an attractive alternative to the means of determination now used: curves, found in the references previously cited and in most electrical handbooks, these being plotted originally by Professor H. B. Dwight[5] from the above-mentioned formula derived by him. It is illustrated in section III that from equations 17 or 18 one can calculate rapidly, with but *pencil* or *slide rule*, the value of k for two symmetrically located, identical strap conductors.

The mentioned formulas for solid and tubular rectangular conductors obtained, ease and rapidity of use are illustrated by the numerical solution of several problems typical of bus design.

I. The Formal Solution for k

As derived in a previous paper by the writer,[6] the electromagnetic energy associated with a unit length of an isolated circuit constructed of two identical rectangular tubular conductors, symmetrically located as in Figure 1, is

$$W = w^2[W(r, s)+W(R, S)+2W(t, S+t)+2W(R+t, t)-2W(R+t, S+t)-2W(t, t)] \quad (3)$$

where, typically, $W(r, s)$ is defined by

$$W(r, s) = (1/6)[2F(D, s)-F(D+r, s)-F(D-r, s)+2F(r, s)-2F(0, s)+4\pi r^2 s(3D-r)] \quad (4)$$

and, typically, $F(r, s)$ is defined by

$$F(r, s) = (r^4-6r^2s^2+s^4) \log (r^2+s^2)^{1/2}+4rs(r^2-s^2) \tan^{-1} (r/s)-r^4 \log |r| \quad (5)$$

All units are in the absolute system: the current density w in abamperes per square centimeter; D, r, and s in centimeters; W in ergs per centimeter of line length.

As is well-known, the mutual electro-

Paper 42-142, recommended by the AIEE committee on basic sciences for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted February 13, 1942; made available for printing May 19, 1942.

THOMAS JAMES HIGGINS is assistant professor of electrical engineering, The Tulane University of Louisiana, New Orleans, La.

magnetic force exerted between the two conductors is given by

$$f = \partial W/\partial D \text{ dynes per centimeter of bus length} \quad (6)$$

Equating equations 2 and 6 and solving for k yields

$$w^2 k = [D/2(rs-RS)^2]\partial W/\partial D \quad (7)$$

Substituting equation 3 in equation 7 gives

$$k = [D/2(rs-RS)^2]\left[\frac{\partial W(r, s)}{\partial D} + \frac{\partial W(R, S)}{\partial D} + 2\frac{\partial W(t, S+t)}{\partial D} + 2\frac{\partial W(R+t, t)}{\partial D} - 2\frac{\partial W(R+t, S+t)}{\partial D} - 2\frac{\partial W(t, t)}{\partial D}\right] \quad (8)$$

From equation 4 we have

$$\frac{\partial W(r, s)}{\partial D} = (1/6)\left[\frac{\partial}{\partial D}\{2F(D, s) - F(D+r, s) - F(D-r, s)\} + 12\pi r^2 s\right] \quad (9)$$

The bracketed expression in equation 9, considered as a function of r alone, can be expanded in a power series about the point $r=D$. Substituting this expansion in equation 9 we have

$$\frac{\partial W(r, s)}{\partial D} = (1/6)\left[\frac{\partial}{\partial D}\left\{-r^2\frac{\partial^2 F(D, s)}{\partial D^2} - \frac{r^4}{2\cdot 3!}\frac{\partial^4 F(D, s)}{\partial D^4} - \frac{r^6}{3\cdot 5!}\frac{\partial^6 F(D, s)}{\partial D^6} - \ldots\right\} + 12\pi r^2 s\right]$$
$$= (1/6)\left[-r^2\frac{\partial^3 F(D, s)}{\partial D^3} - \frac{r^4}{2\cdot 3!}\frac{\partial^5 F(D, s)}{\partial D^5} - \frac{r^6}{3\cdot 5!}\frac{\partial^7 F(D, s)}{\partial D^7} - \ldots + 12\pi r^2 s\right] \quad (10)$$

The details of the expansion and expressions for the various derivatives, in terms of the dimensions and spacing of the conductors, are given in the appendix. Substituting appropriately in equation 10 and collecting terms, we have

$$\frac{\partial W(r, s)}{\partial D} = 2r^2\left[\left[2s\tan^{-1}(s/D) - D\log\left(1+\frac{s^2}{D^2}\right)\right] + \frac{r^4}{3}\frac{s^2}{D(D^2+s^2)} + \frac{r^6}{45}\left[\frac{1}{D^3} + \frac{-D^3+3Ds^2}{(D^2+s^2)^3}\right] + \ldots\right.$$
$$= 2DM(r, s) \quad (11)$$

where $M(r, s)$ is defined by

$$M(r, s)/r^2 = 2m\tan^{-1} m - \log(1+m^2) + \frac{n^2m^2}{6(1+m^2)} + \frac{n^4}{90}\left[1 + \frac{-1+3m^2}{(1+m^2)^3}\right] \quad (12)$$

where $m = s/D$ and $n = r/D$.

Substituting equation 11 in equation 8 yields

$$k = [D^2/(rs-RS)^2][M(r, s) + M(R, S) + 2M\times(t, S+t) + 2M(R+t, t) - 2M(R+t, S+t) - 2M(t, t)] \quad (13)$$

If $R=S=t=0$, we have solid rectangular conductors, and equation 13 becomes

$$k = (1/m^2r^2)M(r, s) \quad (14)$$

Having determined k—note that k is a dimensionless quantity; thus D, r, and s can be measured in any unit of length—the electromagnetic force f can be determined from equation 1.

II. Approximate Expressions for M(r, s)

In most calculations the conductor cross sections and spacing are such that in equation 11 the terms involving powers of n are negligible. If so, equation 12 reduces to

$$M(r, s)/r^2 = 2m\tan^{-1} m - \log(1+m^2) \quad (15)$$

Although equation 15 can be calculated directly by the aid of appropriate tables or by use of a slide rule, it is more desirable to have $M(r, s)/r^2$ expressed directly in powers of m. Accordingly, substituting in equation 15, the usual power series for $\tan^{-1} m$ and for $\log(1+m^2)$ and collecting terms, we have the more desirable form

$$M(r, s)/r^2 = m^2 - m^4/2\cdot 3 + m^6/3\cdot 5 - m^8/4\cdot 7 + \ldots \quad (16)$$

where $m<1$.

Substituting equation 16 in equation 14 we have for solid conductors

$$k = 1 - m^2/2\cdot 3 + m^4/3\cdot 5 - m^6/4\cdot 7 + \ldots \quad (17)$$

where $m<1$.

Occasionally, in equation 12 the term in n^2 is not negligible in comparison with the first two terms. In this case, expanding $(1+m^2)^{-1}$ in powers of m and adding to equation 16 we have

$$M(r, s)/r^2 = m^2\left(1+\frac{n^2}{6}\right) - m^4\left(\frac{1}{6}+\frac{n^2}{6}\right) + m^6\left(\frac{1}{15}+\frac{n^2}{6}\right) - \ldots \quad (18)$$

where $m<1$.

III. Some Illustrative Examples

Example 1

Conductors a, b, c of a three-phase bus are of four- by one-half-inch strap, spaced six inches between adjacent axes, with four-inch edges perpendicular to the plane of axes. To calculate k for conductors a and b, and for conductors a and c.

Part A. $D=6$ inches; $r=0.5$ inch; $s=4$ inches; $n=0.5/6=1/12$; $m=2/3$. From equation 12 for the terms taken in order

$$M(r, s)/r^2 = (4/3)\tan^{-1}(2/3) - \log(13/9) + 1/2808 + \ldots$$
$$= 0.7840 - 0.3677 + 0.0004 = 0.4167$$

Accordingly, from equation 14

$$k = (9/4)(0.4167) = 0.938$$

For comparison, we have from equation 17

$$k = 1 - 4/54 + 16/(81)(15) - 64/(729)(28) + 256/(6561)(45) - \ldots$$
$$= 1 - 0.0741 + 0.0132 - 0.0031 + 0.0009 = 0.937$$

Part B. $D=12$ inches; $r=0.5$ inch; $s=4$ inches; $n=0.5/12=1/24$; $m=1/3$. As n and m are smaller even than in part A, k is best calculated directly from equation 17.

$$k = 1 - 1/54 + 1/(81)(15) - 1/(729)(28) + \ldots$$
$$= 1 - 0.0185 + 0.008 = 0.982$$

These two values of k computed from equation 17—with a ten-inch slide rule and with purposely exaggerated accuracy—indicate the rapidity with which this expression yields values of k for strap conductors. As in practice but the first two digits are used in actual computations, but the first two or three terms in equation 17 need normally be calculated.

Example 2

Conductors a, b, c of a three-phase bus are 2.5- by 2.5-inch square tubular conductors, 0.5 inch thick, spaced 10 inches between adjacent axes. To calculate k for conductors a and b

$D=10$ inches; $r=s=2.5$ inches; $R=S=1.5$ inches; $t=0.5$ inch. For the data given we have from equation 13

$$k = (100/16)[M(2.5, 2.5) + M(1.5, 1.5) + 2M(0.5, 2) + 2M(2, 0.5) - 2M(2, 2) - 2M(0.5, 0.5)] \quad (19)$$

To determine k each of the terms of equation 19 must be calculated. From equation 18 we have for the terms taken in order

$$M(2.5, 2.5) = 6.25(0.063151 - 0.000692 + 0.000019) = 0.39049$$
$$M(1.5, 1.5) = 2.25(0.022584 - 0.000086) = 0.05062$$
$$M(0.5, 2) = 0.25(0.040017 - 0.000267 + 0.000004) = 0.00994$$
$$M(2, 0.5) = 4.00(0.002517 - 0.000001) = 0.01006$$
$$M(2, 2) = 4.00(0.040267 - 0.000277) = 0.15996$$
$$M(0.5, 0.5) = 0.25(0.002501 - 0.000001) = 0.00063$$

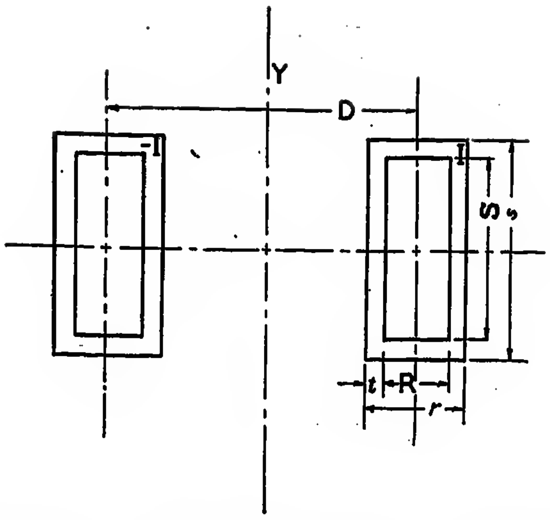

Figure 1. Rectangular tubular conductors symmetrically located

Substituting these values in equation 19 we have for k

$$k=(100/16)[0.39049+0.05062+0.01988+0.02012-0.31992-0.00126]=0.999+$$

This example is of particular interest, as, in addition to illustrating the method of calculating k for rectangular tubular conductors, it reveals that for *square tubular conductors*—and these are commonly used—*the value of k for practical conductor spacings is unity.* If the conductors are rectangular with long sides perpendicular to the plane of axes, k will be less than unity; and if the short sides are perpendicular to the plane of axes, k will be greater than unity: in either case k can be calculated as above.

Appendix

Considered as a function of r alone

$$F=2F(D,s)-F(D+r,s)-F(D-r,s)$$

can be expanded in a power series about the point $r=D$. Accordingly, by Taylor's theorem we have

$$F=-r^2\frac{\partial^2F(D,s)}{\partial D^2}-\frac{r^4}{2\cdot3!}\frac{\partial^4F(D,s)}{\partial D^4}-\frac{r^6}{3\cdot5!}\frac{\partial^6F(D,s)}{\partial D^6}-\ldots$$

where

$$F(D,s)={}^1/_2(D^4-6D^2s^2+s^4)\log(D^2+s^2)-D^4\log D+4(sD^3-Ds^3)\tan^{-1}(D/s)$$

$$\frac{\partial F(D,s)}{\partial D}=(2D^3-6Ds^2)\log(D^2+s^2)-4D^3\log D+4(3sD^2-s^3)\tan^{-1}(D/s)-3Ds^2$$

$$\frac{\partial^2F(D,s)}{\partial D^2}=6(D^2-s^2)\log(D^2+s^2)-12D^2\log D+24Ds\tan^{-1}(D/s)-7s^2$$

$$\frac{\partial^3F(D,s)}{\partial D^3}=12D\log(D^2+s^2)-24D\log D+24s\tan^{-1}\times(D/s)$$
$$=12D\log(D^2+s^2)/D^2-24s\times\tan^{-1}(s/D)+12\pi s$$

$$\frac{\partial^4F(D,s)}{\partial D^4}=12\log(D^2+s^2)-24\log D$$

$$\frac{\partial^5F(D,s)}{\partial D^5}=-\frac{24s^2}{D(D^2+s^2)}$$

$$\frac{\partial^6F(D,s)}{\partial D^6}=24\left[\frac{1}{D^2}-\frac{D^2-s^2}{(D^2+s^2)^2}\right]$$

$$\frac{\partial^7F(D,s)}{\partial D^7}=48\left[-\frac{1}{D^3}-\frac{-D^3+3Ds^2}{(D^2+s^2)^3}\right]$$

The Carbon Arc—a Valuable Industrial Tool

W. C. KALB
FELLOW AIEE

Synopsis: The versatility of the carbon arc as a source of both visible and invisible radiation is shown to be due, in part, to the three basic types of operation to which it is adapted and also to the fact that the character of its energy emission can be modified by changes in core composition. It is used in its various forms for many photochemical and irradiation processes, some of which require specific bands of ultraviolet radiation or close reproduction of the effects of natural sunlight. The carbon arc is preferred in other instances, because the optical requirements of the application necessitate a light source of small area and extreme brilliancy. Several industrial and commercial uses are cited together with the characteristics which give preference to the carbon arc as a source of radiation.

THE present widespread industrial use of the carbon arc is due to certain characteristics or combination of characteristics in which it is superior to other available sources of artificial radiation. Capable of efficiently producing a large volume of light, the original commercial application of the carbon arc was in the field of general illumination. It has been used extensively for street lighting and for the illumination of factories, auditoriums, and other large areas. Its present value is due, in large measure, to its versatility as a source of invisible as well as visible radiation and extends into many fields other than those of general illumination. In some instances preferred solely for its visible radiation, the carbon arc is selected for other applications because of the character and intensity of its invisible rays, while the choice at times may be due to the combination of visible and invisible rays which it supplies.

Besides being a highly efficient source of radiant energy in the visible and adjacent invisible bands of radiation, the carbon arc is highly flexible in respect to quality of emission. This flexibility is due, in part, to the three basic types of operation to which the electric arc between carbon electrodes can be adapted:

1. Low-intensity operation between solid or "neutral-cored" electrodes.

2. Low-intensity operation between electrodes having cores containing flame-supporting materials.

3. High-intensity operation.

Distinguishing characteristics of these three types of arcs have been described in previously published articles.[1,2] Briefly, the low-intensity arc between solid or neutral-cored carbons is adapted to a relatively simple type of lamp mechanism. At high arc voltage it is a very efficient source of ultraviolet in the range from 3,700 to 4,000 angstroms. The positive crater of the d-c low-intensity arc provides a steady concentrated light of the greatest brilliancy and whiteness available from a purely incandescent source. With a peak brilliancy of 180 candles per square millimeter and an average color temperature of about 3,550 degrees Kelvin, this type of arc has been extensively used for searchlights and for motion-picture projection. It has yielded its dominant position in these fields only to the higher brilliancy, whiteness, and efficiency of the high-intensity carbon arc.

The low-intensity flame-type arc, with the greater portion of its radiation emanating from the long arc stream at a brilliancy on the order of eight candles per square millimeter, is not so well adapted as the other basic types of arcs to use with optical systems that require a light source of small area and very high brilliancy. However, due to the large area of the flame, this type of arc emits a large volume of radiation which is produced at high electrical efficiency. An important advantage of the flame arc is the wide range in quality of radiation that can be obtained by varying the composition of the core[3] and the uniformity in both quality and intensity of radiation obtained from a particular type of carbon, when operated at specified arc conditions. When cored with certain rare earth compounds, the flame arc produces radiation so similar to that of natural sunlight in spectral composition that for many applications its effects are practically identical with those of sunlight. This light is the closest approach to natural sunlight of any artificial source having sufficient intensity for numerous industrial applications. Other combinations of core materials provide high emission of infrared or ultraviolet and permit emphasis on specific bands of ultraviolet, corresponding to the wave lengths at which most rapid reaction is obtained in certain photochemical and irradiation processes.

The high-intensity carbon arc is characterized by its very high crater brilliancy, 350 to 1,200 candles per square millimeter, and—with the core composition used in all but certain high-intensity therapeutic carbons—by the even distribution of all colors in its spectrum. The crater brilliancy of 1,200 candles per square millimeter is obtained from a new positive carbon only recently made available for use. A brilliancy of 2,000 candles per square millimeter has been attained with an experimental type of carbon not yet available for commercial application. The appearance of the d-c high-intensity arc is illustrated in Figure 1. Color temperature of the light from high-intensity arcs used in motion-picture projection averages about 5,800 degrees Kelvin. Maintenance of the high-intensity effect is dependent on the position of the electrodes in relation to each other. This relationship is maintained by continuous and accurately controlled feeding of the electrodes, and, in some of the larger high-intensity arc lamps, the positive carbon

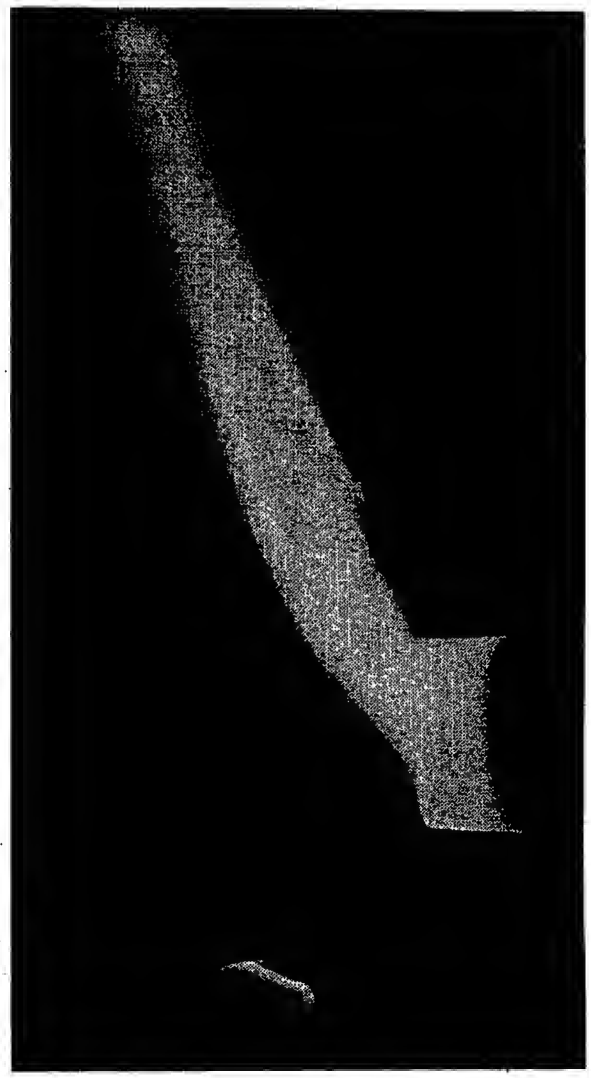

Figure 1. High-intensity carbon arc with rotating positive electrode

Paper 42-97, recommended by the AIEE committee on production and application of light for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 3, 1942; made available for printing May 6, 1942.

W. C. KALB is commercial engineer, carbon sales division, of the National Carbon Company, Inc., Cleveland, Ohio.

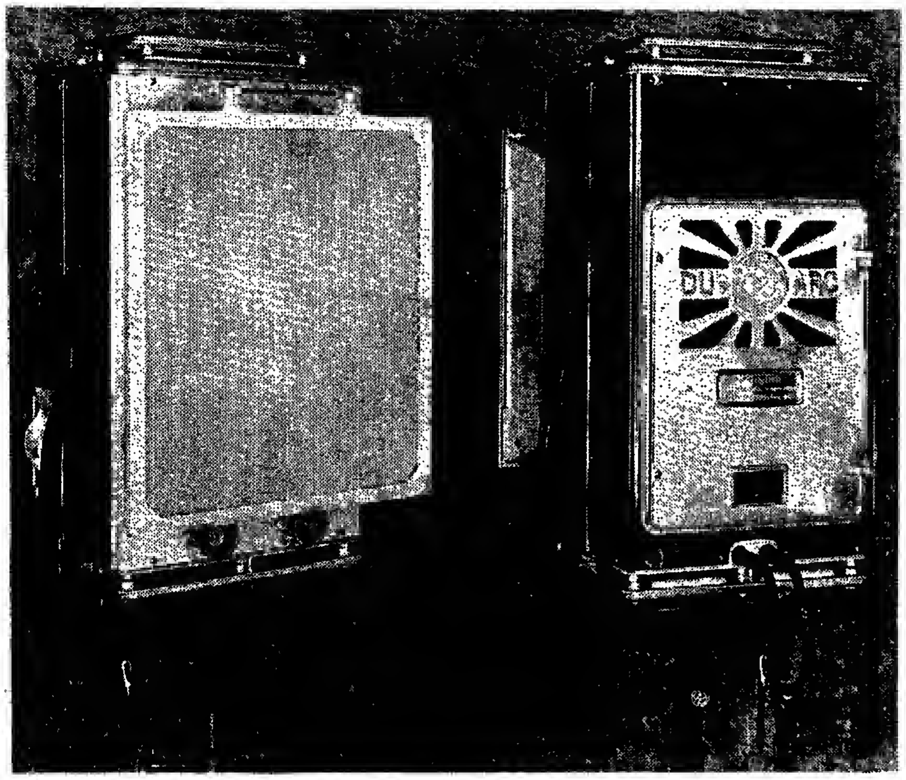

Figure 2. Twin-arc, motor - controlled lamp used for broadside lighting

is rotated, in order to maintain a symmetrical crater formation. The principal use of this highly concentrated source of illumination is for searchlights and for motion-picture production and projection.

Summarizing the advantages which give the carbon arc an important place in industry, the following points may be noted as available in one or more of the basic types:

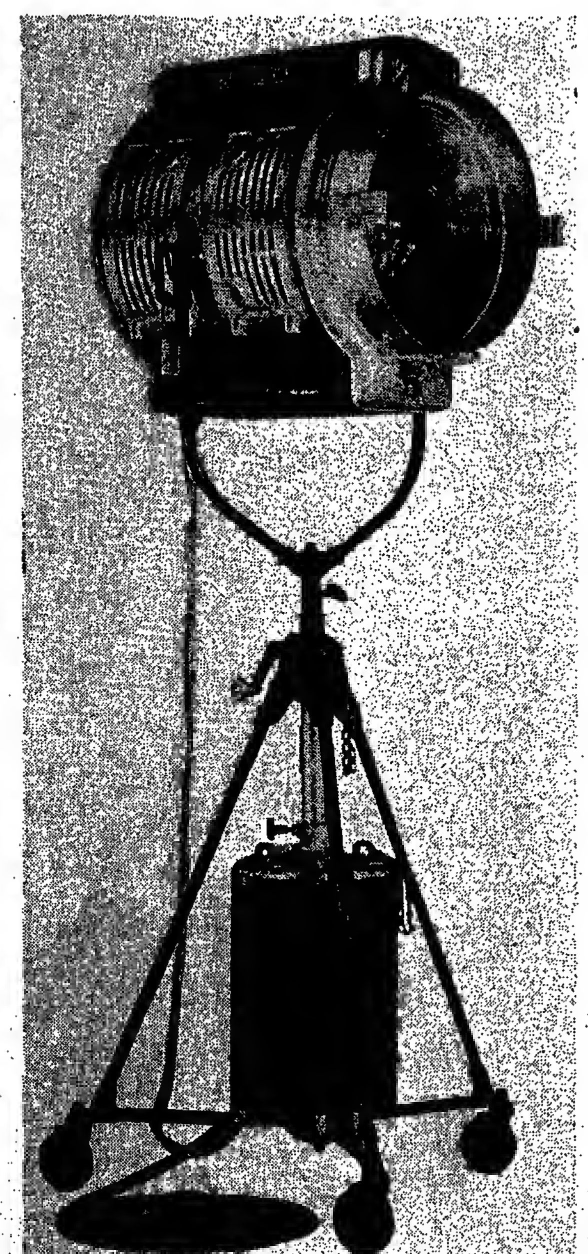

Figure 3. High-intensity carbon-arc lamp with Fresnel-type lens

1. Very high output of radiant energy from a single source.
2. Flexible quality of energy emission.
3. Close approximation to natural sunlight.
4. Uniform quality and intensity of emission at specified arc conditions.
5. Output unaffected by age or period of operation,

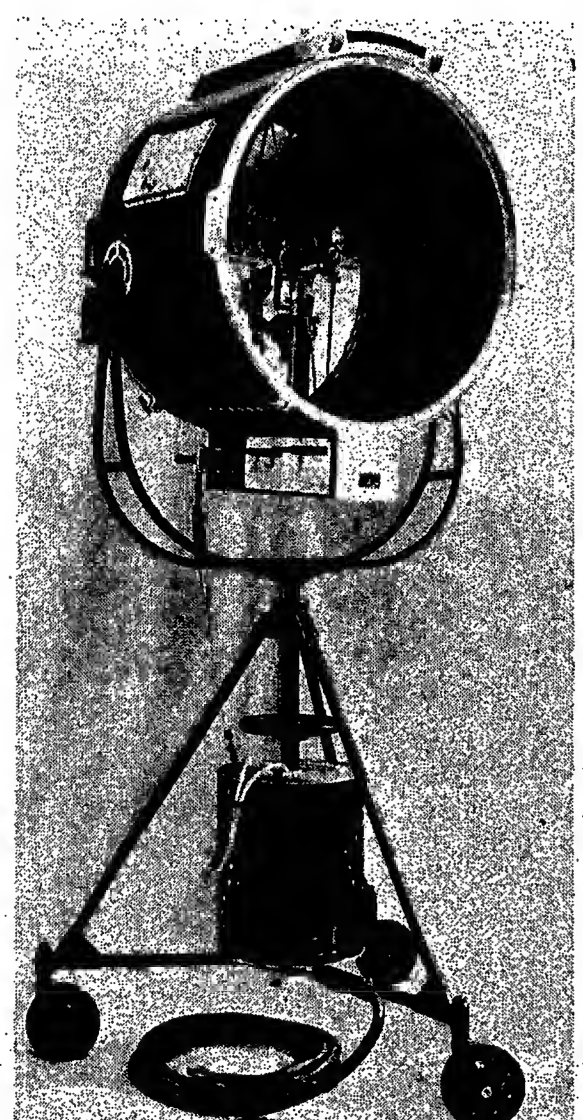

Figure 4. 36-inch sun arc

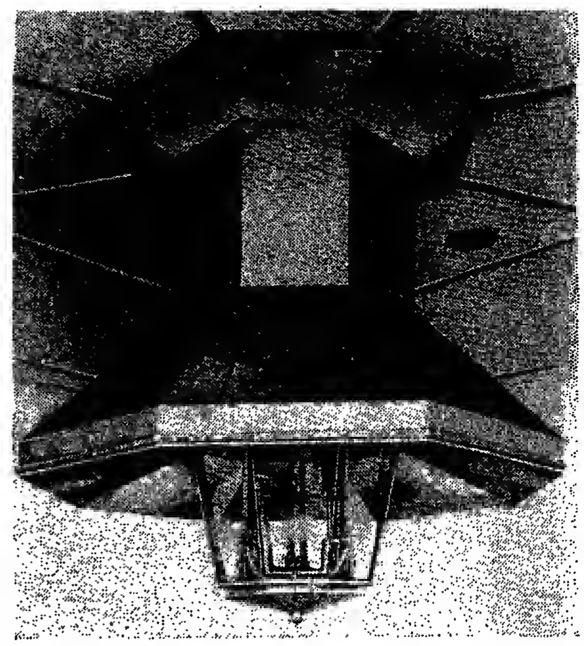

Figure 5. Four-arc carbon-arc solarium unit

6. High intrinsic brilliancy, adapted to optical systems requiring a highly concentrated source of radiation.
7. Shape of light source and distribution of brilliancy adapted to simple optical systems.
8. High efficiency in production of both ultraviolet and visible radiation.

The carbon arc was adopted at an early date as an artificial source of illumination for photography and allied photochemical industrial processes, such as blueprinting, photoengraving and photolithography. High actinic power, color quality, and adaptability to high illumination intensities are among the major reasons carbon-arc lighting was adopted by these industries and are still major factors in the extension of its use. Early photographic emulsions, sensitive principally to blue, violet, and ultraviolet radiation, react rapidly to the light of the low-intensity arc. This was the only type of arc available when photographers first turned to artificial lighting. As the sensitivity of photographic emulsions was extended through green to yellow and orange wave lengths, the white-flame arc, by that time available, was adopted, because its higher output of visible radiation gave greater speed and better photographic quality than the neutral-cored carbon arc. With modern photographic emulsions, sensitive to all colors of the spectrum, the advantages of the even distribution of color in the light from the white-flame arc have been further emphasized.

The high photographic speed of the white-flame carbon arc and its similarity to daylight made it the preferred artificial light source for photoengraving and photolithography, even when production in these industries was predominantly monochromatic. The growing popularity of natural-color reproduction in the graphic arts emphasizes the value of a light which provides all of the spectral

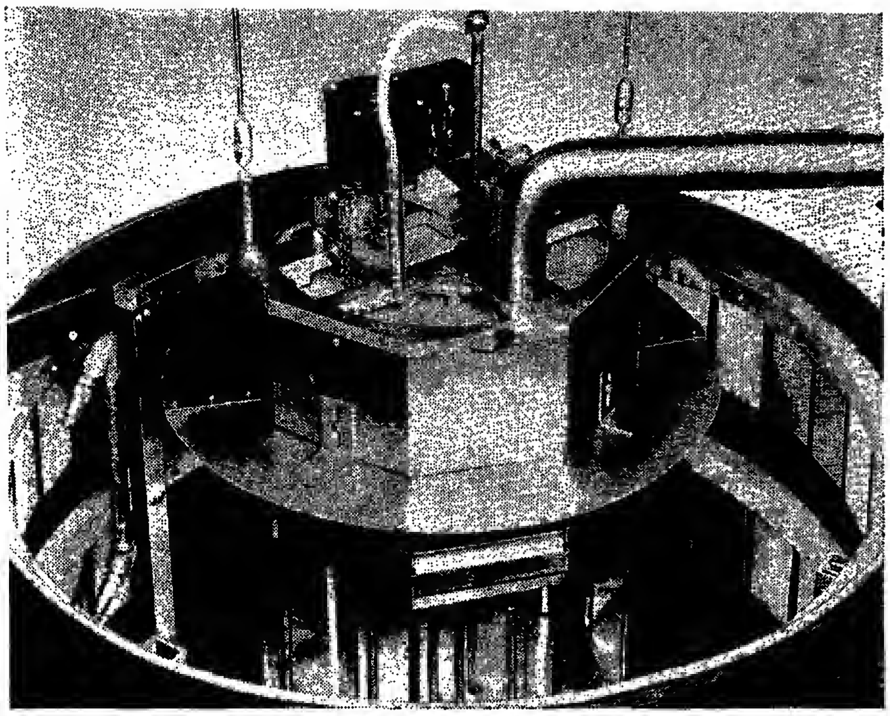

Figure 6. Interior of carbon-arc accelerated-weathering unit

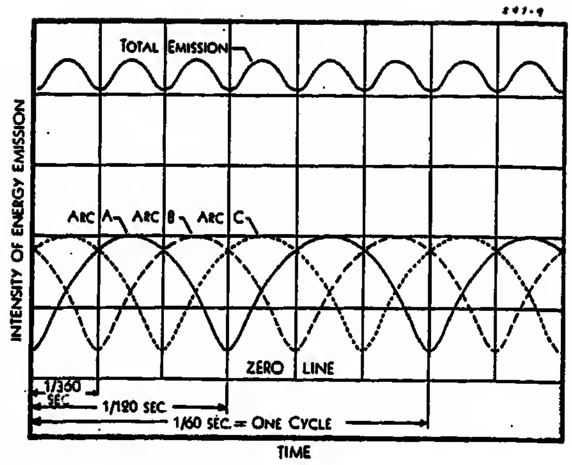

Figure 9. Energy emission from three-phase 60-cycle flame arc

colors at essentially equal intensity. High-intensity arcs are used in photolithography for large-sized reproduction by the projection method.

The motion-picture studios depend chiefly on carbon-arc lighting for natural-color photography. This also is due to the need for an even balance of the primary colors. The color balance of the light from carbon arcs, as adapted to studio use, conforms so closely to that of sunlight that the two are considered essentially equivalent for photographic purposes. The type of lamp generally used for broadside lighting is shown in Figure 2. This lamp has a motor-driven feeding mechanism which maintains very steady light output and is extremely quiet, permitting operation in proximity to the microphone without difficulty. It uses a special white-flame carbon producing light with a color temperature of 4,650 degrees Kelvin almost perfectly balanced to the color sensitivity of motion-picture film, and requiring no color-correcting filter.

High-intensity arc lamps equipped with a Fresnel-type lens, as illustrated in Figure 3, are used for back lighting, cross lighting and key lighting and for both wide and narrow beam front and effect lighting. High-intensity "sun arcs," with 24-inch and 36-inch mirrors, Figure 4, are used for extremely long throws, for sharply outlined shadows, or to provide a clearly defined beam of light through the general illumination. Because of their ready adaptability to the needs of the studio and to modern photographic technique, many cinematographers are using carbon arcs as the principal source of illumination for monochromatic as well as for color productions.

For background projection or process photography a light source of tremendous power is required to project the background scene through the screen at an intensity comparable to that of the lighting on the set. Only the high-intensity carbon arc has sufficient power for this purpose. In fact, three background projectors are sometimes used, synchronized with each other and with the camera, each projecting the same scene in exact register through the screen. The precision of mechanism and optical elements which has made possible this intricate projection system is a major engineering accomplishment.

The high-intensity carbon arc is an ideal light source for searchlights, because its tremendous output is concentrated in a very small area. This permits the light

to be focused by the lens or reflector of the searchlight into a beam of small divergence and high penetration. The high-intensity searchlight with 16-millimeter positive carbon, operated at 150 amperes and 78 volts, and using a 36-inch reflector, projects a beam of considerably more than 100-million beam candle power and, with a 60-inch reflector, the beam candle power is well over 500 million. At 195 amperes and 84 arc volts the beam candle power is 30 to 50 per cent higher than at 150 amperes. Exact candle power of the beam is dependent on shadow losses, glass absorption, and the optical characteristics and reflection factor of the mirror.

Carbon arcs were used for motion-picture projection from the earliest days of the industry and are in practically universal use for theater projection today. No other commercially available light source provides light of suitable power, concentration, and color quality to meet the projection requirements of motion-picture theaters. The present trend is toward replacement of low-intensity projection lamps with high-intensity lamps of simplified design. This trend results from increasing recognition of the need for higher levels of illumination and also from popular demand for fidelity of color reproduction in the presentation of natural color features. Approximately 50 per cent of the light from the low-intensity carbon arc is in the orange and red portion of the spectrum. This color composition overemphasizes the red components in color pictures. Theatrical film of this type is processed for projection with light having approximately equal intensities of the three primary colors, a condition which the high-intensity arc fulfills most acceptably. The development of high-intensity projection lamps which require little more than one kilowatt at the arc has put the cost of high-intensity projection light essentially on the same level as that of low-intensity light, and has made it available to theaters which could not previously afford to operate high-intensity lamps. Other applications of the carbon arc for projection purposes include stereopticon projectors, spotlights, and theatrical "effect" lighting.

Since the discovery by Finsen that radiation from the carbon arc provides a cure for certain physical disorders, carbon-arc lamps have been extensively used in light therapy. The flame-type carbon arc is at present preferred for this purpose, because of its versatility in respect to quality of radiation. With one type of carbon close simulation of the physiological effects of sunlight is obtained. Other types give powerful emission in specific bands of ultraviolet. Still another type has mild ultraviolet emission, combined with a high output of penetrating radiation of longer wave length. All of these carbons can be burned in the same lamp. A large carbon-arc solarium unit, such as that illustrated in Figure 5, provides radiation of suitable intensity for light therapy over a circle of 20 standard solarium cots.

The increasing importance of quickly determining the resistance of various materials to deterioration under the action of sunlight has resulted in the almost universal adoption of the carbon arc as the source of radiation in accelerated testing units. This, again, is due to the fact that the quality of radiation delivered and the resulting effects are comparable to those of natural sunlight. Furthermore, radiation can be provided at an intensity which greatly accelerates the rate of deterioration and, being available 24 hours a day at constant intensity every day of the year, allows conclusive evidence of product quality to be obtained in much less time than is possible by means of outdoor tests.

In accelerated weathering units, such as that illustrated in Figure 6, test samples are carried on a rack which revolves slowly around the arc. At a portion of their revolution the samples are exposed to a water spray. The weathering action of water, air, thermal shock, and radiation of sunlight quality are thus combined in one test, the conditions of which can be exactly reproduced at any time and in any location. The unit illustrated employs a 60-ampere, 50-volt single-phase, a-c flame arc operated through a transformer from a 230-volt line. There are two upper and two lower carbons, but the arc burns between only one pair at a time. This unit accommodates 64 samples at one time. Paints, lacquers, enamels, varnishes, plastics, rubber and rubberlike materials, roofing and building materials, materials for leggings, tents, and tarpaulins, and special types of glass are included in the list of products for which accelerated test-

ing is now a standardized procedure. Comparative records made by users of these units indicate that an exposure of 30 hours in the unit described is approximately equivalent to one month of outdoor exposure.

Units designed for comparing the color fastness of dyes, dyed fabrics, paper, plastics, and other products do not have the water spray that is provided in the weathering unit but usually have provision for maintaining an adjustable degree of humidity. The unit shown in Figure 7 has a 30-ampere, 40-volt, single-phase arc lamp, operated through a transformer from a 230-volt line. This lamp has three upper and three lower carbons, but the arc burns between only one pair at a time. This allows it to operate continuously for 24 hours without retrimming. The revolving rack carries 18 sample holders, curved to the mean radial distance of $10^1/_4$ inches from the arc.

Recognition of the dietary importance of vitamin D has led to extensive use of carbon-arc lamps as a source of ultraviolet for increasing the vitamin-D potency of milk. Several types of carbon-arc milk irradiators are in use, one of the most efficient of which employs a 12- to 14.4-kw, three-phase, carbon-arc lamp with 80 amperes and 50 to 60 volts at each arc. This unit is shown in open position in Figure 8. In operating position the lamp is centrally located within the large drum. Besides making available in small space a high intensity of radiant energy, the three-phase carbon arc insures a continuously high level of energy emission as illustrated in Figure 9. Ultraviolet, the activating agency, does not penetrate milk to appreciable depth, and portions of the rapidly flowing film of milk in an irradiator may reach the exposed surface only during low-emission portions of the energy cycle from a single-phase source. Experience has demonstrated that the effectiveness of the irradiation process is increased by maintaining a continuously high level of energy emission. Since the flame-type arc operates more efficiently on alternating than on direct current, due to the use of reactance instead of resistance ballast, the polyphase arc is the most practicable means of maintaining a high-emission level.

Some objection to the irradiation process for increasing vitamin-D potency of milk has resulted from the use of sources of ultraviolet which produce considerable ozone and result in impaired flavor. The carbon arc is free from this objection. Coltman and MacPherson[4] have shown, by a method of spectroscopic analysis capable of clearly detecting 14 parts per hundred million, that no ozone above that concentration is present in the gases surrounding the carbon arc. Furthermore, producers of both fluid and evaporated milk have found that a vitamin-D potency of 400 USP units per quart can be obtained by carbon-arc irradiation without impairing the natural flavor of the milk.

Figure 10 shows the distribution of radiant energy from the type of flame carbon found most effective for milk irradiation. With these carbons the unit shown in Figure 8 is capable of activating 8,000 to 10,000 pounds of fluid milk per hour to a potency of 400 USP units per quart.

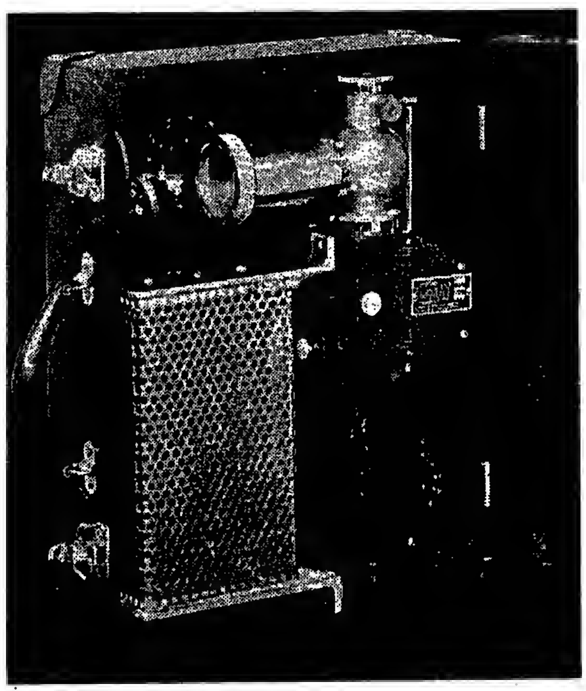

Figure 12. Portable ultraviolet carbon-arc lamp in carrying case

Uniformity of radiation from the large carbon-arc lamps used in the industrial testing and irradiating units here described is obtained by a motor-driven carbon feeding mechanism which provides automatic control of arc current. Accuracy of control has been greatly improved by the use of a 96-pole, 75-rpm reversible synchronous motor to drive the feeding mechanism. Because of its slow speed the rotor of this motor has little momentum and does not have the tendency to overrun, after opening of the motor-control relay, which is characteristic of high-speed motors. Hunting is thereby practically eliminated. Steadiness of arc-current control realized in practice is shown by the recording ammeter chart from an accelerated weathering unit reproduced in Figure 11. The momentary peaks at approximately 40-minute intervals indicate the shift of the arc from one pair of electrodes of the dual carbon trim to the other.

The applications of the carbon arc which have been cited are representative of the more extensive uses of this versatile source of radiation for industrial purposes. Carbon-arc lamps are used also to provide light of daylight quality, closely controlled in color composition and intensity, for critical matching of color. Ultraviolet radiation from carbon arcs is used in the processing of tobacco and other commercial products and in the preparation of certain pharmaceutical materials. Spectroscopic carbon and graphite electrodes of very high purity are used for spectroscopic analysis and as a source of radiation of reproducible intensity and spectral energy distribution for high temperature calibration and for color standardization.[5] The ash content of these special electrodes is considerably below 0.001 per cent. A portable carbon-arc lamp fitted with ultraviolet filter, Figure 12, is used in both laboratory and field for fluorescence inspection and analysis. Many of these lamps are used in crime detection. Other important industrial applications of the carbon arc, entirely outside the field of illumination, are in electric welding and in electric arc furnaces used for a variety of electrochemical and electrometallurgical processes. Although no longer before the eye of the general public, as when carbon-arc lamps hung on every street corner, this source of radiant energy is today more widely used and of greater industrial value than at any time in the past, and further extension of its commercial and industrial applications may confidently be expected.

A New Moving-Magnet Instrument for Direct Current

H. T. FAUS
MEMBER AIEE

J. R. MACINTYRE
ASSOCIATE AIEE

Synopsis: A new type of d-c instrument is described in this paper. It comprises a diametrically magnetized cylindrical moving-magnet element, a hollow copper damping cylinder surrounding the moving element, a fixed coil, control magnets having a very high coercive force, and an enclosing magnetic shield made of mumetal. The field of the control magnet and the field of the fixed coil have a relatively large angular displacement. The angular position of the vector sum of these fields varies with the current through the coil, and the moving element follows this vector. The scale distribution is nearly uniform for a 90-degree scale. The characteristics compare favorably in many respects with those of a D'Arsonval instrument.

OERSTED'S discovery that a compass needle tends to set itself at right angles to a wire carrying an electric current provided the basis for the design of the first electromagnetic indicating instrument, which consisted of a coil of wire surrounding a magnetized needle.[1] This in turn led to the development of the astatic galvanometers of Nobili and Kelvin and of the sine and tangent forms of galvanometer. These latter instruments, which depended upon the earth's field for their control torques, were obviously unsuited for use as portable instruments.

Ayrton and Perry, in designing the first portable d-c ammeter, used a large permanent magnet to produce a controlling field. In this instrument the polarization of the vane was derived from the fixed permanent magnet rather than from its own permanent magnetism. Since the field of the control magnet had to be so strong that the earth's field was negligible by comparison, the field of the coil had to be correspondingly strong in order to deflect the vane. This made the sensitivity of the instrument inherently low, since so many ampere turns were required to excite the field. Modifications of the Ayrton–Perry instrument are used for automobile ammeters, and similar applications where low cost and ruggedness are important, and where sensitivity and high accuracy are not required.

The principle of the permanent-magnet moving-coil galvanometer as developed by Sturgeon, Kelvin, and D'Arsonval was used by Weston in the design of the first moving-coil portable instrument. This principle is now generally used in all d-c instruments of high accuracy and high sensitivity.

Development of New Moving-Magnet Design

Although highly sensitive suspended magnet instruments have been built, no portable moving-magnet instruments have come into general use. "Moving-magnet instrument" is here intended to denote an instrument in which the magnetomotive force of the moving element is much greater than that produced by the fixed coil or by the fixed control magnets.

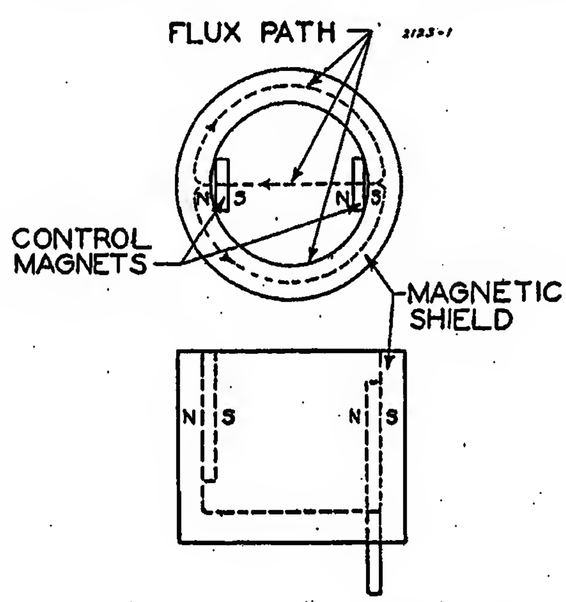

Figure 1. Path of control-magnet flux in magnetic shield

In an instrument of high sensitivity, the field of the fixed coil will be rather weak because of the small power available for producing it. This means that the instrument must be well shielded against stray fields which, even in the case of the earth's field, would be comparable in strength with the field produced by the instrument coil. This is accomplished by enclosing the moving magnet, coil, and control magnets in a cylindrical cup of magnetic material of high permeability and low coercive force. Permalloy or mumetal[2] are suitable materials for this shield.

Controlling torque may be obtained either from a magnet or from a spring. In this instrument a magnet was preferred because of ease of adjustment and other considerations. Since the control magnet must be placed within the shield, it must be very short in the direction of its magnetization and must have its magnetization unaltered by the field of the moving magnet. It is apparent that a material of very high coercive force is required. This requirement is met by an alloy of silver, aluminum, and manganese which was first described by Potter.[3,4] This alloy has a coercive force ($_BH_c$) of 6,000 oersteds and a residual induction of 610 gausses. It is unique among permanent-magnet materials in having a coercive force of this high value. The high coercive force enables the control magnets, which are in the form of thin strips, to be magnetized in the direction of their thickness. As shown in Figure 1, these magnets are mounted on opposite ends of a diameter inside the cup so as to produce a control field in the direction of this diameter. The strength of this field may be decreased or increased by inserting or withdrawing one magnet through a hole in the bottom of the shield as shown in the right-hand magnet in Figure 1. This adjusting motion is parallel to the axis of the cylinder and does not affect the direction of the control field in the plane in which the moving magnet turns. Thus, it controls the sensitivity without affecting the zero setting or the scale distribution of the instrument.

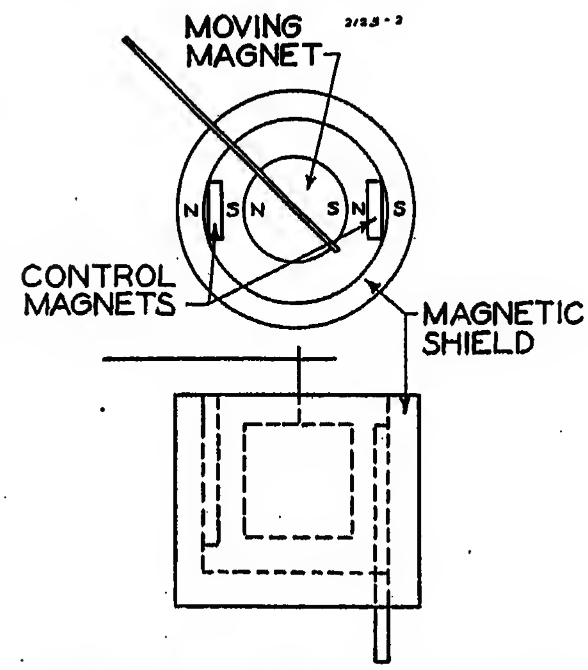

Figure 2. Relative positions of moving magnet, control magnets, magnetic shield, and pointer

The moving magnet should have a small moment of inertia in order to give good responsiveness and damping. At the

Paper 42-123, recommended by the AIEE committee on instruments and measurements for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted November 26, 1941; made available for printing May 11, 1942.

H. T. FAUS is development engineer, and J. R. MACINTYRE is design engineer, aircraft instrument department, both with General Electric Company, West Lynn, Mass.

same time it should provide a strong field in order to give as high torque as possible. Since the moving element must revolve through an arc of 90 degrees or more, the largest volume of permanent-magnet material can be put into a rotor which is bounded by a surface of revolution. From these considerations it appears that a cylindrical shape will be suitable for the moving magnet. A cylindrical magnet, magnetized along its diameter, has a very small ratio of length to cross-sectional area and, hence, should have a much larger ratio of coercive force to residual induction than that of any of the commonly known magnet steels. The silver alloy used in the control magnets does not have a sufficiently high residual induction for this application. A very good material is an oxide magnet made of a mixture of iron and cobalt oxides.[5] This material has a coercive force of approximately 950 oersteds, a residual induction of 2,200 gausses, and a $B \times H$ maximum value of

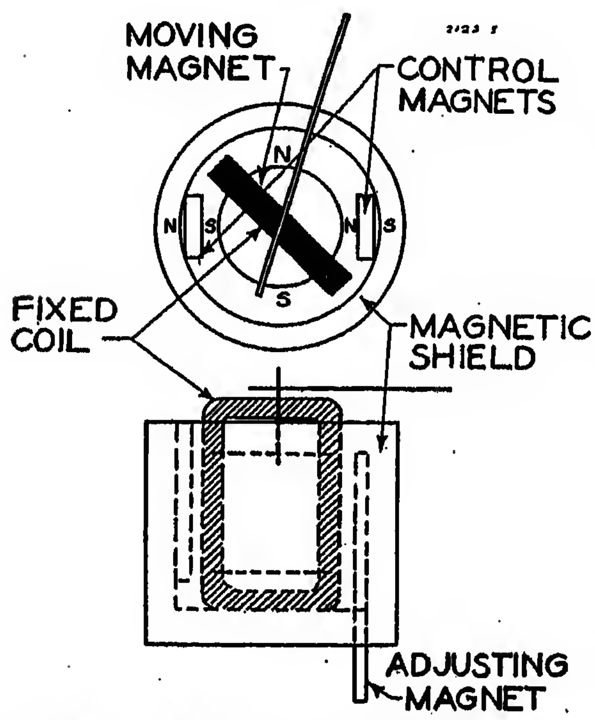

Figure 3. Diagram of complete moving-magnet-instrument element

approximately 10^6. The specific gravity of this material is half that of steel. Since the factor of merit of an electrical instrument depends on the weight of the moving element, this material is equivalent to steel having twice this $B \times H$ maximum value. Figure 2 shows the cylindrical magnet mounted within the shield and control-magnet assembly.

The field of the moving magnet has no appreciable effect on the permanent magnetization of the control magnets, because their coercive force is so high as to require a much stronger field to magnetize or demagnetize them. The field of the control magnets is much weaker than that of the moving magnet and likewise has no appreciable effect on its permanent magnetization. The shield material is of such low

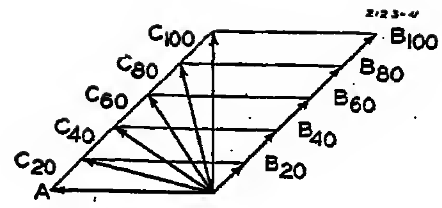

Figure 4. Vector diagrams of fluxes at intervals of 20 per cent of full-scale current.

(A) Control magnet flux

(B) Coil fluxes for currents indicated by subscripts

(C) Resultant fluxes

coercive force as to be practically incapable of acting as a permanent magnet. It is evident that under the conditions of operation no appreciable shift in the permanent magnetization of any of the parts is possible, and hence the instrument will have negligible hysteresis errors.

The current-conducting coil is placed in the circuit to produce a magnetic flux at an angle of 135 degrees from the flux of the control magnets. This coil is shown schematically in Figure 3.

The vectorial relationship of the control-magnet flux and coil flux is shown in Figure 4. Vector B represents the coil flux. This flux is proportional to the current flowing in the coil and is shown in various magnitudes with the subscript indicating the percentage of maximum current. These B subscript vectors add to vector A to produce vector C with subscripts as shown.

The polarized rotor will turn to a position parallel to vector C subscript. It should be noted that, although vector C may vary in magnitude as well as direction, only the directional changes can cause the rotor to turn.

In Figure 5 the angular position of vector C is plotted with the per cent coil current. Since this angular position is the same as the pointer position, the plot shows the scale distribution obtained from an instrument of this type. The maximum deviation from uniformity, as shown by the straight dotted line, is five degrees.

It is at once apparent, if changes in magnitude of vector B produce directional changes in vector C, that like changes in magnitude of vector A will also produce the same effect. Use of this fact is made in calibrating the instrument to a predetermined full-scale current value. This is accomplished, as previously mentioned, by sliding the adjusting magnet of Figure 2 in or out of the metal shield cup, and thus changing the amount of control-magnet flux as represented by the magnitude of vector A.

Figure 6 is a cut-away view of one of the instrument elements.[5]

The element shown has polished steel pivots moving in brass bearings. This type of bearing can be used where torque-to-weight ratios are sufficiently high.

The copper damping cylinder is used to bring the rotor to rest rapidly, by means of eddy currents induced by the rotor.

The field coil is wound at an angle across the molded coil form and not parallel to the rotor axis, as shown schematically in Figure 4. This was done for mechanical reasons and in no way changes the previously discussed considerations, since the field of the coil has a component in the plane of vector B.

Zero adjustment is accomplished by rotating the whole element assembly by means of an arm welded to the bottom of the shielding cup.

The magnetic shielding is completed by means of a mumetal washer on the top of the molded coil form.

The element as measured on the outside of the shielding cup is approximately three-fourths inch in diameter, and one-half inch long.

Conclusions

In production quantities the element has been applied to only one device. This is a dual-range storage-battery testing type of voltmeter shown in Figure 7. Here it was possible to use brass bearings. In all applications seen by the authors of moving-coil permanent-magnet instru-

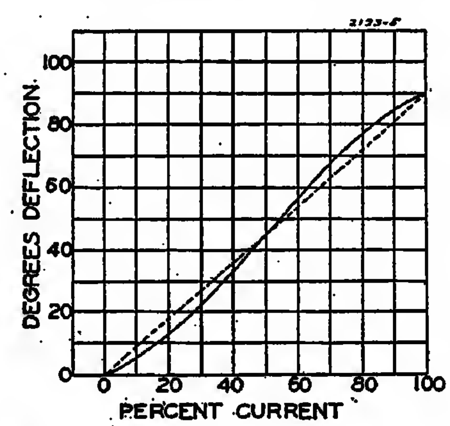

Figure 5. Scale-distribution curve for moving-magnet instrument

ments to similar devices, jewelled bearings are used.

Table I shows the physical constants of these voltmeters.

The elements are adjusted to fit predetermined scales to an accuracy of ±2 per cent of full-scale reading.

No hysteresis error (measured by taking calibration at the same point with descending and ascending currents) can be detected.

The instrument, when placed in a stray field of ten gausses in such a manner as to produce maximum errors, changes read-

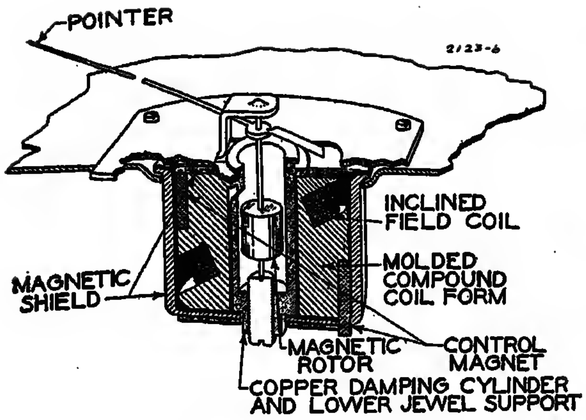

Figure 6. Cross section of moving-magnet instrument

ings approximately one-half of one per cent of full-scale reading.

The temperature errors of these indicators show some peculiar characteristics because of the high magnetic temperature coefficient of the silver alloy control magnets. With 10 per cent copper in the circuit, the element shows an error of −4 per cent at −40 degrees centigrade and +2 per cent at +50 degrees centigrade. With 35 per cent copper the error at −40 degrees centigrade is +1 per cent, and at +50 degrees centigrade approximately 0 per cent. The per cent errors are deviations from readings taken at 20 degrees centigrade. This makes it possible to build a voltmeter of low temperature coefficient with a high ratio of coil to series resistor resistance. Temperature compensation of ammeters may be obtained by a shunt resistor having a low temperature coefficient of resistance.

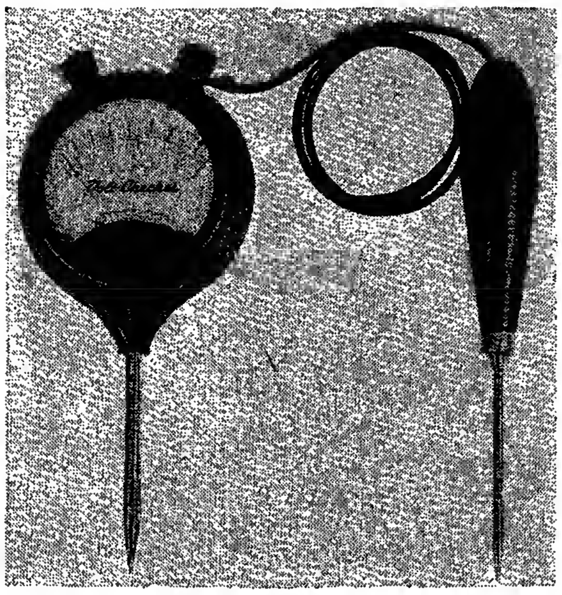

Figure 7. Battery-testing voltmeter with moving-magnet element

The element as used in these battery testers withstood considerable abuse. Several were tested by dropping 30 inches onto hard wood and concrete floors. No changes were noted except in one case where the adjusting magnet came loose.

The authors feel the element has inherently lower cost features and will withstand more abuse than the conventional moving-coil permanent-magnet element. By extending the design to the use of jewels, the sensitivity can be increased. Although it cannot reach the higher sensitivities of moving-coil permanent-magnet design, this moving-magnet element can be produced in sensitivities high enough to fit many applications now using the latter design.

Table I

1. Scale angle	90 degrees
2. Scale radius	$1^{15}/_{32}$ inches
3. Scale length	$2^{5}/_{16}$ inches
4. Full-scale torque (T)*	0.35 millimeter-gram
5. Weight (W)	0.205 gram
6. Ratio T^*/W	1.7
7. Ratio T^*/W 1.5	3.9
8. Response	1.5 seconds
9. Rating	3/10 volts
10. Ohms per volt	20
11. Coil resistance	20 ohms
12. Coil watts (full-scale)	0.05
13. Coil ampere-turns (full-scale)	14

*The full-scale torque shown (T) should be multiplied by approximately 3/2 to be comparable to the conventional 90-degree torque of moving-coil instruments. This is for the reason that the torque-versus-angular-displacement curve of the moving-magnet instrument is roughly sinusoidal and not linear as in the case of the moving-coil instrument. The 3/2 figure comes from extending the slope of the torque-displacement curve from near the origin, to the 90-degree point. This is logical, since it is the increment of torque-near-zero displacement which determines the inherent friction "stickiness" of the indicator.

Sleet Problems on Electrified Railroads

H. F. BROWN
MEMBER AIEE

Synopsis: Sleet storms, or more properly ice storms, have always presented serious difficulties to the operators of overhead electric conductors of all classes. For more than 25 years some electric-power companies have been using the circulation of electric current to heat the conductors, either to melt off the ice or to prevent it from forming. The technique of such procedure is well-known and will not be dealt with in this paper, other than to present fundamental theoretical data.

Electrified railroads operating with overhead contact systems have similar ice storm problems, and, in addition, a number of special problems caused by such ice. These problems are outlined in this paper, and some means which have been used or proposed for their solution are described. Operating experience with one special application to a case of severe exposure to ice storms and high wind velocities is cited. Some of these special railroad problems have not yet been satisfactorily solved.

General Problems

THE accumulation of ice caused by freezing rain, also known as sleet or glaze, on overhead electric conductors has always presented problems to be dealt with by operating engineers as well as by the designing engineers of such systems. Ice loads must be taken into account in calculating the strength of the conductors and their supporting structures, and the National Electrical Safety Code[5] has set forth the different values of radial thickness of ice which may be expected to occur in the various parts of the United States. However, even the most liberal provisions for ice loads are exceeded during the occasional unusually severe ice storms, and the conductors and even their supporting structures may then fail.

Ice storms are frequently followed by a drop in temperature accompanied by high-velocity winds, and both the designers and the operators are then faced with additional problems, for to the static ice loads may be added dynamic forces caused by swaying loads, and under certain critical wind velocities ice-covered conductors will whip up and down and "dance" violently even to the extent of destroying themselves or their attachments to their supporting structures.

To mitigate all these effects, which cannot always be provided for economically in the design, ice melting by heating the conductors with electric current has been resorted to by many power companies. This is done by loading the lines to capacity where possible, by load concentration or exchange with connected supply lines, or by the circulation of sufficient electric current at a voltage lower than normal; and routine procedures have been established during such storms to remove or to prevent the forming of ice on the conductors by these means.

The theory of such current requirements and the various operating techniques used have been reported in the technical press and in papers before operator associations from time to time during the past few years, some of which are listed herein for reference.

Special Railroad Problems

Electrified railroads having overhead contact systems and associated power feeders must deal not only with the same general problems of this nature that electric-power-transmitting companies have, but in addition they have a number of associated problems peculiar to themselves to contend with during ice storms. Some of these are:

1. On the contact wire, the ice accumulation, in itself a poor conductor, interferes with the current collection if it becomes too thick and causes severe arcing, which can seriously damage the contact conductor by burning and pitting; and can even cause flashovers where clearances to grounded structures are limited or reduced. Frequently the collector shoe can be burned in two by such arcing before many miles have been traveled. Contact wire wear is increased by the roughened collector shoe, and the fine polish acquired by months of lubrication or otherwise, may be destroyed.

2. The static ice load on the catenary contact system may become great enough to distort the vertical alignment by greatly increasing the sag at the center of the span, causing the collector shoe to skip and arc at the suspension points, since the pantograph is usually sluggish in its action under such conditions. Where heavy ice accumulations are known to be possible, the designer should weigh this factor in the selection of span length, especially if high-speed operation is involved, since this distortion will increase directly with the square of the span length for the same weight of ice. With inclined catenary construction, the increase in static load may distort the horizontal alignment enough to dewire the collector shoe on long spans on curves of long radius. Here again the remedy lies with the designer by using shorter spans or applying adequate horizontal bracing.

3. The additional wind load on the ice-covered contact system may result in further alignment distortion caused by horizontal sway, or in vertical "dancing," which, even if not severe enough to damage the overhead system, is in itself detrimental to continuous current collection and to high-speed operation and continuous tractive effort. Violent dancing may under extremely severe conditions wreck the line. Adequate bracing to take care of horizontal sway may have no beneficial effect on and may even augment this vertical dancing under critical conditions.

4. The ice accumulation on the pantographs and overhead collector shoes may add so much extra weight to these parts as to completely nullify the normal spring tension which holds the shoe against the contact wire. Then the pantograph will drop away from the wire or will not rise again after having been depressed, where the contact wire is lower than normal, as under a highway bridge or other low overhead structure. A means of augmenting the normal spring pressure, by added air pressure or otherwise, is one means of overcoming this difficulty; but it must be remembered that the pantograph pressure cannot be made too great without affecting the contact system.

5. Electric melting of ice on the overhead contact system may require larger currents than are available, since such systems are, in general, designed with more conductivity and for heavier currents than in the average power-transmission lines, which are usually of much higher voltage. Further, even when large currents can be applied, they may concentrate in the messenger or in some associated wire other than the contact wire, as some contact systems may be designed to have most of the conductivity in some member other than the wearing wire. In general, it is desirable to have the heating take place in all the members of the contact system, to overcome the difficulties outlined in paragraph 2 above as well as those in paragraph 1.

6. Unlike ice-melting schemes used on power-transmission lines, any electric ice-melting scheme used on an overhead contact system must allow of being superimposed on the contact system circuit while it is normally energized with traction power for train operation; that is, the heating current must be of such characteristics that it will not interfere with the electric operation of trains supplied with power from that same wire or circuit. For example, it is obvious that direct current cannot safely be superimposed on a-c circuits without the danger of saturating the a-c equipment and rendering it inoperative or possibly damaging it by overheating. If it becomes necessary to remove the traction power to apply a heating current of different voltage or characteristic—as may be done often on power transmission lines—there would be no advantage of such a method over the suspension of elec-

Paper 42-121, recommended by the AIEE committee on land transportation for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 14, 1942; made available for printing May 11, 1942.

H. F. Brown is assistant electrical engineer with the New York, New Haven, and Hartford Railroad Company, New Haven, Conn.

tric operation entirely and the substitution of steam or other form of motive power for the duration of the storm—an extremely inefficient, if not impossible procedure on a system having dense traffic.

Within the past two or three years, several unusually severe ice storms in the northeastern part of the United States have caused all of the electrified railroads in this section which operate under an overhead contact system to give more attention to these special problems, with the objective of preventing the ice from forming on the contact wire or collector parts, or of removing the accumulated ice before the deposit becomes unduly troublesome.

This paper will discuss some of the various solutions which have been found or suggested for these special railroad problems, rather than those which have generally been applied to power transmission lines. Some of the fundamental data are applicable to these special problems, as well as the general problems, and hence are included herein for reference.

Electric Heating of Overhead Conductors

Pender's Handbook gives the following formula for the value of the current, I, required to heat a conductor:

$$I = K\sqrt{\frac{Td^3}{r}}$$

where

- T is the temperature rise in degrees centigrade
- d is the diameter of the conductor in inches
- r is the resistance of the conductor in ohms per mil-foot at final temperature
- K is a constant depending upon surface condition of wire; whose value is (approximately) 800 in still air and 1,000 in open air for solid wire; and 1,200 in open air for stranded conductors

F. R. Longley of Western Massachusetts Companies in an excellent paper on this subject presented at a symposium of System Operators of New England at Montpelier, Vt., June 25, 1937, has developed the curves shown in Figures 1 and 2, which show the amperes required to heat conductors in still air, and the cooling effects of cross winds on the temperature rise, respectively. His formula was developed from data reported by Schurig and Frick.[2] It is to be especially noted that low wind velocities cause a marked reduction in temperature rise, while wind velocities in excess of 15 or 20 miles per hour do not produce much additional reduction. It is obvious that all these formulas are applicable to railway feeders and to the various wires of the catenary contact system.

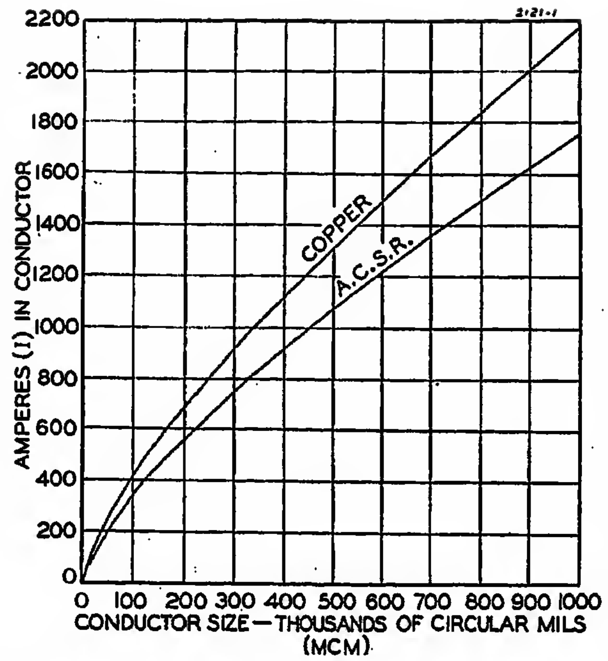

Figure 1. Current required to raise the temperature of a conductor from 0 to 150 degrees centigrade in still air (Longley)

This current is recommended for ice melting. Maximum temperature rise out of doors probably will not exceed 120 degrees centigrade, due to cooling effect of minimum crosswise wind velocity of one mile per hour. Conductors will not anneal below 175 degrees centigrade

For copper $I = 17.5\ (\text{MCM})^{0.606}$

For steel-reinforced aluminum $I = 14.3\ (\text{MCM})^{0.606}$

Mechanical Removal of Ice From Contact Wires

Most of the railroads which have been electrified in the northeastern part of the United States have rather frequent and dense traffic—in most cases one of the factors responsible for the electrification. Under such conditions, the usual ice storm presents no especial problem, as the ice or glaze is scraped off or shaken off from the contact wire before it has a chance to build up to a troublesome thickness, by the frequent passages of the pantographs. This is one method of ice removal which power-transmitting companies cannot use. On branch lines where traffic is light, or during the night or at other times when traffic is less frequent, if the ice formation and accumulation is mainly because of infrequent train operation, a special car or locomotive (electric) may be assigned to operate frequently to and fro over such lines to keep these lines as clear by this means as those having denser traffic.

A method of prevention of the formation of ice coatings which has been tried out on some of the 600-volt d-c urban lines, especially where trolley coaches with sliding collectors are used, and where even a light ice covering presents a very real problem to continuity of service, has been to coat the contact wire with a waxy or greasy substance which will not become wet enough by light rain to allow the formation of a continuous film but will cause the water to collect in drops. This may be partially successful in light ice storms of short duration, but since the drops which adhere and freeze have the same surface tension as the rain drops, they finally unite to form a continuous coating. Very possibly the waxy coating causes the ice coating to be less adherent, but when the temperature drops, it remains on the wire until scraped off by the collector shoe. This measure obviously is ineffective for very severe storms and is not economically applicable to the contact systems of electrified railroads.

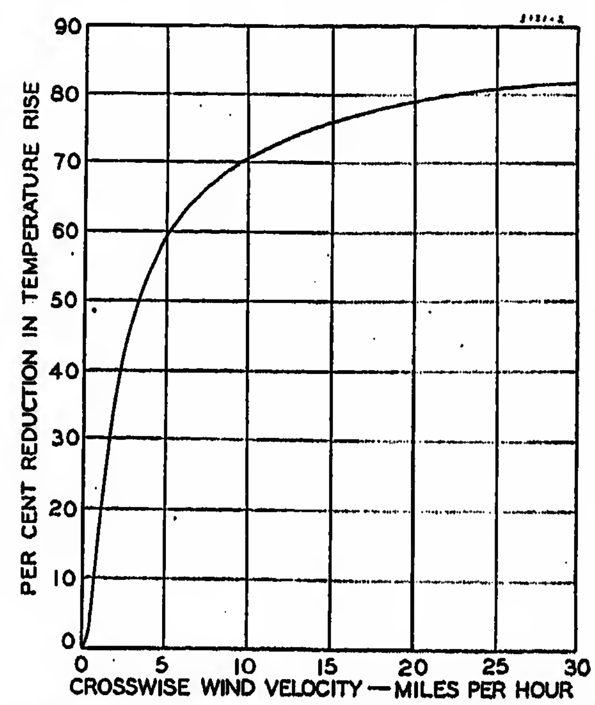

Figure 2. Cooling effect of crosswise wind on heated conductor (Longley)

Special Cases and Their Treatment—an Example

Certain sections of railway line may be exposed to unusual conditions favorable to the frequent and very rapid formation and accumulation of ice and to very high winds. On such sections even frequent traffic is not in itself sufficient to keep the contact wires clear of ice, and some other method of ice removal must be employed if service is to be maintained.

An example of such a section, having unusually severe exposure to both heavy and rapid accumulations of ice and to very high wind velocities, is that part of the electrified system of the New Haven Railroad known as the New York Connecting Railroad which operates over the Hell Gate Bridge in New York City between the Bronx and Long Island. For a distance of nearly four miles this part of the

railroad is on a viaduct which is from 75 to 165 feet above the ground or river level and at a considerable distance from any shielding structures. Ice seems to form very rapidly under certain conditions in this section and at times when it is not troublesome elsewhere, and the wind velocities in winter, especially after such storms, assume unusually high values. Consequently, this part of the overhead line has been damaged by ice and wind to the extent of being rendered inoperative electrically on several occasions since its construction in 1917. In contrast to this unsatisfactory record, the remainder of the line from New York to New Haven has operated successfully through a number of severe ice storms since its completion in 1914. With the exception of one extremely severe ice storm in December 1915, when accumulations were two inches in radial thickness in many places, causing the breakage, chiefly at splices, of some number 3 American Wire Gauge copper-stranded conductors used in 300-foot spans for control circuits, this overhead system has withstood a number of severe ice and wind storms (including the hurricane of 1938) without serious damage.

Mechanical Methods Applied

A number of studies of and changes in the Hell Gate Bridge section have been made in an endeavor to overcome the difficulties with ice and wind. Very possibly a fundamental difficulty is that some of the spans used are too long for such severe exposure. In 1927 an extensive horizontal wind-bracing system was applied to the catenary system in this section. This bracing did not eliminate the vertical "dancing" of the catenary spans, and in 1933 some additional vertical stays were added to the horizontal bracing system. Obviously these measures did nothing to eliminate the ice problem. Ice on the contact wires was scraped off when possible by special "ice breaker" locomotives, operated as a routine procedure during each ice storm. The vertical dancing was still so great at times that even these locomotives were unable to keep their pantographs on the wire. The difficulties from ice and high winds continued on the feeders, which were on occasions during subsequent ice storms broken in two and torn from their supporting pin insulators in many places by the violent wind whipping. The ground wire suffered the same fate, and it is safe to say that there are but few spans in this entire section where some of these conductors have not been broken and spliced. The feeders are 4/0 American Wire Gauge hard drawn stranded copper, having a normal sag of five feet in a 300-foot span, and it is a rather awesome sight to see these heavy conductors whipping up and down in a storm for 10 or 15 minutes at a time, with a frequency of about 25 vibrations per minute and with maximum amplitudes of twice the sag at the center of the spans.

In 1937 a number of experimental changes was made to the feeders, including the installation of some experimental dampening devices similar to the Stockbridge dampeners, but of various weights and dimensions. Some experimental spring suspensions and spring dampening devices were included, and in a number of spans the feeders were removed from the pin insulators and attached to suspension insulators. None of the dampening devices proved of great value during the following winter, but the wind whipping seemed to be materially reduced on those spans where the suspension insulators had been substituted for the original pin insulators. These experiments led to the general substitution in 1941 of suspension insulators for pin insulators on all the feeders throughout this entire section, except on the very short spans in the 1,100-foot section across the main arch span of the Hell Gate Bridge, where pin insulators with a flexible mechanical clamping arrangement are used.

The ground wire also has been flexibly suspended, so that any structure vibration caused by the whipping of the catenary will not be communicated to this wire. Some additional lateral and cross bracing of the catenary contact system was also installed in 1941, and to date these changes have seemed to be effective, as no serious difficulty has been experienced this past winter, although the season has not been a severe one.

Electrical Methods Considered

During the summer of 1939 serious consideration was given to the possibility of melting sleet from the wires in this section by electric heating.

There are four tracks in this section, an eastbound and westbound track each for freight and for passenger service, not connected by crossovers except at some distance east of the section, so that this section is operated as two two-track railroads. There are four contact wires with catenary construction at 11,000 volts to rail, and four feeder circuits, also 11,000 volts to rail, but 22,000 volts to the contact circuits, thus making with the rails a three-wire system. All contact circuits and feeder circuits are sectionalized at switching stations at each end of the exposed section approximately four miles apart. All trolley contact circuits are connected to a "trolley" bus, and all feeder circuits are connected to a "feeder" bus at each station, with a 3,000-kva "balancer" transformer having center point of winding connected to rails, connected across these trolley and feeder busses at each station. The west switching station is unattended and is operated by supervisory control from the east switching station, which is located at a signal interlocking tower, thus making the east station the more desirable location for any additional switching or heating apparatus.

In order to electrically remove the ice after it had been once formed, it was assumed that the temperature of the wire would have to be raised about ten degrees Fahrenheit between the two switching stations. It was calculated that about 750 amperes would be required in the catenary system (consisting of a bronze messenger, copper auxiliary wire

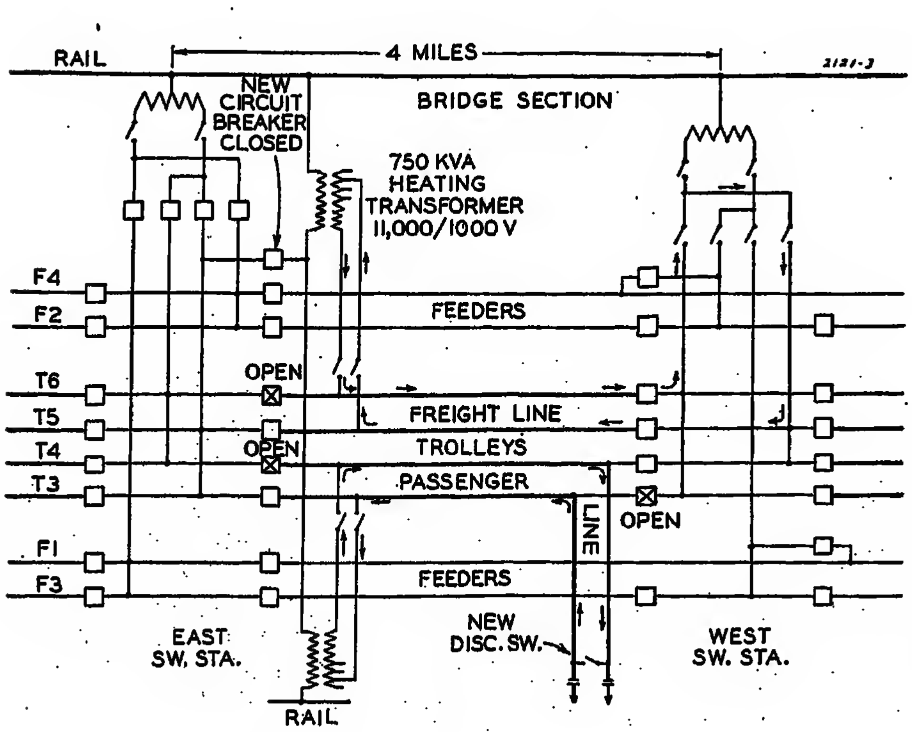

Figure 3. Scheme I proposed for heating contact wires on Hell Gate Bridge

and 4/0 bronze contact wire) to cause enough current (approximately 200 amperes) to flow in the contact wire to raise its temperature the required ten degrees Fahrenheit, since the greater part of the current would flow in the auxiliary wire and a smaller part in the messenger. The d-c resistance of this four-mile section of catenary is approximately 0.5 ohm, which gives a drop of 375 to 400 volts between stations. The a-c impedance is approximately ten per cent higher.

The problem, therefore, was to circulate in a loop circuit between sectionalizing points approximately 750 amperes at 900 to 1,000 volts a-c, or about 750 kva. A smaller amount of power and current would be required if a smaller rise in temperature would keep the lines clear when applied before and during the ice storm. The air temperature during an ice storm is always between 30 and 34 degrees Fahrenheit and if the temperature of the wire could be maintained at, say, 37 degrees Fahrenheit ice could not form on it.

Two schemes, both believed to be practical, were proposed and developed. Scheme I, shown diagrammatically in Figure 3, contemplated using two special 11,000/1,000-volt 25-cycle transformers, having their 11,000-volt winding connected to the trolley bus through a circuit breaker at the east switching station. The 1,000-volt winding would be provided with five or six taps at 50-volt intervals, with tap-changing facilities to suit temperature conditions, and would be insulated to withstand the normal contact-wire voltage plus the usual surges experienced on the system. This winding of each transformer would be connected through disconnecting switches, one to the two freight-line contact wires, and the other to the two passenger-line contact wires. These switches would be closed prior to the advent of the ice storm, and if the storm developed, the circuit breaker would be closed by the tower operator, and two of the trolley circuit breakers would be opened at the east switching station to disconnect one side of each loop circuit from the bus to prevent short-circuiting the low-voltage windings. The heat would then be on the bridge section without further switching operations, and train operation could be maintained and handled as required with no interference from the superimposed heating power. Two trains, both passenger or both freight, when passing near the easterly end of the section might temporarily bypass a small amount of this current, but it would be negligible because of the high impedance of the locomotive transformers to the 1,000-volt heating current.

The passenger line diverges from the freight line at the west switching station and continues for another mile, where it joins another system. If it were desirable to heat these circuits, a new disconnecting switch could be installed at the end of this section as shown in the diagram, closed during an ice storm, and one of the circuit breakers on this line could be opened at the west station to avoid short-circuiting this part of the line. This scheme could be expanded by additional switches, or by separate transformers to heat the feeders in the same manner, although this was not felt to be so urgent at that time.

This scheme was believed to be practicable but was not applied—partly because of the necessity for investing in the special transformers, when at that time it was unknown just how efficacious the heating current would be on the trolley circuits, but mainly because another method, involving no investment or additional equipment of any kind, was immediately available for experimental work by the simple expedient of power exchange between supply points on either ends of this section.

This second scheme is shown in Figure 4 and involved the exchange of traction power from the supply station several miles east of this section, over one circuit at a time in the section, either trolley or feeder, to the supply point several miles west of the section. At both supply points power is purchased from the same power company, but under separate contracts, because the supply at the western end is to a different railroad company over whose lines the New Haven circuits extend. This supply is through a 7,200-kva motor-generator set, designed for power flow in either direction, which was ideal for the purpose in mind.

It will be seen that scheme II involved the use of a single trolley-rail circuit for contact-wire heating, or a feeder-rail circuit for feeder heating, in the bridge section, which necessitated some experimental tests to satisfy the local communication interests that no inductive disturbances serious enough to cause any interference with their plant could be detected; and after some further tests to develop operating technique, this scheme was adopted as a regular operating procedure to be used throughout the duration of ice storms and has been in successful operation for three seasons. This scheme has been more fully described elsewhere.[4] One of the features of the power exchange is that it is done on a half-hour basis; that is, power is taken from one supply for one half-hour and delivered (less losses) to the other supply, after which interval the power flow is reversed for the next half-hour. This is because both contracts have the maximum demand on an hourly basis, and in this way neither contract demand can be exceeded by the power exchanged. A typical power curve illustrating this feature is shown in Figure 5.

With scheme II ice already formed can be melted from the feeders in from six to ten minutes and from the catenary in about twice this time, depending upon the temperature and wind conditions and the amount of power exchanged, which is limited by the capacity of the motor-generator set at the western supply.

With the improvements made during the past year in the feeder system in this section, there is some question as to the value of ice removal from the feeders, if they no longer dance and whip so violently under storm conditions. The writer has personally observed dancing or whipping of feeders in this section, when formerly supported on pin insulators, with no ice coating whatever, and at temperatures above freezing, so that there is some question as to whether such dancing is always a function of ice coating; and if not, the solution of the problem of "dancing conductors" may be mechanical rather than (or as well as) thermal. More winter experience with the changes re-

cently made must be had before it can be definitely stated that this problem has been solved.

Further Considerations

It will be noted that scheme II involves the continuity of service of all equipment involved in the power exchange; and if the equipment at the western supply point, which is not in duplicate, should be out of service for any reason during an ice storm, the scheme could not be used. This actually did happen during a very severe ice storm early in 1941, and, consequently, later in the year the proposal was made that a scheme similar to scheme I, outlined above, be installed until it was learned that it would be impossible to obtain the necessary transformers because of the war.

A third scheme therefore, to be used only as an alternate to scheme II, has been devised and is now being installed. This scheme consists of taking one trolley or feeder circuit at a time in this section and switching the westerly end through a water rheostat, adjusted to allow the passage to ground (rail) of approximately 800 amperes of traction power supplied from the east end. Most of this power is necessarily lost, being dissipated through heat in the water rheostat; possibly five per cent is used in heating the wire. This scheme requires a number of disconnecting switches at the west switching station, a large tank of water with a continuous supply, and the necessary drains, to dissipate the large amount of waste heat, also sending operators to this unattended station and housing them there for the duration of the storm. It is expected that this installation will be ready for the next winter season.

It is obvious that a similar method might be applied to any electrified railroad, a-c or d-c, if the economics of the situation warranted.

Ice or Sleet on Pantographs and Collectors

The problem of ice accumulations on pantographs and collector shoes has been approached from a number of different angles. The usual and time-honored practice is to work the pantograph up and down by means of its own operating mechanism at frequent intervals during ice storms to jar off the ice accumulations mechanically. Obviously this means cannot be employed on long high-speed runs. It is also customary practice to use higher spring pressure during the winter, partly for the purpose of compensating for the expected additional ice load, and partly to exert more pressure on the wire for knocking off the ice on it. Mention has already been made of the possibility of augmenting the normal pressure at will by auxiliary air pressure, to overcome excessive added weight.

Another proposal is to provide steam jets on top of the locomotive to blow steam from the train-heating boiler at will over the pantograph frame in the lowered position. Obviously this scheme is not applicable to pantographs on motor-cars, since they carry no steam-heating equipment. Another method which has been proposed for a-c electrified railroads is to have the pantograph frame split electrically at the base and all up through the frame, connected electrically only at the top by the contact shoe, and to circulate through this split frame a low-voltage current applied across the base from a separate special transformer, sufficient in value to raise the temperature of the entire frame and shoe. This current would be applied when necessary by the engineman. The traction power circuit would be connected to one side only of the base. Obviously, this scheme is not applicable to pantographs on equipment operated by direct current, at least without additional conversion apparatus.

Coating the frame and shoe with a waxy or greasy substance has been tried and is thought by some to be helpful in delaying the formation of adherent ice on pantographs. This measure has already been commented on in connection with the mechanical removal of ice from contact wires, and those comments apply here. It is possible that accumulated ice can be more easily jarred off the pantograph by working it up and down, when such coatings are applied, but again, this is a function of the temperature as well as the thickness of the accumulation.

Summary

Ice storms cause special problems on electrified railroads which power transmission systems do not have, most of them involving the current collection.

Ice accumulations may be removed from overhead contact systems by mechanical or electrical means.

Electrical heating of the contact system has been used satisfactorily on one a-c electrified railroad for a special case, and three methods of doing this have been devised, some of which may be applicable to other railroads.

The problems caused by high winds on ice-covered conductors are shared with other power-transmission systems and are serious ones. Changes to existing plant may help, but the possibilities of these difficulties should not be overlooked in the original design.

Ice accumulations on pantographs present special problems which are recognized and are being solved in various ways.

Sealed-Tube Ignitron Rectifiers

M. M. MORACK
MEMBER AIEE

H. C. STEINER
ASSOCIATE AIEE

In the past decade the advantages of the rectifier, when compared to other forms of conversion equipment, have led to the development of multianode steel tank and glass-bulb rectifiers. The desirable structural features and operating characteristics, however, have not been fully realized when pump-evacuated tanks and fragile glass-bulb rectifiers have been applied to small conversion units of low-voltage rating. Development of a means of starting or igniting[1] a cathode spot, each positive half cycle, on a pool of mercury has stimulated the design of a practicable half-wave or single-anode rectifier. The low density of ionization during the inverse cycle so reduced the shielding necessary to prevent arcback and, in consequence, the arc losses, that these rectifiers could be efficiently applied in the lower-voltage (250 volts d-c) fields.

Sealed, permanently evacuated steel ignitron tubes have been used in the control[2] of resistance welding currents for the past ten years; and in such service these electronic devices have given a degree of control, speed, and reliability not previously matched by mechanical means. Sealed, permanently evacuated steel ignitron tubes for rectifiers ranging in capacity from 75 to 400 kw (at 250 to 600 volts d-c), have been developed and placed in service, and it is the purpose of this paper to describe the design, characteristics, and performance of these rectifiers.

The Field for the Permanently Evacuated Tube-Type Rectifier

The field of application of the mercury-arc rectifier is considerably enlarged by the use of permanently evacuated tubes in circuits which have output characteristics similar to those of a d-c generator with nominal field control. Despite almost universal use of alternating current for generation and distribution, direct current still provides the most suitable source of power where adjustable speed or controlled torque characteristics are desired. D-c motors for machine tools, business machines, magnetic chucks, and separators, grinding machines, and elevators are typical examples of these d-c loads.

In comparison with other forms of converting equipment, the sealed-tube ignitron rectifier offers several distinct features for such service. The equipment is completely static, thereby eliminating special foundation requirements. The rectifier is quiet in operation which permits installation in locations where any appreciable noise would be objectionable. The over-all efficiency is high and practically constant over the entire load range. The no-load losses are small when compared with rotating equipment of like capacity. Rectifier equipments are factory-assembled, thereby minimizing installation time and expense.

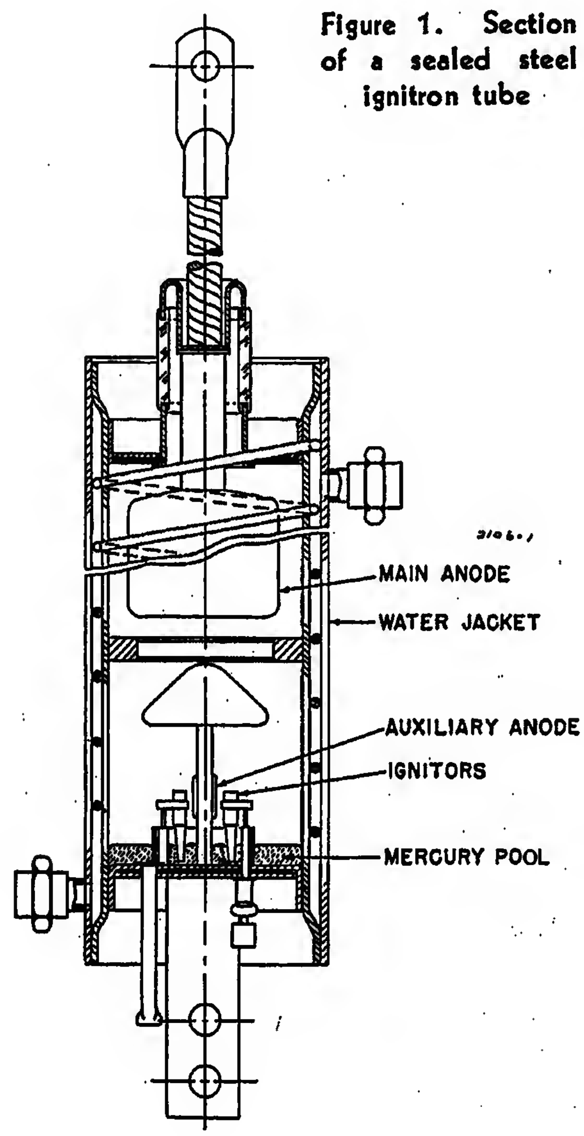

Figure 1. Section of a sealed steel ignitron tube

Tube Design and Operation Characteristics

Two sizes of ignitron tubes have been developed. The general tube design and construction are shown in Figure 1. The tube elements consist of a main anode, mercury-pool cathode, two ignitors, an auxiliary or holding anode spray, and deionization shields. Water jacket, flow spiral, and inner cylinder are of stainless steel.

Ignition[3] of a cathode spot is accomplished by passing an impulse of current from the ignitor to the mercury pool. Passage of current from the ignitor to the pool generates sufficient heat to break momentarily the contact of the mercury with some crystal in the ignitor. If the magnitude of the current, its duration, and the voltage gradient along the ignitor are sufficient, a cathode spot is established.

Figure 2 shows the variation in ignition voltage, current, and time for a typical ignitor, when supplied from the voltage of the main anode. When the ignitor is started at the beginning of the applied voltage wave, the current rise is slow, and the time required to reach the critical ignition value is long. When the applied voltage is high, as near the middle of the wave, the critical ignition current is quickly reached and the time correspondingly short.

Arc-drop voltages are given in Figure 3 in terms of anode current and outlet water temperature. These data were determined from cathode-ray-oscillograph measurements, while the tubes were supplying an inductive load of sufficient magnitude to insure essentially flat-topped current waves. Arc losses represent a design compromise between the minimum obtainable with no baffling and those with the shielding required to produce satisfactory freedom from arcback.

Cathode spots on a free surface of mercury become unstable when the instantaneous current decreases below approximately three amperes. To provide stable operation in this current range, an auxiliary anode has been added to the tube elements. This anode is usually excited from a low-voltage source inphase, or slightly ahead of the period of main anode conduction.

The tubes are water-cooled. Water-flow rates, cooling area, and temperature are determined by the requirements of removing the arc losses while maintaining vapor[4] pressure control. The outlet water temperature varies inversely with the load as is shown in the performance data of Figure 4. Maximum water temperatures are determined by the point at which the vapor pressure reaches arcback conditions. Minimum water temperatures are determined by the ability of the tubes to conduct current without "surging." This phenomenon is the result of insufficient vapor pressure to provide ions for the load-current demand. Momentarily con-

duction ceases, and the rapid current changes in transformer and lead inductance generate high voltages. Surging is usually limited to the first few cycles of conduction and for the particular designs does not occur at full-load currents with water temperatures as low as ten degrees centigrade. At less than full load the temperature may be lower. Optimum operating temperatures are in the range of 30 to 50 degrees centigrade, since under these conditions the arc losses are nearly a minimum, and there is more reserve vapor pressure control to take care of current demands.

Ignitron tubes in common with most vacuum-tube devices have elements of relatively small mass. The time for averaging the heating effect of sustained current demands is therefore a matter of minutes rather than hours as found in more massive machinery. This time is adequate for clearing feeder fuses, starting motors and for the usual types of overloads that are encountered in service.

Rectifier Design and Performance

Power Circuits

The choice of rectifier power circuits permits the grouping of different numbers of tubes to obtain various rectifier capacities. Figure 5 shows some of the more common of these circuits, together with the number of rectifying elements required, and the nominal ratings which are obtained in 250-volt service. These nominal ratings are made on the basis of the continuous duty. The usual overload factors are 125 per cent for two hours and 200 per cent for one minute. For most applications the circuits in which several tubes conduct simultaneously are preferable. In such circuits the total load is divided. Arc losses are therefore a minimum, since the instantaneous tube currents are low, and current capacity is a maximum. In certain cases, however, ease of control makes circuits preferable in which each tube carries the full load current. Rectifiers[5] which supply field currents for synchronous machines are in this category. To provide rapid response for both increasing and decreasing line voltage, the rectifier must be capable of inversion as well as of rectification, and the control is simplified when circuits of the three-phase, quarter-phase, or six-phase type are used.

Two-wire service is readily obtained from the usual rectifier circuits. Three-wire service may be obtained in two ways. A balancer set capable of carrying unbalanced currents of the order of 25 per cent of the set rating is usually sufficient to provide the required neutral. Three-wire systems may also be obtained electronically through the use of a three-phase, double-way[6] circuit shown in Figure 6. A practicable installation may consist of two-wire circuits to carry the main part of the load and sufficient three-wire circuits to carry the unbalanced load.

Ignitor Excitation

Anode excitation[7] is the most direct method of establishing a cathode spot. In this case a portion of the load current is diverted through the ignitor by means of a

suitable thyratron control tube. Establishment of the main arc effectively shorts the excitation system and thereby limits the average ignitor current to practicable values. This system is shown schematically in Figure 7A. The anode firing excitation system has two limitations. When the rectifier is feeding a counter electromotive-force load, and the current is low, the anode currents tend to become discontinuous. The voltage which can be applied to the ignitor becomes the difference between the instantaneous transformer voltage and that of the counter electromotive-force load. This voltage difference is so low that either a relatively long period is required for the ignitor current to reach the critical ignition value or the counter electromotive-force voltage decreases sufficiently to provide the required ignition current. Momentarily, therefore, the rectifier ceases to deliver its normal output voltage. This effect can be corrected by providing sufficient series inductance in the d-c load to assure that the current is continuous. Even though the load current is continuous, it may drop below the critical ignition value. In effect the ignitor resistance is suddenly placed in the circuit. The resulting reduction in output voltage can produce a very annoying light flicker when lamps are part of the connected load.

One form of separate excitation is shown in Figure 7B. In this case a capacitor (*FC*) is charged through dry-plate rectifier (*DPR*) and discharged at the proper instant through a thyratron tube. Phase control is obtained in the usual manner through the thyratron grid. An inductance in the discharge circuit establishes the desired rate of rise in the ignitor current. The circuits are so designed that a relatively high peak current, approximately 25 to 30 amperes, is available prior to ignition. This current value is in excess of the usual requirements, but, since the available energy is fixed, a design factor must be included for any possible contingency. The duration of the impulse is approximately 500 microseconds and the average ignitor current one-half ampere. Losses are of the order of 100 watts per ignitor. The ignition current is of such short duration that the cathode spot is maintained for the remainder of the main-anode conducting period by an auxiliary anode. Average current in this circuit is of the order of two amperes and losses 50 watts.

The required peak excitation current may be obtained[8,9] magnetically as shown in Figure 7C. Operation of the circuit is as follows: The linear reactor (*LL*) has an iron core with an air gap and is designed to give a constant reactance up to rated voltage and frequency of the circuit. The saturating reactor (*SL*) is built with a closed high-permeability core and a winding which will draw a large magnetizing current at the saturating point. This peak of current occurs when the capacitor (*FC*) is charged to its maximum voltage. The capacitor discharges through the saturating reactor, giving an impulse of ignitor current. A dry-plate rectifier (*DPR*) prevents reverse current from flowing in the ignitor circuit. The autotransformer (*AUT*) allows one circuit to supply excitation power to two tubes, which are in 180-degree phase relation.

The phase position of the impulses

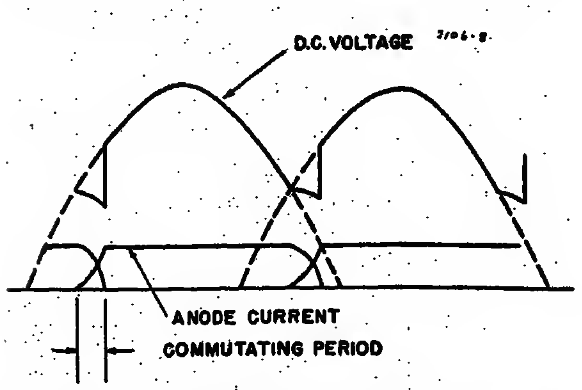

Figure 8. Diagram showing voltage loss due to commutation

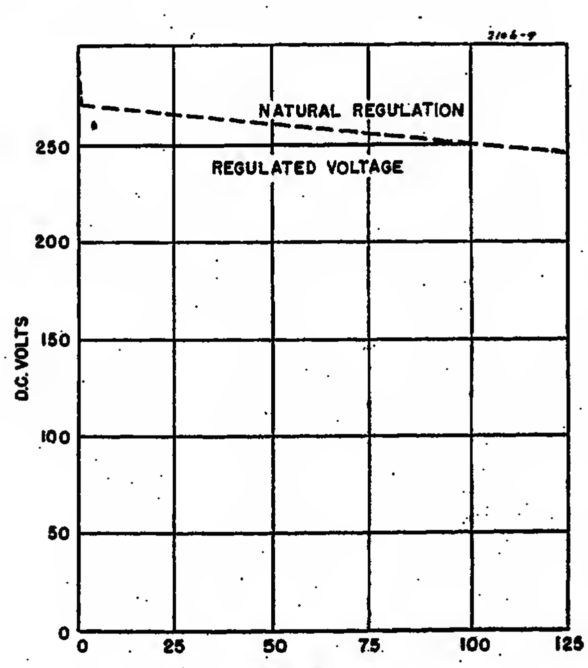

Figure 9. Typical output-voltage characteristics obtained by phase control

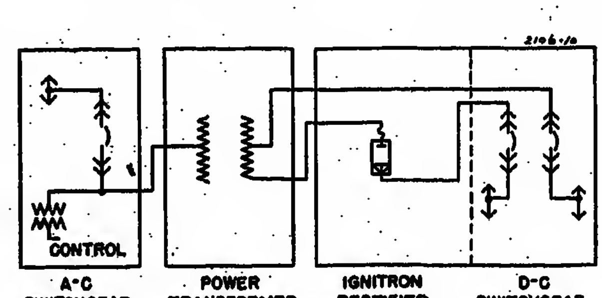

Figure 10. Line diagram showing rectifier component parts

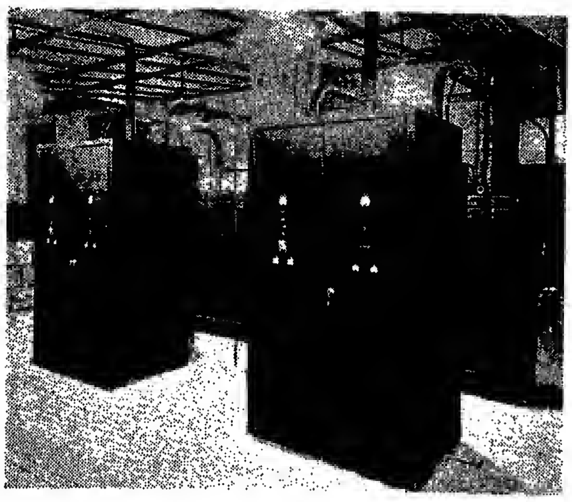

Figure 11. Metal-enclosed ignitron rectifier with automatic d-c switchgear for general purpose use

which establish the cathode spot are controlled by shifting the supply voltage (E_{34}) to the excitation circuit. This is accomplished by means of the network, consisting of reactor (*CL*) and (*PL*), and capacitor (*PC*). The reactor (*PL*) is capable of gradual change in reactance over a 10 to 1 range by means of d-c saturation. The reactor (*CL*) and capacitor (*FC*) operate with a circulating current larger than that drawn by the excitation circuit and act as a power source for this circuit. The phase position of the voltage (E_{34}) can be adjusted by controlling the point of saturation in the phase-shifting reactor. In this manner a 40-volt-ampere d-c source may be used to vary the firing point of the ignitor over an angle of approximately 50 degrees.

Fault Protection

Fault protection must be provided for a-c and d-c short circuits and for tube arcback conditions.

A-c protection for the transformer circuits is taken care of most satisfactorily by means of circuit breakers. The interrupting capacity of such a breaker is determined by the system capacity from which power is obtained.

The d-c protective equipment should provide for the usual functions of overload

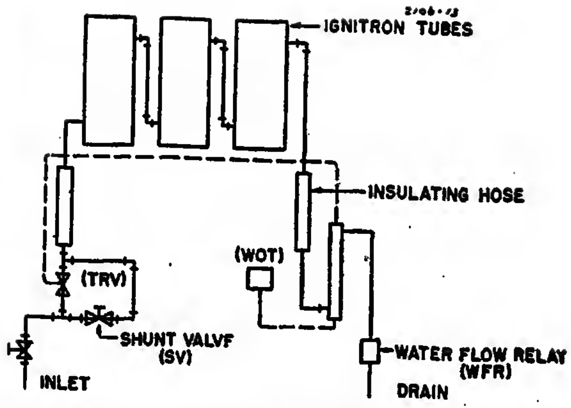

Figure 13. Water-cooling system of a 75-kw ignitron-tube rectifier

and short circuit. Again breakers are usually preferable, at least for the main feeders.

In spite of almost complete freedom from arcback when circuit, tube, and load conditions are properly co-ordinated, provision must be made for the possibility of arcback. Anode fuses of proper characteristics and capacity have proved satisfactory for this service. Differential protection can be obtained by the co-ordination of the tube current-carrying capacity with the transformer current-limiting reactance. The proper relationship of these two factors permits the remaining tubes in the circuit to carry the transformer short-circuit current without arcing back, for the eight or ten cycles required for the fuse to open. Likewise d-c short circuits may be cleared with the rectifier remaining available for service.

Voltage Control and Regulation

Regulation in rectifier circuits is due primarily to the voltage lost during the commutation period. At this time two anodes are conducting simultaneously, and the output voltage is the average of the instantaneous voltages. These conditions are shown in Figure 8. The voltage loss[10] during the commutation period is

Voltage drop $= PFLI$

where

P = number of phases or anodes which commutate consecutively

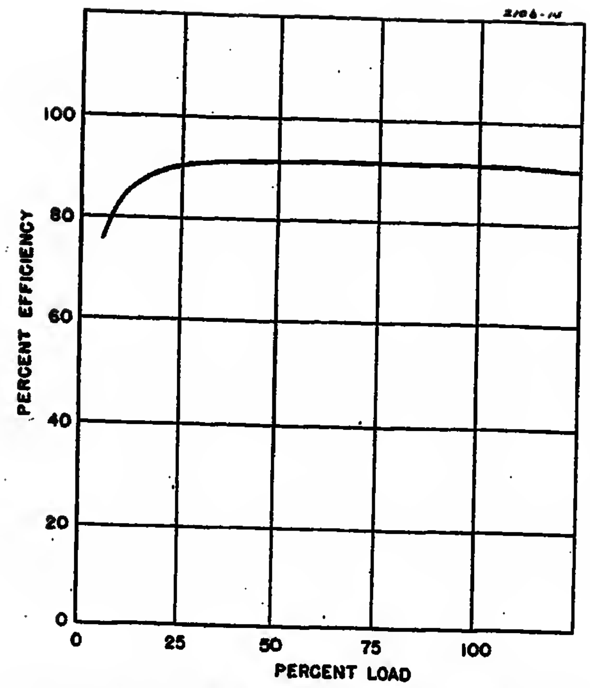

Figure 14. Over-all efficiency for a 250-volt 75-kw ignitron rectifier

F = system frequency

L = commutating inductance of one phase in henries

I = d-c current at the beginning of current transfer

The commutating reactance is that of any two phases whose anodes conduct in turn. It may be determined by shorting the transformer primary and applying excitation current to the secondary phases.

Rectifiers of this type usually have voltage regulation of six to seven per cent. This regulation is often greater than is desirable. To mitigate this effect, as well as compensate for variation in the voltage supply to the rectifier, the phase of the ignitor impulse is varied with respect to the positive half cycle of anode voltage to control the starting point of the anode current.

For magnetic excitation circuits, the simplest method of controlling the rectifier output voltage is to vary the d-c saturating current in accordance with the variation in the d-c output of the rectifier. In Figure 7C the voltage sensitive element (*VR*) of a torque-type regulator is connected across the d-c voltage to be regu-

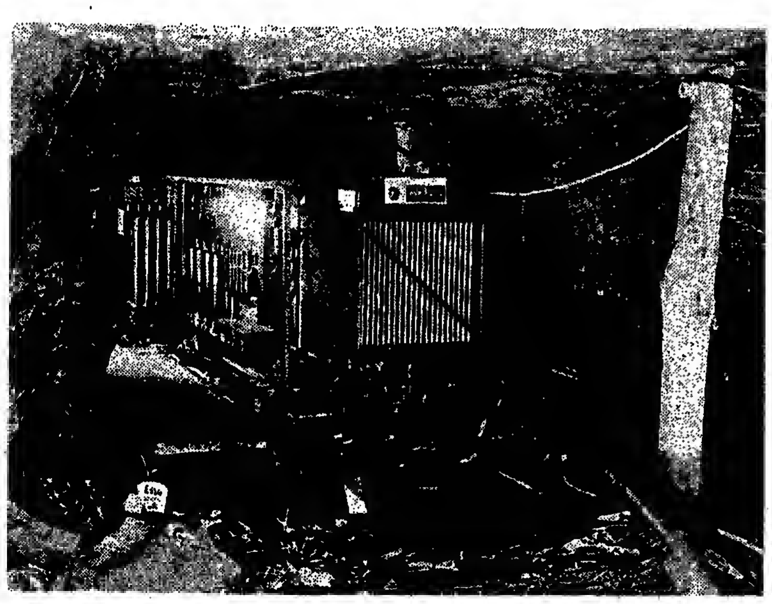

Figure 12 (left). Installation of a portable ignitron rectifier for mining service

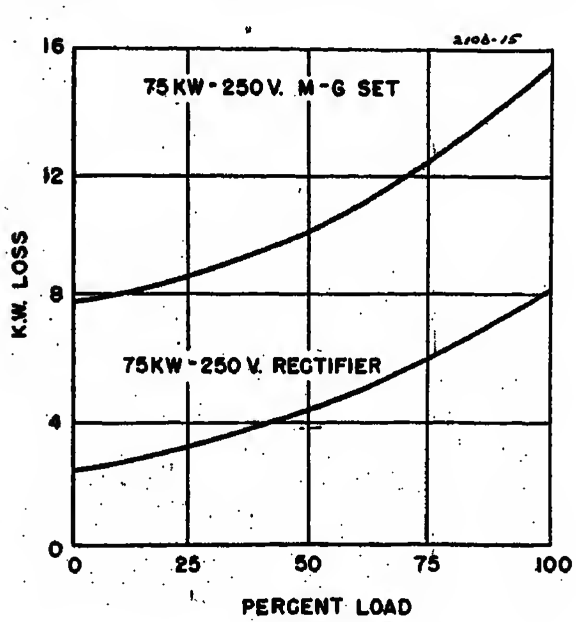

Figure 15 (right). Comparison of motor-generator and ignitron-rectifier losses

lated in series with a reactor and a variable resistor. The regulator rheostat element (*RR*) is connected in parallel with the saturating windings of the phase shift reactors. The voltage drop across the rheostatic element varies from a maximum to zero, thereby varying the current in the saturating winding of the reactor (*PL*). Parallel operation of one or more rectifiers can be obtained by use of an equalizer bus between the regulating elements of the various units.

Figure 9 shows a typical characteristic in which the rectifier voltage output is regulated from zero to full load. Beyond full load the output voltage follows the natural regulation.

Where extremely rapid response is desired, such as in the case of an electronic exciter operating to control the output voltage of a synchronous condenser, an electronic regulator[5] may be used.

Equipment Design

In general, the equipment design allows complete factory assembly of the units. The tubes, excitation, and control form one unit; the transformer another; and the required switchgear a third. A typical rectifier equipment is shown on the line diagram of Figure 10 and consists of the following components:

(*a*). Metal-enclosed manually or automatically operated a-c switchgear.

(*b*). Main, interphase, and control power transformers which are oil- or Pyranol-filled, natural or forced air-cooled, depending upon location and service.

(*c*). Metal-enclosed water-cooled ignitron mercury-arc rectifier with manually or automatically operated d-c switchgear.

Figure 11 shows a rectifier installation that is suitable for general purpose use such as lighting, power, or elevator loads.

Mine-service rectifiers require special designs in that the available head room is limited. Figure 12 shows a typical unit in which the rectifier, the transformer, and the switchgear form an articulated train. The cars are sufficiently short to permit moving around the usual track curves encountered in mine service. Portable rectifiers are particularly adapted to mine service, because they permit movement to new load centers as the coal is progressively removed.

Application

Rectifier ratings and the number of units required depend upon the application. In essential service it is considered good practice to have in reserve a stand-by unit which will permit the largest rectifier in service to be removed. Where requirements are less severe, and where the units may be removed for maintenance and inspection, rectifiers may be used to full capacity.

Elevator loads, particularly in hotels, apartment houses, and office buildings provide an excellent example of the essential service type of load. For reasons of safety such transportation must continue in operation. A satisfactory solution of the problem is to provide two complete and independent rectifiers with automatic change-over in case of d-c voltage failure. Simple switching provides preselection of the normally operating and reserve rectifiers, and the order may, of course, be periodically changed to equalize the use of the two units.

Tap water is usually used for removing the rectifier-arc losses. Full-load arc losses in 200-kw 250-volt rectifiers are approximately six per cent. Hence the transfer of this loss into the water rather than into the air is desirable, particularly in locations having limited ventilation facilities. The cooling water is not contaminated in passing through the tube jackets, and may be used in plant processes. Figure 13 shows the usual arrangement in which water is supplied to the rectifier at line pressure and passes through regulating valves to the tube jackets. Valve *SV* is a shunt valve used to adjust minimum flow. Valve *TRV* is controlled thermostatically and regulates the water flow in response to load. Thermostat (*WOT*) protects against water over temperature while the water flow relay (*WFR*) will remove the rectifier from operation on loss of cooling water flow. The flow relay utilized depends for its operation upon a physical displacement requiring both hydraulic pressure and water flow.

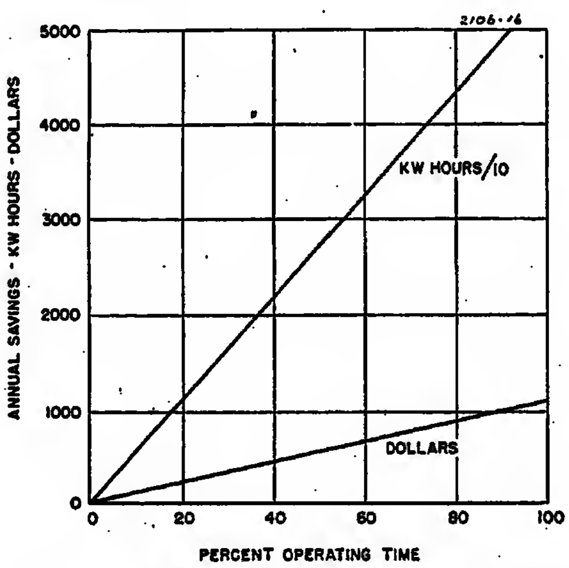

Figure 16. Annual savings for a 75-kw 250-volt rectifier

In general, most waters which are suitable for industrial or public use are satisfactory for cooling requirements. Waters which readily deposit lime or silt are to be avoided. The stainless-steel jackets are resistant to most corrosive elements, and the usual temperature of operation is not conducive to lime deposits. Stainless steel, however, is subject to slight corrosion by waters containing chlorides. Generally waters containing below 20 parts per million are satisfactory. Most public water supplies do not contain more than 8 to 15 parts per million.

Where local water conditions are unsatisfactory for direct use, heat exchangers may be employed. For mine service, air-to-water heat exchangers have been found to be the more practicable. Mine waters, in general, are very corrosive and very dirty. Air temperatures, on the other hand, are relatively constant and sufficiently low to make air-to-water heat exchangers attractive.

Maintenance

Rectifier maintenance outside of the usual inspection which should be given any electrical apparatus is primarily a matter of tube renewals. The number and frequency of such renewals depend upon the ultimate tube life. This ultimate life logically seems to depend upon the ignitor or loss of tube vacuum. To provide for the former, sealed tubes have two ignitors, one of which is held in reserve. Actually, examination of ignitors which have operated for two to three years shows that no appreciable erosion has taken place. Experience over a four-year period indicates there is no impairment in the tube vacuum.

A direct approach to the problem of maintenance is to evaluate the annual savings in power cost resulting from the higher efficiency and lower no-load losses of rectifiers. Figure 14 shows the over-all rectifier efficiency, and Figure 15 the kilowatt loss of a typical 75-kw motor–generator set and an equivalent ignitron rectifier at various loads up to full rating. Between 20 and 80 per cent of rated load, the difference in losses varies from 5.5 to 6.8 kw. Since the usual load characteristics are such that the load on either a motor–generator set or a rectifier will rarely lie outside of this range, the annual savings in kilowatt hours obtained by using a rectifier can be approximated very closely by multiplying the number of hours in service by 6.1. The gross saving depends upon the cost of electrical energy. Although power costs vary considerably, rates of one to three cents per kilowatt hour are representative. Figure 16 shows the annual saving on the basis of a power cost of two cents per kilowatt hour in

Practical Design of Counterpoise for Transmission-Line Lightning Protection

E. HANSSON
MEMBER AIEE

S. K. WALDORF
MEMBER AIEE

I. Introduction

EXPERIENCE has shown that preventive lightning protection, involving the installation of overhead ground wires and the co-ordination of tower-ground resistances with insulation level, can be quite effective in preventing flashovers due to lightning. Studies presented in an earlier paper[1] indicated that the efficiency of preventive protection can be made practically 100 per cent for high-voltage lines having insulator flashover levels of 1,600 kv and above. If the flashover level is reduced, the efficiency of protection becomes less.

Tower-ground resistance directly affects the protection efficiency obtained, and for satisfactory line performance resistance usually must be reduced below the values obtained with tower foundations alone. Buried counterpoise offers a practical means for accomplishing this, and, although many papers have been written on the theoretical aspects of the counterpoise, there is very little published on the problems encountered in actual installations.[2] This paper gives some methods that have been used in the installation of buried counterpoise at approximately 1,800 steel towers of the Pennsylvania Water and Power Company, as well as some of the results obtained.

When a counterpoise installation was contemplated, it was first necessary to determine the level of tower-footing resistances theoretically desirable. Next it was estimated how closely this objective could be approached and the amount of counterpoise conductor required. The data and methods presented are not sufficiently comprehensive to be applicable to all cases in all localities, but they may prove useful as a guide in making similar installations.

Paper 42-91, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted January 8, 1942; made available for printing April 20, 1942.

E. Hansson is transmission engineer and S. K. Waldorf test engineer, both with Pennsylvania Water and Power Company, Baltimore, Md.

II. Determination of the Optimum Tower-Footing Resistance

Experience has shown that in most cases flashovers will not occur at towers where the footing resistances are kept below the value indicated by the relation[3]

$$R=\frac{V}{I(1-CF)}$$

where

R = Tower-footing resistance
V = Impulse-flashover level of line insulation
I = Maximum natural tower lightning current
CF = Coupling factor between overhead ground wires and line conductors

This equation fixes the upper limit of footing resistance for any assumed value of tower current I, I usually being taken in excess of any tower currents that have ever been measured in the field.

Towers have suffered flashovers when the footing resistances and tower currents were appreciably less than the upper limit set by the above expression.[1,4] This has occurred more frequently than can be attributed to freak conditions. Apparently there is an impedance voltage drop in tower structures and grounding systems which accompanies heavy lightning discharges and which causes flashovers when the ohmic resistance drop appears low. As a practical consideration the effect has been evaluated in terms of tower currents.

For instance, on a 66-kv line having eight $4^3/_4$-inch insulators the upper limit for tower-footing resistance is obtained by substituting in the preceding equation

$$R=\frac{V}{I(1-CF)}=\frac{635{,}000}{150{,}000(1-0.25)}=5.6\text{ ohms}$$

It is assumed that 150,000 amperes is approximately the largest tower current that has ever been measured under natural lightning conditions. It would be logical to expect that towers having footing resistances of this level or less would not be subject to flashover; yet it has been found that flashovers have occurred on towers having footing resistance of this order of magnitude, when the indicated tower currents have been only about 60,000 amperes.[1] This leads to a modification of the desired level of tower-footing resistance based on economic considerations. With insulator flashover levels of about 600 kv, footing resistance can be considered the controlling factor for indicated tower currents up to only 60,000 amperes. Due to the uncertain

---

terms of the percentage of time the set is in operation. In general the average savings exceed the average replacement cost.

Conclusion

The design and application of rectifier equipment using sealed ignitron tubes has involved the solution of many new and interesting problems. Light flicker, control, voltage regulation, the problems of excitation, overload, and arcback protection have necessarily formed a part of the evolution of this type of rectifier equipment. The basic problems have been solved, and it is believed that the continuous and reliable operation of the sealed steel-tube rectifiers will demonstrate that these electronic devices have the same high standards of performance as the older forms of conversion equipment.

220	20–$5^1/_4$ in.	1,605	16

accuracy of tower-current measurements, it has been suggested that tower currents measured by surge-crest ammeter links mounted on tower legs be multiplied by a factor of 2 to correct for the currents carried by cross members of steel towers.[5] This gives a maximum safe tower current of about 120,000 amperes and a practical working value of about seven ohms for the optimum tower-footing resistance on an actual transmission line having an insulator flashover level of 635 kv. As all the factors in the equation are not known exactly under natural lightning discharge conditions, it has been found that a good working rule for the desired footing resistance is that it shall be not more than one ohm for each 100 kv of insulation flashover level, using the $1^1/_2$x40 microsecond value. This is referred to as the optimum tower-footing resistance.

Some examples of optimum tower-footing resistances are given in Table I.

III. Selection of Counterpoise Length

Usually counterpoise is installed principally as a convenient auxiliary means for reducing tower-footing resistance. For this reason the amount of counterpoise conductor used is that required to bring the ground resistance as close as practicable to a desired level. There are some notable exceptions to this principle. The section of the Boulder Dam–Los Angeles lines in high resistance territory[6] and the High Knob section of the Wallenpaupack Tap[5] are published instances of effective counterpoise installations where ground-resistance criteria do not apply. It is significant that in both of these cases lines operate at high voltage and have high insulation levels.

Based on traveling wave theory, Bewley and Hagenguth[7] have suggested that counterpoise conductors should be no less than 200 feet long. This minimum length has proved to be a satisfactory one in the field, from the viewpoint of both installation and performance. The maximum length that has been used on the 66-kv lines considered in this paper has been 400 feet where spans are greater than 800 feet, and continuous from tower to tower where the spans have been less than 800 feet. On 132-kv and 220-kv lines where the insulation levels are higher (see Table I), continuous counterpoise has been installed where ground resistances could not be reduced sufficiently by buried conductors 200 to 400 feet long. The basis for this difference in procedure for the two classes of insulation levels is the observed phenomena that the 66-kv towers flash over when low measured ground resistances are due to good grounds at some distance from the tower bases,[1] and that the higher-voltage lines can apparently withstand heavy discharges even though the necessary low ground resistances are obtained only by counterpoise extending for some distance from the tower foundation.[5,8]

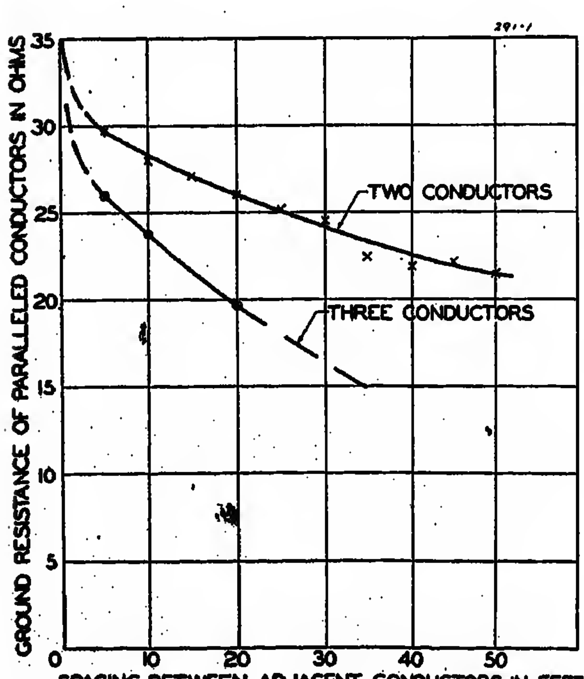

Figure 1. Effect of spacing on ground resistance of parallel buried conductors as determined by test

IV. Selection of Number and Spacing of Counterpoise Conductors in Parallel

Dwight[9] has published formulas for calculating the ground resistances of buried conductors, and they show that the greater the spacing between parallel wires the lower is the ground resistance of the system.

To indicate the practical limits for spacing, a set of measurements was obtained with seven 400-foot buried lengths of bare solid copper rod of one-fourth-inch diameter. The conductors were laid in straight parallel lines, 18 inches below the surface of the ground, five and ten feet apart. After a suitable weathering period, the resistances to ground of the individual conductors were 37, 37, 35, 35, 35, 30.5, and 32 ohms. The results plotted in Figure 1 emphasize the fact that two or more wires in parallel with reasonable spacings cannot produce so low a resistance as might be expected from the common relation for parallel resistances.

Table II. Reduction of Ground Resistance Due to Addition of Third Counterpoise Conductor Midway Between Two Others

Distance Between Two Outer Wires (Feet)	Ground Resistance in Ohms: Two Outer Wires	Ground Resistance in Ohms: All Three Wires	Per Cent Reduction Due to Third Wire
10	28	26	7.1
20	26	23.8	8.5
40	21.8	19.7	9.6

Table II, based on the data of Figure 1, gives a comparison of the ground resistance of two parallel conductors with that of a set of three when a third conductor is installed midway between the original two. It can be seen that the third conductor reduces the ground resistance only slightly, but the reduction in the surge impedance would be greater theoretically than that in ground resistance.

Another investigation was made in the field to determine the relative merits of the installation of two counterpoise conductors parallel to each other on one side of a tower, as positions 1 and 2 in Figure 2B, and the installation of the two conductors on opposite sides of the tower, as in Figure 2A. Four wires, 540 feet long, were buried in the ground in the pattern shown in Figure 2B, with 26-foot spacing between parallel conductors. The ground resistances were as given in Table III, and show about a 25 per cent advantage for the arrangement of Figure 2A.

Based on field data, Table IV gives the order in which it has been found that

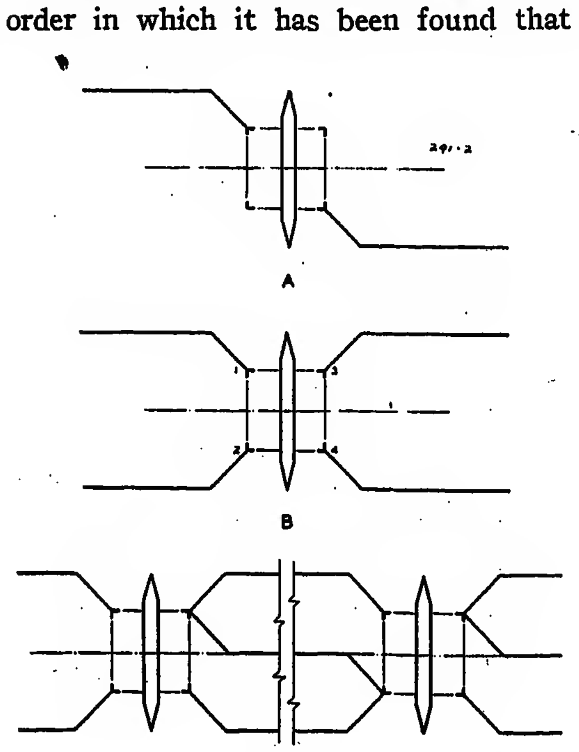

Figure 2. Arrangement of counterpoise conductors

Table III. Ground Resistance of Counterpoise Conductors at Test Installation Arranged as Shown in Figure 2B

All	10.1

counterpoise can be most effectively installed to reduce footing resistances to a desired level. The individual conductors are spaced as far apart as right-of-way restrictions allow, and the grounding conditions at each tower determine the type and extent of the counterpoise system to be installed.

V. Estimating Counterpoise Conductor Requirements

When tower foundations have been placed and a few weeks are allowed to elapse for the soil to settle around them, ground resistances are measured and used as indicators of the amount of counterpoise required. This procedure does not usually delay construction; when necessary, counterpoise can be laid and its resistance measured with a transmission line in operation. Incidentally, this fact has permitted counterpoise to be applied readily to the improvement of old lines. Tower-footing resistances have been found to be more reliable indicators of counterpoise requirements than spot soil-resistivity measurements, because of the abrupt changes in soil characteristics which occur in the territory under consideration. This territory varies from comparatively level ground, partly wooded, partly cultivated, up to hilly country where abrupt changes in elevation of a few hundred feet occur. Wherever rolling or hilly country is encountered, the soil consists of heavy clays liberally interspersed with broken shale or large boulders. In level country near sea level, the soil is generally sand or river silt.

Table IV. Recommended Order for Installation of Counterpoise Conductors

1. Two 200- to 400-foot conductors at opposite sides of tower (Figure 2A)
2. Four 200- to 400-foot conductors (Figure 2B)
3. Conductors extended to adjacent tower on one side, then to adjacent tower in opposite direction as required (see section III)
4. Third conductor laid midway between other two (Figure 2C)

It would be desirable to predetermine two characteristics of a counterpoise installation:

1. The levels to which ground resistances can be reduced from given initial tower-foundation resistances.
2. The amount of counterpoise conductor which will be required to attain the desired result.

No satisfactory method of doing either of these things was found until some actual field experience was accumulated. Based on data such as that given in section VII, estimates could be made of the average wire needed and final ground resistance to be attained for towers having foundation resistances in a given range. Even then, accurate estimates could not be made unless a large number of towers was considered, because the actual installation at a given tower frequently varied a good deal from the average result. Each tower and span was considered separately, taking into account situations in which long counterpoise conductors were required, and the installation would serve to improve conditions at both towers at the end of the span. In some cases it was found that certain towers would themselves require short counterpoise, while the neighboring tower would require a continuous one. An installation of this type, designed to make satisfactory the worse of two grounding conditions, would reduce the final ground resistance of the low-resistance tower much below the optimum value.

At those towers where large amounts of counterpoise conductor were called for, not more than three conductors in each direction from the tower were specified, because of considerations which were discussed in section IV.

VI. Ground-Resistance Measurements

A common method for making ground-resistance measurements is the three-electrode method.[10] With counterpoise conductors several hundred feet long, the required spacings of the two temporary probes used in the three-electrode method become impractically large. A simple and practical substitute for the three-electrode method is the direct reference method, using the completed transmission line and its grounds as the reference electrode.[10] The ground resistance measured by this method includes that of the reference electrode as well as that of the system being investigated. The ground resistance of an entire transmission line is usually only a fraction of an ohm, making the observed resistance the ground resistance of the counterpoise system for all practical purposes.

When applying the direct reference method, the counterpoise conductors are disconnected from the tower at which it is desired to obtain measurements and also from the next adjacent tower on each side, if the counterpoise is continuous. The counterpoise conductors are then electrically connected in parallel, and the resistance measured between their common point and the tower. The overhead ground wire serves to connect the tower to the rest of the system. It has been found by tests that the ground resistance of a counterpoise system and a tower in combination is approximately the same as that of the counterpoise system alone. The reason for this phenomenon is that the tower foundation lies within the extensive counterpoise system and does not contribute appreciably to the conductivity of the system as a whole.

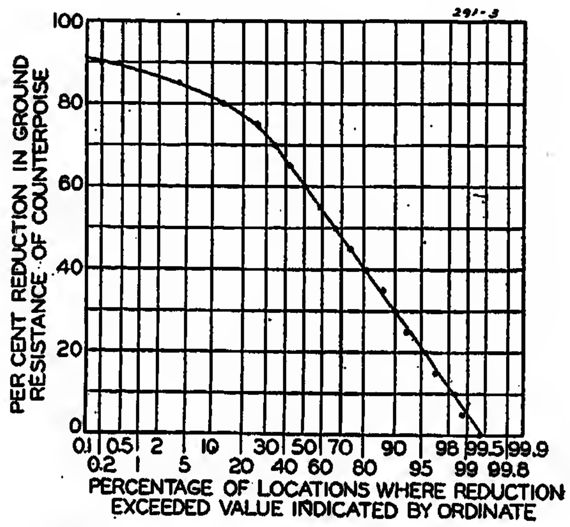

Figure 3. Reduction of counterpoise ground resistance due to weathering, at 483 tower locations

Counterpoise installed with a wire-laying plow

In this connection it is of some importance to note that the same effect is present when ground rods of moderate length are used at tower foundations. Due to the size of a tower foundation in relation to that of the rod and the small amount of additional soil contacted, the ground rod has been found to reduce ground resistances only slightly below that of the foundation alone. Exceptions occur in those special cases where a conducting stratum has been reached by rods of moderate length or very long rods have been driven.[11]

Practical considerations when making field measurements require that care be taken that corroded contacts do not cause inaccurate measurements. Defective electrical contacts may appear in the ground

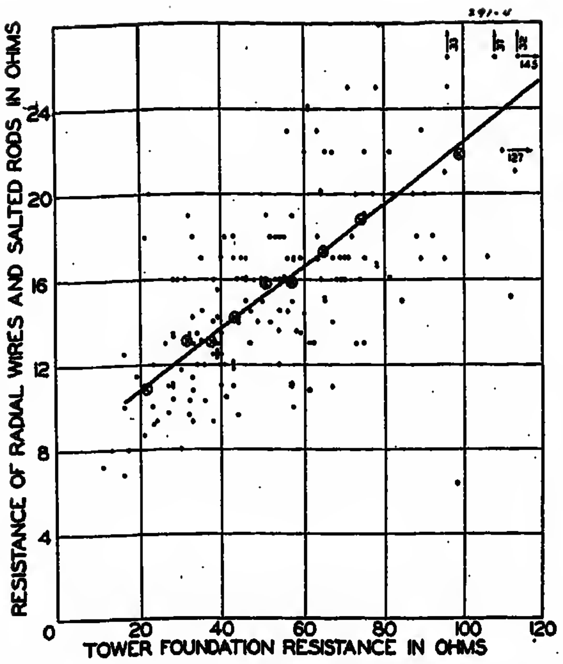

Figure 4. Ground resistances produced by four 50-foot buried radial wires terminating in salted rods at 171 locations on the Safe Harbor–Westport 220-kv line

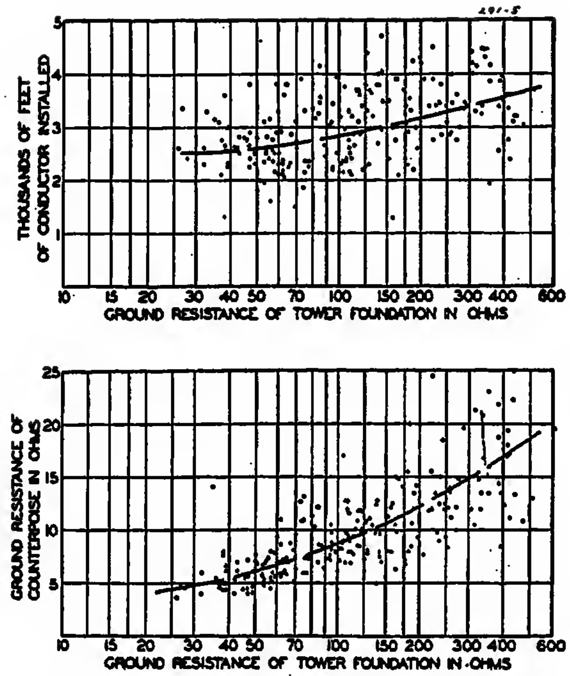

Figure 5. Counterpoise characteristics at 216 locations on the Holtwood–Coatesville 66-kv line

In many cases, counterpoise is continuous from tower to tower and serves to reduce ground resistance at two towers

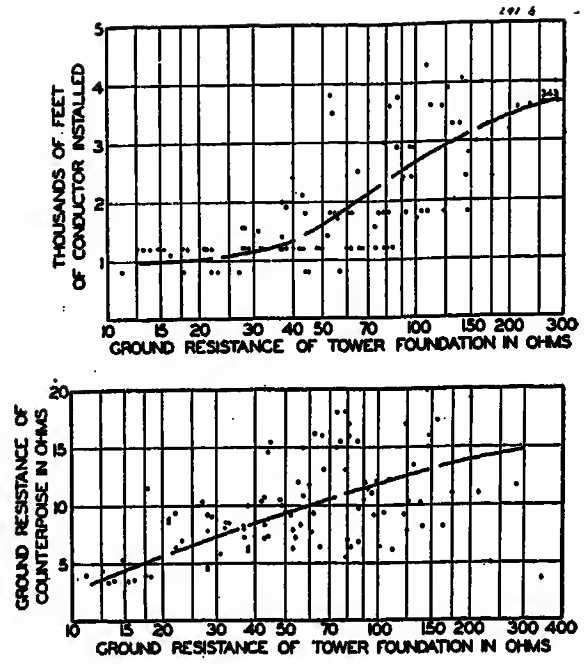

Figure 6. Counterpoise characteristics at 100 locations on the Safe Harbor–Perryville 132-kv line

The longer counterpoises are usually continuous and serve to reduce resistances at two towers

at bonded joints in the counterpoise conductors and also at the tops of towers where the overhead ground wires are supported.

VII. Field Data

Following the installation of counterpoise with a plow, there is a decrease in ground resistance during the ensuing period while the weather packs the soil into better contact with the buried conductor. This phenomenon has been found to be a highly variable one, indeterminate at any given location except by actual measurements of ground resistance. For instance, it can be seen in Table V that the variations in reduction have been from 0 to 91 per cent of the resistances measured at time of installation. After the initial weathering, further changes in counterpoise resistance have been found to be inappreciable. When making an installation, it has been the practice to allow for a reduction in ground resistance in order to limit the amount of wire used. In making this allowance, a balance was struck between an occasional installation of an excessive amount of counterpoise conductor as against the probable hazard of an occasional high footing resistance. In some cases where little or no reduction materialized, additional counterpoise was installed after weathering had occurred. Figure 3 can serve as a basis for establishing a working rule.

On the first line to which the principles of preventive lightning protection were applied, attempts were made to reduce the ground resistance of tower foundations by the addition of four 50-foot buried radial wires terminating in salted eight-foot ground rods. The results of this work are shown in Figure 4. In addition to the individual points shown on the graph, the encircled crosses each represent the average for 19 locations. This method of improving ground resistance was not satisfactory, because it did not reduce most of the tower-footing resistances below the desired level of 16 ohms. Subsequently footing resistances were improved by the addition of counterpoise conductor.

Figures 5 and 6 show the characteristics of counterpoise on two lines on which counterpoise alone was used to improve footing resistances. On the 66-kv line it was desired to obtain footing resistances below six ohms. On the 132-kv line the optimum value was ten ohms. As would be expected from the relative magnitude of the two desired final values, the economical maximum amount of wire which could be installed at a given location was reached more often on the 66-kv

Holtwood–Coatesville (66 kv)	216	511	147	6	25	167	2,400	1,612

line than on the 132-kv line. It must be borne in mind that the lightning performance of these two lines is very good even though the optimum conditions were not attained in many cases.

The wide scattering of points in Figures 4, 5, and 6 are attributed to the abrupt changes in soil conditions which were frequently encountered. Where salted rods were used, they frequently could not be driven to their full length of eight feet due to rocky conditions. Where counterpoise was used, lower resistances to ground were obtained in cultivated fields and pasture land than in woods, and in low sections, than on hills. As the counterpoise was laid, it frequently would pass from one soil condition to another, producing noticeably different results on one side of a tower from those produced on the opposite side. In spite of the large variations in the results obtained at individual towers having similar foundation resistances, data of the type given have been useful in estimating the average requirements of projected installations.

It has not been the practice to remeasure the ground resistance of counterpoise at every location after weathering has occurred. It has been measured only at those locations where the values at time of installation were greater than the optimum values. For this reason complete data cannot be given for all locations on every line. However, in Table VI an indication is given of the magnitude of reductions in ground resistance that have been obtained by the use of counterpoise. The criterion of the worth of preventive lightning protection is the outage record of the lines to which it has been applied. Such a record is given in Table VII, and counterpoise has played an important role in minimizing interruptions due to lightning.

VIII. Summary

1. There is apparently an optimum value of tower-footing resistance for a given level of insulation on a transmission line. This has been evaluated empirically as approximately one-hundredth of the kilovolt flashover value of the insulation.

2. Three parallel wires in a counterpoise system seem to be the largest practical number. Such an installation provides six electrical paths away from a tower foundation.

Table VII. Lightning Outages of Lines Having Counterpoise as Part of Preventive Lightning Protection

Line	Years of Record	Outages	Outages Per 100 Miles of Line Per Year
Safe Harbor–Westport–Takoma (220 kv)	10	1	0.11
Safe Harbor–Riverside (220 kv)	4	1	0.50
Safe Harbor–Perryville (132 kv)	7	1	0.42
Holtwood–York (66 kv)	6	2	1.46
Holtwood–Coatesville (66 kv)	4	3	2.55

3. The counterpoise system installed at each tower on a line must be graded to the conditions at the tower location if uniformly low ground resistances are to be obtained at reasonable cost. Uniform low ground resistances along a line are to be preferred to a uniform counterpoise system.

4. The ground resistance of a counterpoise system decreases for a period following installation due to settling of the soil around the buried conductors. After the initial weathering period, seasonal variations usually are small in the territory where observations were made.

5. The amount of counterpoise conductor installed and the final resistance obtained at towers having similar foundation resistance varied a good deal due to abrupt changes in soil conditions in the territory studied. In spite of the variations, the average results have been helpful in estimating conductor requirements for new work.

6. Preventive lightning protection, in which counterpoise plays a prominent part by reducing tower-footing resistances, is very effective in preventing flashovers on high-voltage lines.

Electric Control for Steam Boilers on Diesel-Electric and Straight Electric Locomotives

E. H. BURGESS
NONMEMBER AIEE

ELECTRIC control is a necessity in the operation of the modern steam boiler if the boiler is expected to have maximum efficiency, safety in operation, and constant operation at the various outputs required. Installation and operating conditions vary over a wide range; therefore, to meet these conditions the controls used differ in type and quantity in order to supply those actually needed for good operation, as well as those required to comply with rules and regulations under which the installations are permitted. Generally, the method of operation of such boilers can be classified in two categories, namely, automatic and semiautomatic, and these two classes will be discussed in this article.

Electric control is further separated into two component parts, where one group of items consists of the operating necessities for actual boiler operation, and the other of safety features required under legal regulations (including those needed for the safety of the equipment itself in case of failure of any major part).

Automatic-Control Boilers

Operating Necessities

To analyze the operation and use of each of the control items used for a complete automatic installation, it will be advisable to start with the basic boiler and add each electric item in the order of its use for normal operation.

Current for igniting the atomized fuel is generally obtained from high-voltage transformers or magnetos, with the majority of installations using the transformer, because of its ability to give a very hot spark for complete combustion. With transformer ignition a source of alternating current is required, and this is obtained from a suitable rotary converter where the necessary direct current is taken from the locomotive batteries or control source.

To provide constant ignition under all operating speeds of the boiler motor—including the off cycle of the boiler when no steam is being used—the converter is connected directly across the line and is controlled by the master control switch. The rotary converter serves another purpose also by supplying alternating current for the electric-eye operation, which will be discussed later under safety controls.

The pressure switch, operating directly from steam pressure, actuates the balance of the controls to regulate the required output. Where various output capacities are required, a multifinger switch is used to vary the motor speed in accordance with steam output and it automatically cuts in the motor-speed relays to keep the steam pressure up to the operating point.

As less steam is used, the pressure switch causes the contact fingers to operate in a definite sequence to slow down the motor, and thus only sufficient steam is made to replace that amount which is being used. When the steam consumption becomes greater than the output, the contact fingers operate in the reverse cycle and cause the motor to speed up in order that sufficient steam should be available for the requirements.

Connected in the oil line is a solenoid valve used to stop the flow of oil when such operation is required. The valve coil receives its current from the main relay of the motor control and is only energized when the relay is closed and the motor running. During the off cycles of the boiler the motor relays are de-energized; therefore, the oil solenoid valve is closed to prevent any oil from collecting in the combustion chamber which might cause a minor explosion when the fire again lights. This valve is also kept de-energized when the main motor is being run, only for the purpose of filling the boiler with water, and is accomplished by an interlock in the master control switch.

An important item in electric controls is the time-delay relay which has several functions during the normal operation.

Paper 42-127, recommended by the AIEE committee on land transportation for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 13, 1942; made available for printing May 19, 1942.

E. H. Burgess is electrical engineer with the Vapor Car Heating Company, Inc., Chicago, Ill.

When the boiler is ready to run, and the proper switches have been turned to their operating position, the time-delay relay is momentarily energized, but the contacts remain closed for a predetermined length of time. Unless the oil ignites and keeps burning during this predetermined time, the contacts will open and shut the boiler down. If the fire continues to burn, then the relay coil will become energized through the electric eye or stack switch operation. During the off cycles of the boiler, it is also necessary to keep this relay energized in order that the motor will again start when steam is required, and this is accomplished by an interlock on the motor relay or a separate pilot relay. The time-delay relay is generally adjustable, so that the predetermined time setting can be adjusted to suit the conditions required for various sizes and types of boilers.

Safety Features

On any boiler installation safety control features must be included in order to comply with laws or regulations, and also to insure safety in operation of the boiler itself. To provide some means of stopping the boiler in case the fire does not properly ignite or goes out because of some defective part of the controls, some means must be provided to detect this condition, and transmit the proper impulse to the motor controls. Two methods are generally used, one being the photoelectric-cell type and the other a stack switch whose contacts are operated by a bimetallic helix.

The photoelectric-cell method consists of locating the photoelectric cell so that it is affected by the oil flame in the combustion chamber, causing current to flow to the amplifying unit. The rectifying and amplifying unit used in conjunction with the photoelectric cell includes a sensitive relay that remains energized whenever the proper flame is burning in the boiler. If the flame should go out while the motor is still running, the sensitive relay acts on the time-delay relay, which will stop the motor after the predetermined time lag. During normal operation, where the pressure switch stops the motor and cuts off the flow of oil, a pilot-relay interlock keeps the time-delay relay energized even though the sensitive relay contact is open.

Stack-switch control is similar to the photoelectric cell except that the contacts are opened and closed mechanically by the bimetallic helix which is, in turn, affected by the temperature of the gas surrounding it in the smoke stack. These

contacts are normally open and they close when a relatively low stack temperature has been reached such as one resulting from a continuous burning fire.

Where air, under pressure, is used to atomize the fuel oil, an air control switch is incorporated in the controls to insure that sufficient air of proper pressure is fed to the oil nozzle, so that the combustion will be complete and retain a clean fire. The air control switch is usually set to open the control circuit when a reduction of air pressure in the feed line reaches a point that will affect the combustion quantity of stack smoke and efficiency.

To protect against excessive high steam temperature, a high-temperature switch is incorporated in the control circuit to open the motor circuit when the temperature limit is reached. One type of switch uses an alloy that melts at this temperature and, in doing so, opens a spring set contact. To reset, the molten alloy must first cool and harden in order to hold the contacts closed for further operation of the motor controls.

A periodic blowdown of the coils is necessary to remove sediment and other foreign materials from the coils and pipe lines connected with them. To facilitate this operation a coil blowdown valve is

installed in the water intake line, and incorporated with it is an electric push-button assembly. When the valve is open the electric circuit is open, so that the boiler cannot run while steam is being blown back, and the boiler cannot be restarted until the valve is fully closed.

To guard against excessively high stack temperature, which is an indication of some faulty adjustment or badly sooted coils, a stack switch is located in the smoke stack, and its contacts are operated by a bimetallic helix. The high temperature contacts are normally closed and, once opened, have to be reset manually and only after the temperature has decreased sufficiently to enable the contact mechanism to re-engage. Installations that use a stack switch instead of photoelectric cell for a low fire control have both low and high temperature contacts operated by a common helix in one housing.

Alarm Mechanism

Audible or visual alarms are used with boiler controls, depending on the type of installation and rules of the operator. In general, the alarm circuit consists of a suitable relay whose contacts, when closed, ring a bell or light a series of lamps, or both. The alarm relay is connected into the boiler control circuit so that the opening of the contacts of the various safety features will not only shut down the boiler, but it will also give the designated alarm.

Figure 1 shows the front view of a typical automatic boiler equipped with controls as mentioned above. The multi-finger pressure switch is shown to the right of the gauge box and in front of the air intake. Control cabinet directly below the gauge box contains the starting and speed-selection switch, time-delay relay, pilot relay and terminal-connection panel. The master motor for driving the blower wheel, water pump, and oil pump is shown mounted directly beneath the control cabinet. At the lower right-hand corner is shown a cutout box in which is located the electric push button used in conjunction with the coil blowdown valve.

Figure 2 shows the side view of the same boiler. At the upper left position is shown the side view of the multifinger pressure switch as previously described. To the right of the pressure switch is shown the ignition transformer and the high-voltage wires connected to the spark plugs which are near the top of boiler. The oil solenoid valve is shown directly at the top of boiler above the peep sight case. Just below the smoke-stack connection is shown the stack switch, mounted in the smoke hood, and to its right the high-temperature switch is mounted in the steam line.

Figure 3 is a schematic wiring diagram used in conjunction with this type of boiler and shows the connections between the various electrical operating controls and safety features.

Semiautomatic-Control Boilers

Semiautomatic-control boilers are essentially the same as the fully automatic-control boilers except for a few operating differences. The pressure switch is of the single-finger type, which opens and closes in accordance with the steam pressure selected but has no effect on the speed of the driving motor other than start and stop. Speed selections of the motor are made with a manual selector switch which connects to the motor various amounts of resistance, depending on the position of the switch. By this means the operator adjusts the motor speed, so that the steam output of the boiler will be satisfactory for the load it has to carry. Where motors used are of such size that motor starters are required, the necessary step control relays and starting resistance are needed in addition to the manual selector switch for actual speed-control setting.

Controls of this type are naturally limited to installations where the load is relatively constant for considerable lengths of time, or where an attendant is readily available to change the motor speed setting as often as necessary.

Electrical controls for steam boilers play such an important part in their operation, that any amount of time spent in developing the correct type is warranted by the practical results obtained. Full-time operation at maximum output and highest efficiency can be had only with electric controls that perform their respective functions in the way intended. The items mentioned in this article have been selected, from past experiences, to be necessary for proper operation and complete control of all functions of the boiler, including the safety requirements.

Electronics of the Fluorescent Lamp

MARK A. TOWNSEND
ASSOCIATE AIEE

THE fluorescent lamp is one of the recent and rapidly growing additions to the field of electronic devices. In order to understand properly the characteristics of the fluorescent lamp, it is necessary just as with other electronic devices, to know something about the fundamental principles of operation. It is the purpose of this paper to describe the operating principles of this type of lamp, both as an electrical conductor and as a radiation generator. Following a brief outline of the properties of radiant energy as they concern lamp design, a description is given of the phenomena occurring in the separate regions of the lamp. The final section of the paper is concerned with the over-all characteristics of the lamp considered primarily as a circuit element.

The purpose of any electric lamp is to convert electric energy into radiant energy. The usefulness of a lamp depends not only upon the efficiency with which it converts the input energy into radiation, but also upon the suitability of the produced radiation for the particular application involved. The following description of radiant energy is presented to indicate requirements placed on a lamp as regards radiation output. In order to indicate the similarity of lamps to other electrical equipment, radiation is described in terms of frequency rather than by the more conventional wave-length designation. For the benefit of those more familiar with the wave-length description, important values are given in both units.

Radiant Energy

To be useful as light, the radiant energy produced by a lamp must fall within the region of the spectrum to which the human eye is sensitive. This region is shown in relation to the remainder of the electromagnetic spectrum by the chart of Figure 1. Although the ultraviolet and infrared regions of the spectrum immediately adjacent to the visible are not directly useful for illumination, they are increasing in importance for other uses, and the term lamp has been extended by common usage to include sources of radiation in these regions of the spectrum. The range of frequencies covered by commercially available lamps is shown in the expanded portion of Figure 1.

It is desirable to control the processes of energy conversion within a lamp so that the proper frequency of radiation is obtained for each intended application. This may be illustrated for visible light by the curve of Figure 2, which shows the average response of the light-adapted human eye as a function of frequency. This may be compared with the response of a radio receiver tuned to a frequency of 540×10^{12} cycles per second, corresponding to a wavelength of 5,550 angstrom units (A). It is apparent that the greatest possible light-producing efficiency would be obtained with a lamp which converted all the energy input into radiation at this frequency. Such a lamp would be a green light source having an efficiency of approximately 620 lumens per watt. However, the usefulness of such a lamp would be limited because of its color. When a lamp produces radiation at any frequency other than 540×10^{12} cycles per second, its luminous efficiency is necessarily lower than the above value. For example, a lamp which converted all the input energy into radiation within the visible region having the same spectral distribution as average daylight would have a luminous efficiency of only 220 lumens per watt.

In the incandescent lamp, the spectral distribution of the output radiation is continuous throughout the spectrum and is controlled by the operating temperature of the filament. Since the energy distribution is continuous, it is not possible to confine the output to a narrow range of frequencies, except by filtering out and thus wasting the undesired radiation. In a gaseous discharge lamp the frequency of the output radiation is fixed by the kind of gas, each gas having certain characteristic frequencies which it can radiate. The relative amounts of energy radiated at the different frequencies can be controlled by the type of discharge. A good example of this method of control is given by two types of mercury lamps: in the low-pressure germicidal lamp most of the radiation from the mercury is concentrated in the short-wave ultraviolet, while in the high-pressure capillary lamp a major portion of the radiation is produced in the visible and long-wave ultraviolet regions. In the fluorescent lamp the output frequency is controlled by the choice of the fluorescent coating, as will be described later in this paper. However, the operation of the fluorescent lamp also involves a gaseous discharge in which, as in the simple discharge lamp, the most important controlling factors are the nature of the gas and the type of discharge. The electronics of the fluorescent lamp are concerned with the operation of this gaseous discharge, both as a circuit element and as a radiation generator.

Principle of the Fluorescent Lamp

The process by which the fluorescent lamp converts electric energy into visible radiation is analogous to that of two energy converters connected in series. The first of these is a gaseous conduction lamp which is designed to convert electric energy into ultraviolet radiant energy. This lamp usually takes the form of a glass tube having a length of from 10 to 50 diameters. Within the tube is a small drop of mercury producing a mercury vapor pressure corresponding to the temperature of the tube wall. Also present is a low pressure of argon gas. Specially designed electrodes at each end of the tube are connected to the external circuit by means of vacuum-tight glass-to-metal seals. In operation this constitutes a low-pressure mercury vapor discharge lamp which can be made to convert 50 per cent or more of the electric energy input into ultraviolet radiation of wavelength 2,537 angstrom units corresponding to a frequency of $1,182\times10^{12}$ cycles per second.

The second energy converter in the fluorescent lamp is a frequency changer which converts the $1,182\times10^{12}$ cycles per second radiation into visible radiation with frequencies between 750 and 430×10^{12} cycles per second (4,000–7,000 angstrom units). This frequency converter consists of a coating of fluorescent powders which is applied to the inside surface of the discharge tube. This frequency conversion process is relatively high in efficiency so that, when it is combined with an efficient source of the exciting radiation, a high over-all lamp efficiency is produced.[1,2] Although a major portion of this paper is devoted to the gaseous conductor, a brief description of the characteristics of fluorescent powders is necessary in order to illustrate the require-

Paper 42-122, recommended by the AIEE joint subcommittee on electronics and committee on production and application of light for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 20, 1942; made available for printing May 11, 1942.

MARK A. TOWNSEND is lamp development engineer, lamp development laboratory, General Electric Company, Cleveland, Ohio.

The author acknowledges the helpful criticism and advice of his associates in the lamp development laboratory.

ments which the gaseous conductor must meet.

Fluorescent Materials

Certain materials, known as phosphors,[3] have the property of emitting visible light when they are exposed to exciting agents such as cathode rays, X rays, and ultraviolet radiation. The light thus produced is called fluorescent light, and most engineers are familiar with this property as used in the fluorescent screen of the cathode-ray oscilloscope and the X-ray fluoroscope. However, by far the most efficient method of exciting these phosphors is the use of ultraviolet radiation, as in the process used in the fluorescent lamp.

The color of the fluorescent light depends upon the type of phosphor and the methods by which it is prepared and is not, in general, influenced by the frequency of the exciting radiation. Table I lists some of the phosphors used in fluorescent lamps and gives the predominant color of the light which they emit. By properly mixing these different phosphors, one can obtain almost any desired color of light. The curves of Figure 3 show the distribution of the energy output with respect to frequency for daylight, blue, and pink fluorescent lamps. The continuous curves represent the energy radiated from the phosphor; the dotted rectangles represent the relatively small amount of visible energy produced by the mercury discharge.[4] It should be pointed out that the curves given in Figure 3 are plotted with respect to frequency, and they therefore differ in shape from curves plotted with a uniform wavelength scale. Ordinates have been selected so that the total area under the curve gives the total energy radiated by the phosphor.

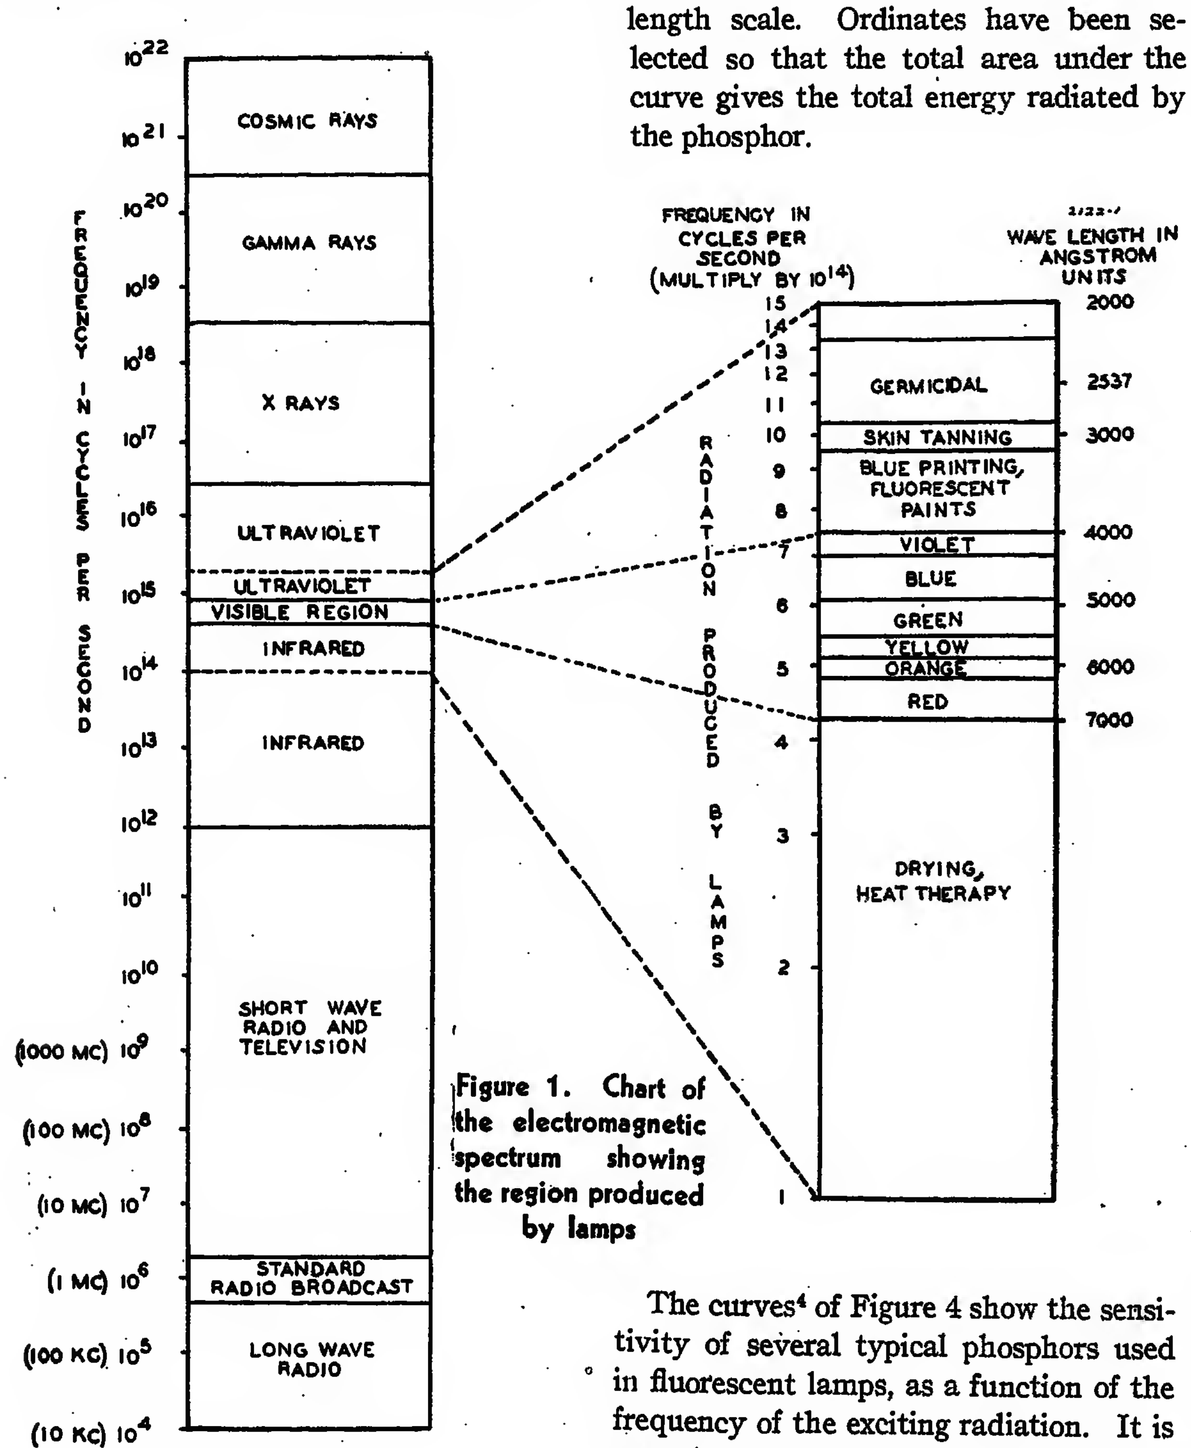

Figure 1. Chart of the electromagnetic spectrum showing the region produced by lamps

The curves[4] of Figure 4 show the sensitivity of several typical phosphors used in fluorescent lamps, as a function of the frequency of the exciting radiation. It is seen that these have their maximum sensitivity in the region near $1,182 \times 10^{12}$ cycles per second (2,537 angstrom units), which is the radiation most efficiently produced by the low-pressure mercury discharge which makes up the gaseous conductor of the fluorescent lamp.

The Gaseous Conductor

A glass tube filled with neutral gas atoms, as, for example, an unexcited fluorescent lamp, is an almost perfect insulator. Even if electrons are freely introduced into the gas, only small currents can be made to flow with the usually available voltages, so long as the gas atoms remain electrically neutral. The reason for this is that the space charge produced by the electrons limits the flow of current. Only by breaking up the atoms of the gas into charged particles, or in other words, "ionizing" the gas, can reasonably large currents be made to flow. This process of ionization is essential to the operation of almost every type of gaseous conductor. In the case of a rectifier, thyratron, or similar device, the passage of current is the chief function of the discharge, and conditions are preferably arranged so that a minimum amount of energy is absorbed by the conductor. The primary purpose of the gas discharge lamp, on the other hand, is to produce radiation. As will be described later in the paper, radiation is obtained from "excited" atoms which have absorbed energy from the discharge. Hence, in the discharge lamp, conditions are preferably arranged so that as much energy as possible is absorbed by the conductor in the formation of excited atoms.

The gaseous conductor of the fluorescent lamp may be separated into three main regions, namely, the cathode region, the anode region, and the positive column. The most important of these is the positive column, which includes most of the length of the lamp, and in which most useful excitation (and hence radiation) is produced. The cathode and anode regions serve to connect the positive column to the external circuit. These are regions of low light-producing efficiency and, for this reason, conditions in general are chosen so that they consume as little as possible of the total lamp wattage. On alternating current the same electrode structure must serve alternately as anode and cathode, although the electronic phenomena are greatly different for the two functions. Before considering in detail these regions of the discharge, a brief description will be given of the fundamental processes of excitation and ionization.

Excitation and Ionization

Although there are many ways in which atoms may be excited and ionized, in a gas discharge lamp, we are primarily interested in excitation and ionization by electron collision. For the purposes of our description an atom may be pictured as a positively charged nucleus surrounded by a number of electrons. The mass of the nucleus is very heavy compared to that of an electron. In the normal state of the atom, the number of electrons is just

sufficient to neutralize the positive charge of the nucleus and in addition the internal energy of the atom is at its minimum value. If this normal atom is struck by an electron, the collision may be as between elastic spheres, and, due to its great mass, the atom will absorb very little energy from the electron. The small amount of energy which is absorbed in such a collision appears as a change in velocity of the atom (increase in thermal energy of the atom). If, however, the colliding electron possesses more than a certain minimum amount of energy, there exists a probability that the atom will make an inelastic collision and absorb a definite amount of energy from the electron. In this process one (in rare

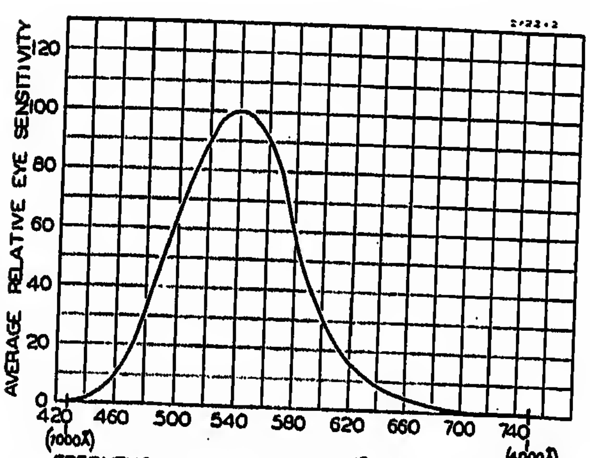

Figure 2. Average relative response of the light-adapted human eye as a function of frequency

cases more than one) of the electrons of the atom is changed from its normal state to a state of higher potential energy, and the atom is said to be "excited." In the new state the electron is more loosely attached to the nucleus but is still a part of the original atom; hence, an excited atom is still electrically neutral. For each different kind of gas atom certain characteristic discrete states of potential energy are possible, and these are usually called energy levels. An atom does not remain in an excited state indefinitely, but in most cases very quickly returns to the normal state and releases the energy of excitation in the form of radiant energy. The frequency of the radiation emitted during the transition from one level to a lower level depends upon the energy difference between the levels, and is given by the equation:

$$f = 242.9 \times 10^{14} V \text{ cycles per second} \qquad (1)$$

where f is the frequency of the emitted radiation and V is the energy difference expressed in electron-volts (an electron-volt is the energy gained by an electron in traversing a potential difference of one volt). When several possible energy levels lie between a given excited state and the normal state, this transition may occur in several steps.

The lowest energy level (neglecting metastable states) from which a mercury atom can return to the normal state corresponds to an energy difference of 4.86 electron-volts. This transition, by equation 1, produces radiation at a frequency of $1{,}182 \times 10^{12}$ cycles per second, which is the radiation desired for exciting the phosphor in the fluorescent lamp.

Ionization is a process similar to excitation except that the energy absorbed by the atom in question is sufficient completely to remove one or more of its electrons. An atom which has lost an electron is positively charged and is known as a positive ion. Ionization may be produced in one step, if the colliding electron has energy greater than a certain value known as the minimum ionizing potential. This value for mercury is 10.38 electron volts. Other types of ionizing collisions exist, but there is evidence that they are

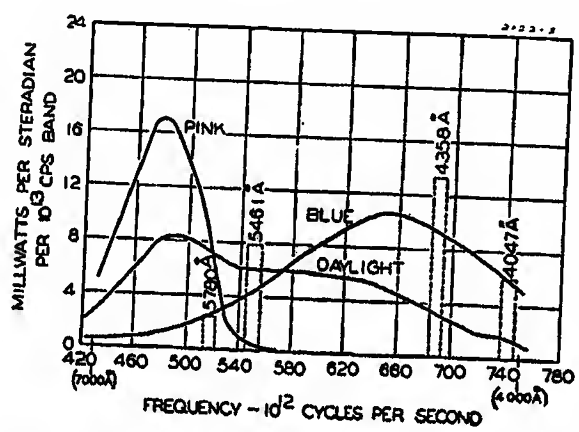

Figure 3. Spectral distribution of radiation from 15-watt fluorescent lamps of different colors

of lesser importance under the conditions of the fluorescent lamp.

The manner in which these fundamental processes of excitation and ionization are utilized in a fluorescent lamp will now be considered.

The Cathode Region

The cathode in a fluorescent lamp is of the type commonly known as oxide-coated (or Wehnelt) and consists of a coil of tungsten wire activated by means of a coating of alkaline-earth oxides such as barium and strontium oxides. During starting, the cathode is preheated, and for this purpose two external leads are provided to permit passage of the heating current directly through the cathode coil. After starting, the discharge provides sufficient heating of the cathode, and external heating is not required.

In normal operation only a small portion of the cathode area is heated by the discharge to an electron emitting temperature, and the available zero-field emission current is considerably less than the total lamp current. Under these conditions a positive-ion space charge builds up at the cathode and produces an electric field at the cathode surface. The region of high electric field is called the cathode sheath. This field very greatly increases the electron emission in a manner which is characteristic of activated surfaces.[5] The generally accepted picture of the cathode phenomena under these conditions is as follows.[6]

Electrons emitted by the cathode are accelerated by the field which exists in the above-mentioned positive-ion cathode sheath. The voltage drop across this region is known as the cathode fall and has a value slightly larger than the minimum ionizing potential of the gas which surrounds the cathode. The electrons from the cathode thus acquire energies capable of ionizing and exciting the atoms with which they collide in the region beyond the positive ion sheath. The positive ions produced in this region diffuse in all directions, and those moving toward the cathode counteract the space charge of the electrons and create the field of the cathode as described above. Because the positive ions have masses

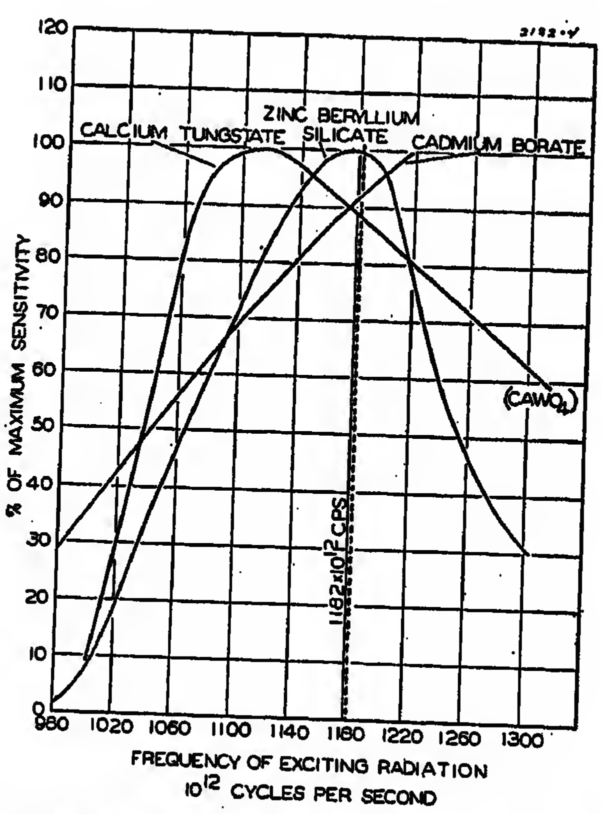

Figure 4. Relative sensitivity of typical phosphors used in fluorescent lamps, as a function of frequency of exciting radiation

many times greater than the electrons, they move much more slowly, and therefore relatively few are required to counteract the space charge of the electrons. In the case of mercury, the relative velocities of an electron and a positive ion, both having the same energies, are approximately 600 to 1.

An approximate calculation of the

zero-field emission current under actual lamp-operation conditions will serve to illustrate the order of magnitude of the quantities involved. For an eight-watt lamp cathode operating at 0.18 ampere, observed values of emitting area and temperature are approximately 0.01 square centimeters and 1,180 degrees Kelvin, respectively. Using the data given by Dushman,[7] the zero-field emission current is calculated to be 0.75 ampere per square centimeter, giving a total current of 0.007 ampere. Thus, for the particular conditions here described, the zero-field emission is only about four per cent of the total lamp current. This figure agrees in order of magnitude with the value of ten per cent given by Found[6] for a similar type of cathode. That the observed current is so much greater than this zero-field value is explained by the above-mentioned action of the electric field at the cathode. In addition a small fraction of the current

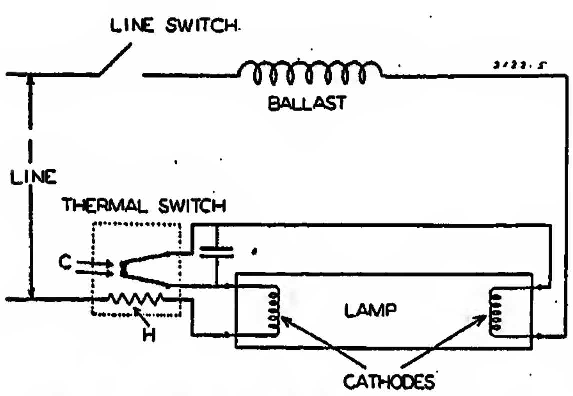

Figure 5. One of the common automatic starting circuits for fluorescent lamps

is carried by the positive ions which move toward the cathode.

The electrons from the cathode, after producing ions in the region beyond the cathode sheath, have relatively low energies. By some mechanism not well understood, these electrons acquire a random distribution of velocities corresponding to a Maxwellian distribution. (When velocities are distributed in this manner, they may be represented by an equivalent temperature T_e, just as the velocities of the atoms of a gas are represented by the gas temperature. Thus we can speak of an electron temperature.) These low-energy electrons and the positive ions both diffuse from the cathode glow region and after a short distance enter a region where the voltage gradient begins to rise. This is where the positive column begins.

The Positive Column—Conduction Processes

The positive column is a region characterized by a uniform voltage gradient and a uniform degree of ionization throughout its length. Electrons entering from the cathode region gain energy from the gradient along the tube but nevertheless maintain a Maxwellian distribution of velocities, which corresponds to a temperature greater than that of the entering electrons, and which is many times greater than the temperature of the gas. These electrons drift toward the anode under the influence of the longitudinal gradient and, because they move faster than the positive ions, constitute all but a negligible fraction of the discharge current. This drift velocity of the electrons is small compared with their random velocities. In moving through the gas, these electrons collide with atoms of the gas, and some of these collisions result in the formation of positive ions and additional electrons. The electrons and positive ions have essentially equal concentrations in the positive column, and both diffuse toward the wall. As a result of their smaller mass, the electrons have higher velocities and tend to diffuse faster than the positive ions. This difference in rate of diffusion produces a radial electric field which accelerates the motion of positive ions and slows up the motion of electrons to the wall, until the two rates are just equal. This condition is necessary, because obviously the net current to the wall must be zero. It is apparent that the greater the electron velocities, the greater must be this radial field, and hence the greater must be the rate at which positive ions are lost to the wall. Tonks and Langmuir[8] have developed a relation called the plasma balance equation which expresses the rate at which ions are lost to the tube wall as a function of the electron temperature.

Not only is the rate at which ions are lost to the tube wall dependent on electron temperature, but also the rate at which they are generated is a function of the electron temperature. This follows from the fact that the probability that an electron will produce ionization by collision increases with the energy of the electron in excess of the minimum ionizing energy. (For very high energy electrons this probability decreases again.) This probability can be measured and is known for mercury vapor.[5] Thus it is possible to calculate the rate at which ions will be produced in a gas by electrons having any given electron temperature.[9]

In the steady state, for the type of discharge used in the fluorescent lamp, the rate at which ions are produced must equal the rate at which they are lost to the tube wall. Therefore the equations expressing the rate of ion generation and the rate of ion loss can be equated as shown by Found.[10]

$$(2V_T+V_i)e^{-V_i/V_T}=\frac{0.9}{B}\frac{s_0}{a}\frac{T_g}{P_g}\cdot\left(\frac{m_e}{m_p}\right)^{1/2} \qquad (2)$$

where V_T is the voltage equivalent of the electron temperature, V_i the minimum ionizing potential of the gas, s_0 is a factor dependent on the geometry of the container and the gas pressure, a is the tube radius, B is a constant relating to the probability of ionization which can be measured for any given kind of gas, T_g and P_g are respectively the temperature and pressure of the gas within the tube, and m_e and m_p are respectively the mass of an electron and the mass of a positive ion of the gas. From this equation it is possible to calculate the electron temperature for a tube containing a given gas at a known pressure by means of known constants. It can be seen that for any given gas the electron temperature (electron energy) decreases with an increase in tube radius and gas density and that the electron temperature remains constant as long as the product of gas density and tube radius remains constant.

This equation does not describe the experimental fact that the tube gradient decreases with an increase in arc current. This property of the positive column of

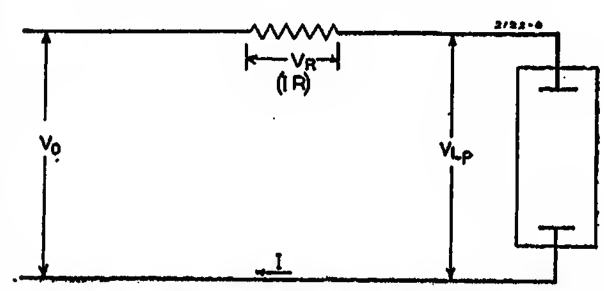

Figure 6. Simple resistively ballasted operating circuit

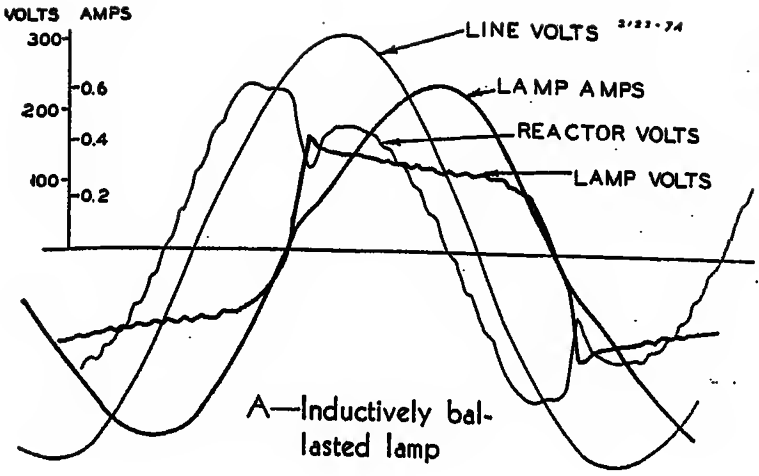
the fluorescent lamp is accounted for partly by an increase in mercury vapor pressure with an increase in input watts. In addition, Tonks and Langmuir[8] propose the explanation that two-stage ionization processes would permit lower energy electrons to produce ions and would therefore require a lower electron temperature than is needed for single-stage ionization conditions.

As was stated above, the positive ions are produced in the positive column only by the higher-velocity electrons in the Maxwellian distribution. This fact is of great importance in the production of radiation from a gas discharge lamp.

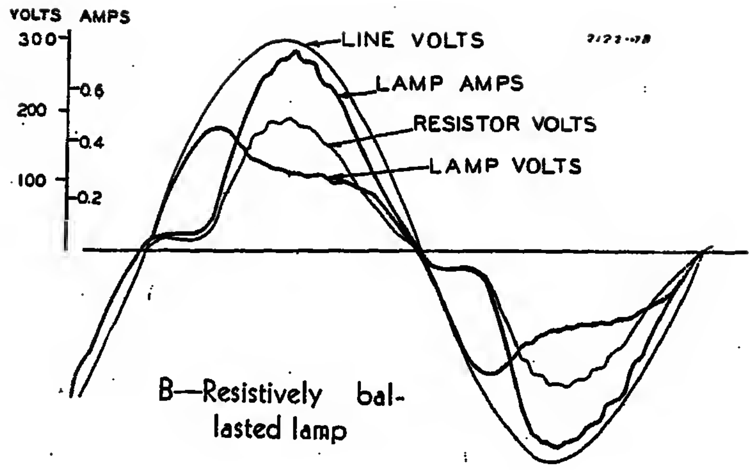
The Positive Column—Radiation Generation

In order to obtain a sufficient number of high-velocity electrons to satisfy the need for positive ions in the positive column, it is necessary (because of the Maxwellian distribution of velocities) to create a much larger number of lower-velocity



A—Inductively ballasted lamp

Figure 7. Oscillograms of current and voltage for two types of ballast



B—Resistively ballasted lamp

electrons. For example, if the average energy of the electrons is two electron volts, only 1.5 per cent of the total number have energies above the minimum ionizing potential of mercury, while 18 per cent have energies greater than the minimum excitation potential of mercury. Thus the process of radiation generation is only indirectly the result of the passage of current through the discharge tube. It follows that in order to increase the amount of radiation at any given frequency it is necessary to adjust the conduction processes so that the resulting electron energy approaches an optimum value for exciting the gas atoms to the desired energy level. In the practical lamp ideal conditions cannot be reached, because of considerations regarding total light output for a given size of lamp and other factors which cannot be considered here, relating to the lamp as a light source rather than as an electronic device.

The Anode Region

The anode region serves to connect the positive end of the positive column to the external circuit. Conditions at the anode are similar to those at the tube wall, except that the electron current reaching the anode must exceed the positive ion current by an amount equal to the current through the tube. If the anode area is large enough, so that the rate at which the electrons strike it as a result of their random motions is equal to the discharge current, no anode drop is necessary. If the anode area is larger than this, it develops a negative voltage with respect to the gas and repels electrons, until the net current reaching it just equals the tube current. If the anode area is too small, it develops a positive voltage with respect to the gas and attracts electrons until the net current collected is equal to the drift current. In this case a sheath builds up around the anode, until the electron current entering the sheath is equal to the discharge current. The area of this sheath is then the effective anode area. By convention, a positive anode drop means an increase in tube volts. In the fluorescent lamp, the anode area is such that the average anode drop has a positive value of approximately seven volts. This value is primarily determined by the requirements of cathode heating.

Electrode Heating

No mention has been made of the manner in which cathode is heated, except to state that this is done by the discharge. This process will now be discussed more in detail. On alternating current, each electrode functions alternately as anode and as cathode. During both half cycles, heat is removed by conduction and radiation, and a small amount of heat is produced by the passage of current through the cathode coil. During the cathode half cycle an additional loss of heat occurs as a result of the evaporation of electrons from the cathode, and at the same time heat is gained from the positive ions which reach the cathode. On the anode half cycle heat is supplied by the electrons, which are accelerated through the voltage drop in the anode sheath and deliver this energy—in addition to their thermal energy and the heat of condensation—to the electrode. This is the most important source of electrode heating in a-c operation. The total net heating is the average of that produced on the two half cycles, and in the usual fluorescent lamp this is more than sufficient to raise the cathode to an operating temperature. In fact, it is usually necessary to attach projections to the electrode to reduce the amount of heat gained on the anode half cycle, in order to prevent evaporation of the cathode material.

Over-All Characteristics of the Fluorescent Lamp

Like most electronic devices the operation of the fluorescent lamp is greatly influenced by the characteristics of the circuit to which it is connected. Consequently, any description of lamp characteristics must be made with reference to a particular set of circuit conditions.

For reasons to be described in this section, the fluorescent lamp cannot be satisfactorily started and operated unless the line voltage is greater than the lamp voltage. Consequently a voltage-absorbing device must be connected in series with the lamp to absorb the difference between the two. This necessary difference between lamp voltage and line voltage is the determining factor in selecting the amount of ballast required. Commercially this ballast consists of a resistance for d-c operation, while on alternating current it may be a resistance, an inductance, or a combination of inductance and capacitance. The commonly made statement that a ballast is required because of the negative volt-ampere characteristic of the lamp is true, but there are other equally important reasons for its use. These reasons are, as will now be described, the need for lamp starting, the need for good regulation with changes in line voltage, and the need for good current wave shape on a-c circuits.

Lamp Starting

In order to start a fluorescent lamp, it is necessary to ionize the gas between the electrodes and to heat the cathodes to an electron-emitting temperature. Perhaps the simplest method of accomplishing this is to apply a voltage several hundred volts in excess of the normal lamp-operating voltage across the lamp terminals. With this method of starting, however, the cathodes are required to emit electrons before the discharge has time to heat them to an emitting temperature, and the resulting high cathode drop may produce destructive sputtering of active material from the cathode surface. Also a disadvantage of this method of starting is the fact that the size and wattage loss of the ballast are greater than would otherwise be required. Conventional starting circuits avoid these difficulties by the use of a switch which connects the cathodes in series with the ballast, so that they are adequately preheated, and then opens the circuit to provide an inductive surge to start the lamp. The circuit of Figure 5 shows a thermal switch arrangement used

for automatic starting of the 100-watt fluorescent lamp. Contacts are mounted on bimetallic elements, so that they can be opened by heat produced in heater *H*. When the main line switch is closed, the short-circuit current of the ballast preheats the cathodes. Heater *H* is connected in series, and after time has been allowed for the cathodes to be heated, contacts *C-C* are caused to open. The resulting inductive surge starts the lamp, and lamp current then flows through heater *H*, keeping the contacts open. This starting action may also be accomplished by means of a glow switch.[11] In the case of direct current, if the ballast consists of a resistor, no inductive surge is produced when the switch opens. This difficulty is overcome by using a series inductance which does not contribute to the ballasting, but which supplies the necessary inductive starting surge.

Operating Stability

On a perfectly regulated line, a fluorescent lamp would theoretically require a ballast just sufficient to offset the negative volt-ampere characteristic of the arc, and the lamp voltage could be made nearly equal to line voltage. In a practical circuit, however, the ballast must be greater than this value, in order to take care of normal variations in line voltage.

This fact can be demonstrated by the following approximate analysis of a resistively ballasted lamp. Over the normal range of operating currents, the lamp voltage changes by only a small amount and consequently can be treated as a constant. Referring to the circuit of Figure 6

$$V_o = V_{Lp} + IR \text{ and } IV_{Lp} = \text{lamp watts} = W_{Lp}$$

$$dV_o = RdI \text{ and } dW_{Lp} = V_{Lp}dI$$

Expressing the change in watts as a fraction of the total lamp watts

$$\frac{dW_{Lp}}{W_{Lp}} = \frac{V_{Lp}dI}{V_{Lp}I} = \frac{dI}{I} = \frac{dV_o}{IR} = \frac{dV_o}{V_o} \cdot \frac{V_o}{IR} = \frac{dV_o}{V_o} \cdot \frac{V_o}{(V_o - V_{Lp})}$$

From the above equations we see that, if the lamp voltage were half the line voltage five per cent change in line voltage would produce a ten per cent change in lamp wattage, while if the lamp voltage were two-thirds the line voltage, a five per cent change in line voltage would produce a 15 per cent change in lamp wattage. How nearly the lamp voltage may be made to approach line voltage is limited by the permissible variation in lamp watts and by the expected variation in line voltage.

With an inductive ballast a similar analysis gives the relation

$$\frac{dW_{Lp}}{W_{Lp}} = \frac{dV_o}{V_o} \cdot \frac{V_o^2}{(V_o^2 - V_{Lp}^2)}$$

so that on this type of ballast the lamp voltage may be made to approach more nearly the line voltage for the same regulation than is the case with resistive ballast. In practice the wattage changes are greater than shown here, because the lamp voltage decreases with an increase in current. For most commercial ballasts the ratio of line volts to lamp volts is approximately 2 to 1.

Table I. Phosphors Commonly Used in Fluorescent Lamps[4]

Phosphor	Frequency, in 10^{12} Cycles Per Second of Maximum Radiation Output	Wavelength, in Angstrom Units, of Maximum Radiation Output	General Color
Calcium tungstate	680	4,400	Blue
Magnesium tungstate	625	4,800	Blue-white
Zinc silicate	570	5,250	Green
Zinc beryllium silicate	505	5,950	Yellow-white
Cadmium borate	484	6,150	Red

In addition to resistive and inductive ballast, a third type of ballast is used in commercial circuits. This consists of a combination of an inductance and a capacitance connected in series. This type of circuit has a more nearly constant current characteristic, and it is possible to operate the lamp more nearly equal to line voltage. Such circuits are usually used in conjunction with inductive ballasts, and the regulation of the inductive ballast controls the choice of line voltage as explained above.

Wave Shape

On alternating current it is necessary also to consider the requirements of wave shape of current and voltage. This results from the fact that on alternating current the lamp must be reignited on each succeeding half cycle. The type of ballast has an important influence upon the wave shape, as is illustrated by the oscillograms of Figure 7. In both oscillograms the rms values of line voltage and lamp current were set at 210 volts and 0.42 ampere respectively. For the inductively ballasted lamp shown in Figure 7A, it is seen that at the instant of current zero the line voltage has a value of approximately 250 volts, while the lamp requires only 150 volts for reignition. The difference between these two is absorbed by the reactor. For the resistively ballasted lamp of Figure 7B the lamp current is in-phase with the voltage, and consequently zero voltage is available for reigniting the arc at the instant of current zero. The current therefore remains at a low value for a period of approximately 20 degrees before reignition takes place. Due to this long wait, deionization of the positive column has begun to take place, so that 175 volts are required to reignite the arc.

A similar lag in reignition may occur on inductive ballast, if the line voltage is not sufficiently greater than the lamp voltage. The type of current wave shape shown in Figure 7B is not so desirable as that of Figure 7A, because of increased flicker, or stroboscopic effect, due to the extended period of zero current.

Regulated Rectifiers in Telephone Offices

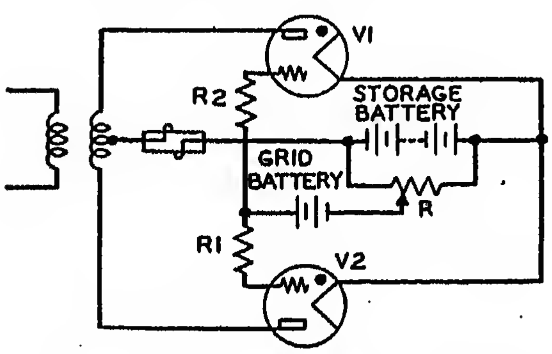
D. E. TRUCKSESS
MEMBER AIEE

FOR many years rectifiers of the garage type were used in converting alternating current to direct current for charging batteries used for communication purposes. These batteries furnish power for relay operation, for talking, and filament and plate supplies for repeaters. The rectifiers were of the manual-control type where the operator selected the charging current by means of tap switches or rheostats.

With the development of the thyratron type of tube, a rectifying means was made available in which the grid of the rectifier tube could be used to control its own output current by an electronic circuit. Rectifier circuits were designed to maintain a constant output voltage. If a regulated rectifier is connected to a battery and the constant rectifier voltage is 2.15 volts per cell, the load current will automatically come from the rectifier and not from the battery. Also the battery will draw from the rectifier sufficient additional current to maintain its charge. If the circuit voltage is held within limits of less than plus or minus one per cent, the maintenance of the battery is reduced and its life is extended.

The thyratron tube differs from the vacuum tube in that the grid does not have a continuous control of the plate current.[1] When a positive potential is applied to the plate, current does not flow until the magnitude of the negative grid voltage is reduced to the critical value, at which time the plate current flows, and the magnitude of the plate current depends upon the voltages and impedances in the circuit. The grid has no further control, and plate current flows until it is stopped by reducing the plate voltage to zero.

Thyratron tubes use various gases and mixtures of gases. The earliest type used mercury vapor, but this type of tube is quite sensitive to temperature changes. The grid characteristics are shifted materially by changes in the room temperature in which it is operated, and in low temperatures it is almost a vacuum tube. Thyratron tubes using argon gas are not affected by temperature changes, but high-pressure argon tubes have a low inverse voltage which limits their application to low-voltage rectifiers. Tubes using low-pressure argon have a higher inverse voltage, but are accompanied by a high arc drop which makes their efficiency low. A mixture[2] of mercury vapor and argon has been found which provides the temperature-stable grid characteristic of the argon tube and the low arc drop of the mercury-vapor tube. This type of tube has been very successful with certain regulating circuits, particularly at voltages less than 60 volts.



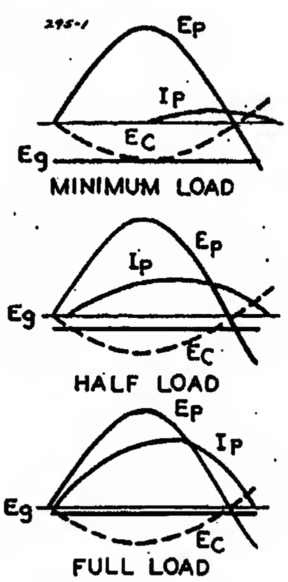


Figure 1. Magnitude control circuit

Five kinds of regulating circuits are used in telephone offices to hold the output voltage of rectifiers constant. The selection of the circuit to be used depends upon the magnitude of the current, d-c voltage, and type of rectifying means to be used. Two forms of regulating circuits using thyratron tubes and one using two-element high-pressure tubes were developed. A fourth circuit using all vacuum tubes was adapted for telephone use. The fifth kind uses a negative resistance.

Magnitude Control

The automatic regulating circuit using the temperature-stable tubes has been called the magnitude method[3] of control, since the voltage applied to the grid is a d-c voltage, and its magnitude is varied to control the plate current of the tube.

Figure 1 shows a schematic circuit and diagrams of the voltages applied to the rectifier tube. The rectifier circuit is the conventional full-wave circuit with a filter coil in the negative output lead. A negative voltage, with respect to the tube cathodes, is taken off a potentiometer connected across the battery to be floated. This negative voltage is opposed by a slightly smaller positive voltage of a grid battery. The net negative voltage of a few volts is applied to the grids of the tubes through grid resistances. The top diagram in Figure 1 shows the positive half of the a-c voltage applied to the tube. The dotted line represents the critical grid voltage of the tube, I_p the plate current that flows, and E_g the d-c grid voltage applied to the grids. If the applied grid voltage is more negative than the critical value, the tube does not fire and no plate current flows. If the magnitude of the grid voltage is decreased until it reaches the critical value, the tube fires and the rectifier delivers output. A further decrease in the grid voltage will result in the critical value being equaled earlier in the cycle, and the average value of the plate current will increase. Finally, with the grid voltage zero, the tube fires at the beginning of the cycle and the maximum average value of current is obtained.

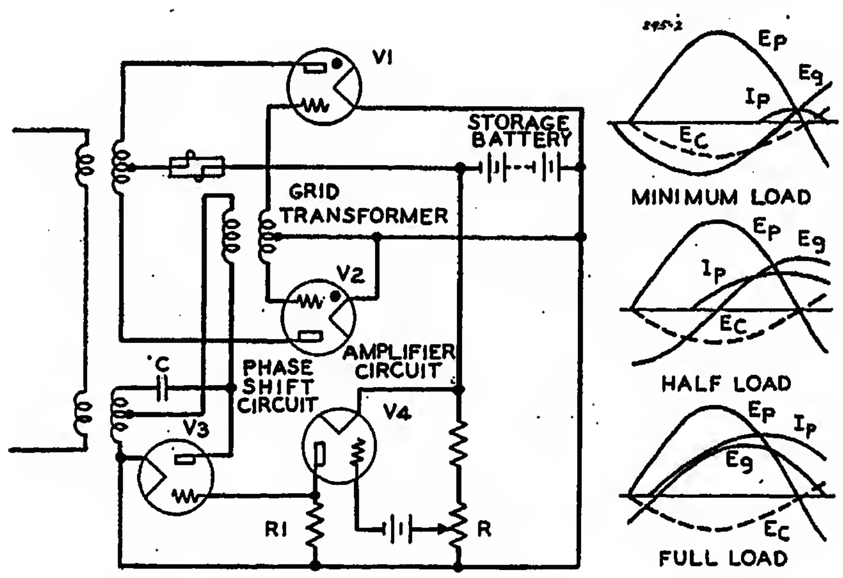

Figure 2. Phase-shift control circuit

If this circuit is operating without a filter coil, the current could be reduced by the variable grid voltage to only one half its maximum value, and then it would drop to zero due to its having control only during the first 90 electrical degrees. A smooth control from full load to light load can be secured by using a filter coil

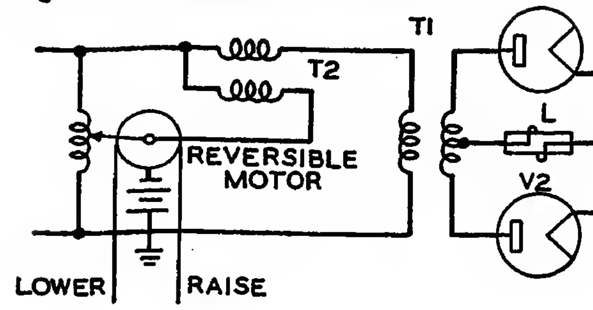
Figure 3. Booster control circuit



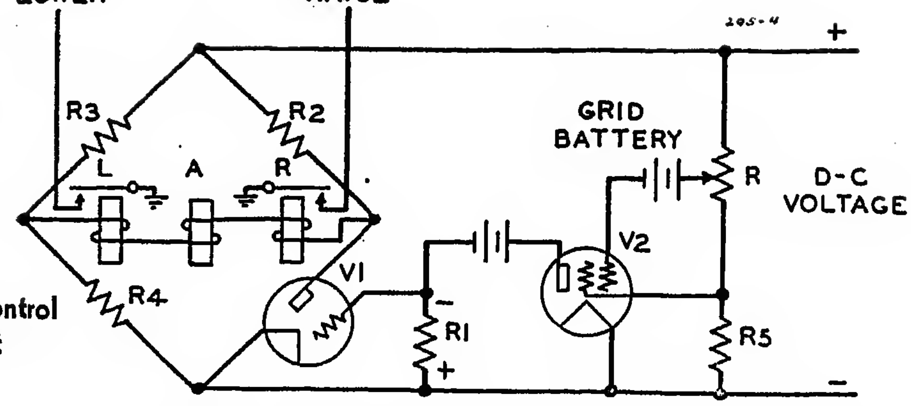


Figure 4. Voltage control for booster circuit

that has a high inductance with small currents, so that even though the tube fires near 90 degrees the current that flows is limited by the reactance of the coil. At full load its inductance is reduced by saturation of the iron to the value required for filtering. With conventional coil design where the no-load inductance can be made approximately five times the full-load inductance, the rectifier output current can be reduced by grid control to five per cent of the full-load value. When a telephone office load is applied to the battery, its external voltage decreases a fraction of a volt. This change is reflected over the potentiometer and grid battery to the grids to reduce the grid bias and increase the plate current of the tubes sufficiently to carry the office load.

With this circuit the battery voltage is held to a change of about one volt from no load to full load. This change in battery voltage is approximately the same for all values of battery voltage, as the grid must be varied about the same amount. Thus a better per cent regulation is obtained at the higher battery voltages. The regulating circuit will compensate for slight changes in the grid characteristics of the tubes. However, the large changes encountered in the case of mercury tubes make them unfit for this type of circuit. The mixture of mercury and argon has been found quite satisfactory when used in rectifiers covering a range of 24 to 60 volts. These tubes, however, have a low inverse-voltage rating and cannot be used in charging the higher-voltage storage batteries. The mercury tube has the necessary high inverse-voltage rating, so that a circuit was developed which has been called the phase-shift type of control; this enables the mercury tubes to be used, in spite of their changes of grid characteristic with temperature.

Phase-Shift Control

Figure 2 shows a schematic diagram of the phase-shift type[4] of control circuit. This circuit differs primarily from the magnitude circuit in that the grid voltage is an a-c voltage of a fixed magnitude, but its phase relation with respect to the a-c plate voltage is varied to control the output of the rectifier. When the grid voltage is out of phase with the plate voltage, the grid is negative all during the cycle that the plate is positive, so that the tube does not fire. As the grid voltage is shifted in a direction to be inphase with the plate voltage, the instantaneous grid voltage reaches a magnitude which is less negative than the critical value so that the tube will fire and deliver current for the remainder of that cycle. When the grid voltage is shifted to be practically inphase with the plate voltage, the tube fires at the beginning of the cycle and carries current during the remainder of that cycle. In this way the output current of the rectifier is controlled by shifting the phase from the out-of-phase to the inphase condition.

The grid voltage of varying phase is obtained from the phase-shift circuit which consists of a bridge circuit with two windings of the transformer furnishing two arms of the bridge, a capacitor the third, and the plate-cathode resistance of a vacuum tube the fourth. A transformer is connected across the galvanometer corners of the bridge which supplies the voltage to the grids of the thyratron tubes. When the plate-cathode resistance of the vacuum tube is at its minimum value, the grid voltage is nearly inphase with the plate voltage, the output current to the rectifier being maximum. When the vacuum tube is biased out (providing an infinite resistance) the grid voltage is practically out of phase with the plate voltage.

The plate-cathode resistance of the vacuum tube is controlled by the d-c bias applied to the tube. This varying grid bias of 2 to 20 volts is obtained from a vacuum-tube d-c amplifier circuit. When a telephone-office load is applied to the storage battery it decreases the battery voltage a fraction of a volt. This small voltage is amplified by the d-c vacuum-tube amplifier and applied to the phase-shift vacuum tube in a direction to shift the grid voltage more nearly into phase and thus increase the output of the rectifier. In this way the storage-battery voltage is held to the regulated value. The accuracy of regulation depends on the amount of gain in the d-c amplifier circuit. This circuit has been built to provide regulation in the order of a few hundredths of a volt, but in most applications one per cent regulation is all that is required. The filter coil is not essential for the operation of this circuit, but a swinging choke whose inductance changes four to one will assist in regulation.

In a thyratron with an oxide-coated filament, operating filament temperature must be reached before output current can be drawn from the rectifier. An inexpensive way to prevent output current is to apply a large negative grid bias to the tubes, which biases them out even though the a-c voltage is applied to the plates. With the magnitude method, the grid circuit can be switched to the battery voltage and in the phase-shift circuit it is only necessary to open the resistance arm of the phase-shifting circuit. This switching can be done with a small telephone-type relay on all sizes of rectifiers. The time delay is provided by a conventional bimetallic-strip type of relay operating the telephone relay.

The cost of the thyratron tube, in sizes above ten amperes per tube, is large in comparison with the cost of the complete rectifier. High-gas-pressure rectifying tubes can be operated with the tube elements at high temperatures if the grid is omitted. This permits a two-element tube to be built at about one fifth the cost of the thyratron, thus making it practical to build low-voltage rectifiers in sizes of 30 to 100 amperes.

Booster Control

In order to regulate the output of a rectifier using two-element tubes, a circuit has been developed which has been called the booster type of control. Figure 3 shows a schematic diagram of this type of circuit. The output current of the tubes is controlled by changing the plate voltage applied to the tubes. The plate voltage is varied by means of a circuit consisting of a continuously tapped autotransformer which changes the voltage applied to the primary of a booster transformer. When the continuously tapped

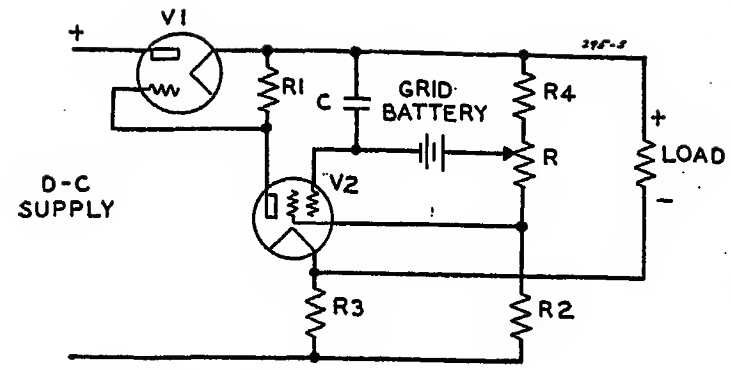

Figure 5 (left). Series-tube control with grid-battery voltage standard

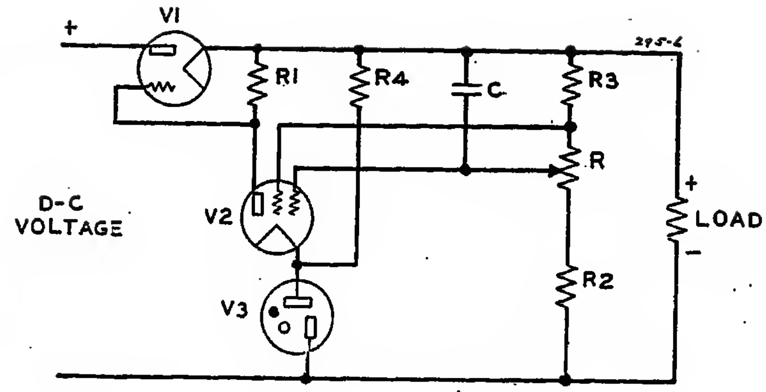

Figure 6 (right). Series-tube control with cold-cathode tube as voltage standard

autotransformer is at its zero end, no voltage is applied to the booster transformer and the ratio of the plate transformer is selected so that the rectifier delivers minimum current. The output current of the rectifier is increased by driving the continuously tapped autotransformer to its maximum boost position which raises the plate voltage until the rectifier delivers its maximum output current. The continuously tapped autotransformer is controlled by means of a small reversible motor so that closing the circuit of the "raise" lead will increase the rectifier output current and closing the circuit of the "lower" lead will drive the motor in the direction to decrease the rectifier output current. The disadvantage of this circuit is that a second transformer 40 per cent as big as the plate transformer is required in addition to the autotransformer. The advantage is that all of the equipment in this circuit operates at a high efficiency, and with the boost type of connection the no-load loss is small. Even the core loss of T_1 is reduced, since it operates at a lowered voltage at light loads. Light-load efficiency is important in telephone applications, as the rectifier must operate many hours at night with practically no load. The input power factor is the same as that of the unregulated tube-rectifier circuit and is not reduced materially by the control circuit.

Various combinations of this rectifier circuit are possible in that the plate voltage, in small sizes of rectifiers, may be connected directly to the continuously tapped autotransformer or the auxiliary transformer may be connected to buck the line voltage. This circuit can be applied to more than one phase with the appropriate tapped autotransformers, booster transformers, and plate transformer to control each phase.

A voltage controller to operate with the booster type of regulating circuit is shown in Figure 4. This circuit is to translate variations in the magnitude of the d-c voltage to be regulated into a raise and lower signal to the reversible motor in the rectifier. The circuit consists of a d-c amplifier to increase the small changes in the load voltage from a fraction of a volt to several volts. This amplified voltage is applied to the grid of a vacuum tube which constitutes one arm of a resistance bridge circuit. Across the galvanometer corners of the bridge are connected two polarized relays in series with a nonpolarized relay.

When the load voltage is at the correct value, the bridge is balanced and no voltage appears across the galvanometer corners of the bridge, so that all relays are released. The change in the load voltage will be reflected through the amplifier and bridge circuit in a direction to unbalance the bridge and cause either the R or L relay to operate, depending on which way the voltage changed, which in turn operates the motor in the rectifier circuit. Plate supply for the bridge tube V_1 is obtained from the d-c voltage being regulated, but a separate source of direct current is required for the plate of the amplifier tube V_2. This may be a battery or a small half-wave disk rectifier with a filter capacitor to provide 50 volts, one milliampere for the plate of V_2. The standard voltage can be either a grid battery or the negative resistance regulating circuit described below. The nonpolarized relay A operates on twice the current of the R and L relays, and is connected in series with them to give an indication when the regulated voltage is approximately twice the variation that causes the R and L relays to operate. In this way, an alarm may be provided to indicate when the regulated voltage goes out of the regulating range.

The accuracy of this control is entirely a function of the amount of d-c amplification provided by tube V_2. A single-tube amplifier operating with a load voltage of 24 or 48 volts will provide regulation in the order of 0.1 to 0.2 volt. An ordinary voltage relay may be used instead of this circuit, but its accuracy is limited by the difficulty of adjusting the span between the high and low contact of the relay to less than one volt. An additional advantage of this circuit over the voltage relay is that the span between the "lower" and "raise" signal is a value fixed by the design of the circuit, but the average value of the regulated voltage may be shifted simply by adjusting the rheostat R.

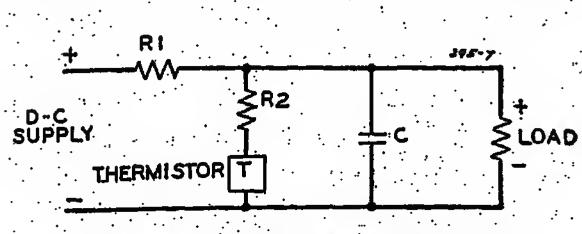

Figure 7. Shunt thermistor circuit

Series Tube Control

Where a small amount of closely regulated power is required, the series vacuum-tube type of regulated rectifier is used.[5] The conventional full-wave vacuum-tube rectifier and filter is used to provide about 100 volts more than the regulated value. A vacuum tube is connected in series with the output and its plate-cathode resistance acts as a dropping resistance. The amount of resistance it introduces into the circuit depends upon the magnitude of the grid voltage. To reduce the rectifier d-c voltage automatically to the regulated value the circuit shown in Figure 5 is used. The output voltage is applied by means of the voltage drop over the potentiometer R, which is opposed to a constant-voltage source such as a grid battery to the grid of V_2. If the grid-battery voltage is of the same magnitude as the load voltage, the maximum accuracy of regulation is obtained. However, with a screen grid or pentode tube sufficient amplification is obtained with lower-voltage grid batteries. By adding the R_3 resistance which is in series with the load current, its voltage drop is applied to the grid of V_2 to compensate for load changes.

With a circuit of this type, plus or minus ten per cent variations of d-c supply can be reduced to the order of 0.05 volt

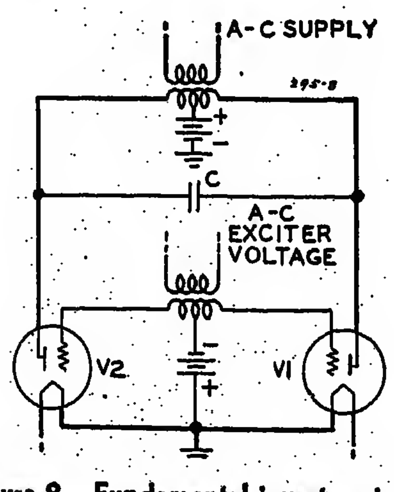

Figure 8. Fundamental inverter circuit

with constant load and to about 0.1 volt with variations in load. Better regulation than this can be obtained by carefully selecting the constants of the circuit or by adding a second stage to the d-c amplifier. However, with regulation of less than 0.05 volt, the contact potential in the grids of the d-c amplifier tube becomes a factor which causes random variations due to temperature changes in the cathode, produced mainly by variations in the heater voltage.

The circuit shown in Figure 6 is a variation of that shown in Figure 5 in that the voltage drop over a cold-cathode gas-filled tube is used as the standard for voltage regulation where accuracy of plus or minus one per cent to plus or minus three per cent is permissible. The arc drop of the tube V_3 is connected in the cathode circuit of the d-c amplifier circuit, and its grid voltage is picked off the potentiometer circuit, consisting of resistances R_2, R, and R_3, at a point which makes the grid of V_2 slightly negative with respect to its cathode. A variation in the load voltage in this way varies the grid of the amplifier tube V_2 whose amplified output appears as a voltage drop across R_1, to control the grid of the series tube V_1. It is desirable to add the R_4 resistance so that the V_3 tube can be operated at its most efficient current value, and the value of the R_1 resistance should be quite large so that the cathode current is small in proportion to the tube current in V_3.

In both of the circuits shown in Figures 5 and 6, feed-back filtering is obtained because the regulating circuit compensates for variations in voltage due to the ripple on the d-c supply in the same manner that it compensates for variations due to load. If the grid is not connected directly to the positive side of the load, the capacitor C should be added to conduct the ripple directly to the grid. Otherwise, a loss in ripple voltage would be obtained in proportion to the potentiometer ratio.

In this type of circuit the amplifier tube V_2 is usually of the heater type so that during starting, or in the event of a failure of the V_2 tube, the output voltage is unregulated and reaches a value approaching that of the d-c supply, except for the zero grid drop of the series tube V_1. This may be reduced by connecting a cold-cathode tube from the plate of V_2 to the potentiometer circuit at a voltage point with respect to the positive output terminal, which is slightly less than the breakdown voltage of the tube. Then with the circuit in normal condition, the tube will not pick up and will be an open circuit. If, however, the output voltage increases above the regulated value, the tube picks up and draws a current through the R_1 resistor which biases the series tube negative, reducing the output voltage. As soon as the V_2 tube is operating normally, the voltage of its plate terminal is drawn toward the negative end of the d-c output sufficiently to cause the cold-cathode tube to drop out. In this way, the load may be protected from an excessive voltage while starting or when trouble occurs in the amplifier tube.

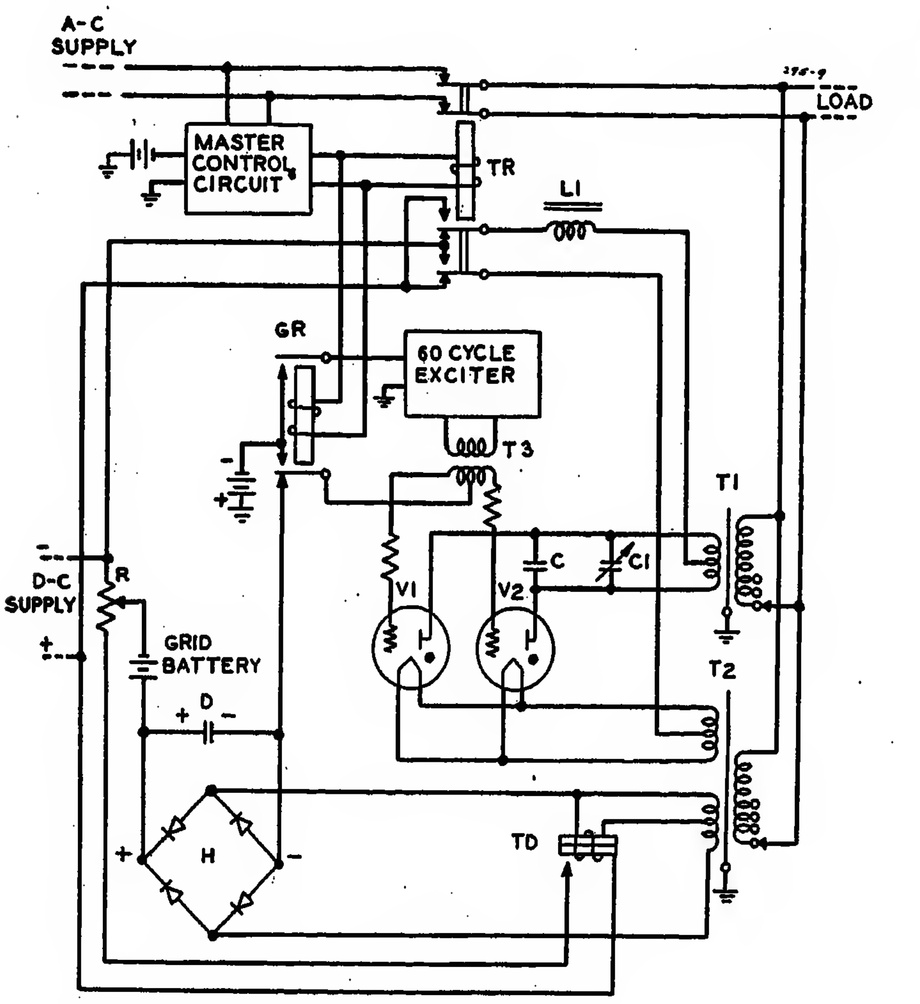

Figure 9. Combined rectifier–inverter circuit

Shunt-"Thermistor" Control

In regulated rectifiers where the use of a cold-cathode tube as a voltage standard does not provide sufficiently accurate regulation, a miniature regulated rectifier is used in place of the grid battery, where its higher cost is justified. The regulating part of the circuit is shown in Figure 7. The negative resistance is a "thermistor" made of a semiconductor. The value of R_2 is selected so that a change in d-c supply voltage causes a positive voltage drop in R_2 equal to the negative voltage drop in the thermistor with the net result that the voltage across the load is approximately constant. A resistance R_1 must be connected in series with the d-c supply to take up the variations in d-c supply voltage. This circuit, in general, is adaptable to voltages less than 100 volts and currents of a few milliamperes. Since most thermistors are sluggish in operation, a large capacitor C is connected across the circuit to smooth out rapid variations in d-c supply. The circuit is compensated for ambient temperature variations, as the resistance of thermistors is affected by temperature. This circuit has been used as a grid supply for amplifiers.

Rectifier–Inverter

With the increase in use of a-c voltages for filament and plate supply for repeaters, it became necessary to provide some means of providing power to operate these circuits when the commercial power supply had failed.[6] The electronic inverter using thyratron tubes provides a means to take energy from a storage battery and convert it into 60-cycle alternating current to keep the circuits functioning until the commercial power is restored. The elements of an electronic inverter are essentially the same as a rectifier, so that with the addition of a pilot source of 60 cycles and suitable switching means, one unit can serve as a regulated rectifier to float the storage battery normally, and during the time that the power has failed the circuit can take power from the battery and deliver 60-cycle power for use in the telephone office.

Figure 8 shows a schematic diagram of the fundamental inverter circuit. The battery is applied to the center tap of the plate transformer, and the grids of the tubes are held negative with a d-c bias sufficient to prevent their carrying current with the positive voltage applied to the plates by the battery. A 60-cycle excitation voltage is applied to the grid through the grid transformer. This ex-

citation voltage has a greater magnitude than the negative d-c bias. When the excitation voltage drives the tube grid toward zero until it reaches a value less than the critical grid voltage, the tube fires, passing current through one half of the plate transformer. When the other tube grid is fired in the same way it passes current in the opposite direction through the other half of the plate transformer. The charge on the capacitor which has accumulated while one tube is firing is connected across the opposite tube by virtue of the firing, which drives the plate negative to interrupt the plate current. The a-c excitation voltage is supplied by a mechanical vibrator of the type that is used in automobile radios or by a vacuum-tube oscillator.

A particularly useful type of power supply has been built which functions normally as a regulated rectifier, taking power from the a-c commercial supply and floating the telephone-office battery. The instant that the power fails, relays convert the circuit from rectifier to inverter operation, and energy is taken out of the storage battery and supplied to the telephone circuits in the form of 60-cycle alternating current.

The control circuit for the combined rectifier and inverter is shown in Figure 9. A master control circuit is provided to measure the a-c supply voltage continually so that when its magnitude reduces to less than 85 per cent of its rated value the *GR* and *TR* relays are operated. The *TR* relay disconnects the rectifier and load from the a-c supply circuit and also reverses the polarity of the d-c supply to the plate transformer. The *GR* relay starts the 60-cycle exciter and switches the grid circuit from the regulated rectifier circuit to the fixed negative bias. The circuit then draws power from the d-c supply and generates a 60-cycle voltage which supplies the load and also supplies its own filament voltage through transformer T_2. When the commercial a-c voltage is restored, the master control circuit releases the *GR* and *TR* relays to restore the equipment to the rectifier operation.

The control of the rectifier output current is by the magnitude method, which has been described. The regulating circuit consists of the potentiometer *R*, grid battery, capacitor *D* and "varistor" *H*.

Table I. Regulated Rectifiers Used in Telephone Offices

Rectifier Output		Type of Regulation	Rectifying Means
Volts	Amperes		
48	0.001	Shunt thermistor	Disk type
20	0.006	Shunt thermistor	Disk type
85	0.23	Series vacuum tube	Vacuum tube
120–130	0.10	Series vacuum tube	Vacuum tube
95–180	0.10	Series vacuum tube	Vacuum tube
150–180	0.15	Series vacuum tube	Vacuum tube
17–45	0.60	Magnitude	Thyratron
48–74	0.6	Magnitude	Thyratron
120–130	0.6	Magnitude	Thyratron
34–48	3	Magnitude	Thryatron
24–34	10	Magnitude	Thyratron
24	30	Booster	2-element tube
48	10	Magnitude	Thryatron
48	30	Booster	2-element tube
130	2	Phase shift	Thyratren
130	8	Phase shift	Thyratron
130	3	Magnitude	Thyratron
130	10	Phase shift	Thyratron

Application of load to the battery reduces its voltage, and this change in voltage is reflected to the grids of the thyratron tubes to reduce their negative bias, which increases the charging current of the rectifier to bring the voltage back to the regulated value. The varistor *H* and capacitor *D* provide a voltage which varies directly in proportion to the a-c line voltage. This change is introduced into the grid circuit to compensate for line voltage changes.

In order to use the same ratio in the plate transformer for both rectifier and inverter operation, it was necessary to have different methods of adjusting the output voltage of the rectifier and the inverter. The output voltage of the rectifier is adjusted by means of taps on the primary of the plate transformer T_1 for charging different numbers of cells in the storage battery. This tap is selected at the time of installation. The output voltage of the inverter is adjusted for various a-c loads by means of the commutating capacitor C_1. The above rectifier then can be adjusted for charging a 132- or 142-volt battery and to provide any a-c output voltage between 210 and 250 volts with current loads of 2 to 5 amperes.

The time required to convert this circuit from a rectifier to an inverter is limited primarily by the operating time of the relays. The master control circuit requires about one cycle to detect a low voltage, and the power relays require about two cycles to make the transfer. Therefore the minimum practical time of transfer is such that approximately three cycles is lost between the time the commercial power fails and alternating current is available from the inverter to carry the load. The transfer back to the commercial power supply will be less because the master control circuit has time to function while the load is carried by the inverter, and the release time of the relays is smaller than the operate time. The practical loss in load voltage is approximately two cycles.

Rectifier Sizes

Table I shows the voltage and current output, type of control of the rectifiers, and the rectifying means that have found widespread use in the Bell System.

The regulated rectifier finds its applications in telephone offices where constant voltage, independent of load and a-c line-voltage variations, is required to supply filament grid bias and plate voltage to telephone repeaters. Certain measuring circuits require a regulated rectifier to supply a stabilized voltage. Regulated rectifiers also find applications where constant voltage is of secondary importance but an automatic power plant is desired for maintaining storage batteries in a fully charged condition to be ready to supply the power for telephone offices if the a-c power fails. A further compensation of regulating the voltage is the increase in life obtained from storage batteries if they are not continually being charged and discharged but are fully floated.

The Dielectric Strength and Life of Impregnated-Paper Insulation—III

J. B. WHITEHEAD
FELLOW AIEE

IMPREGNATED-paper insulation, as used in high-voltage power cables, is subject, during the ordinary processes of manufacture, transportation, installation, and operation, to a wide variety of conditions, nearly all of which militate against the conservation of the original inherent properties of the insulation. Among these conditions are bending and other mechanical stresses, expansion and contraction due to temperature changes, original variations in manufacturing processes of drying and evacuation, and so forth. As a consequence, the electrical characteristics of the insulation of high-voltage cables, as for example power factor, dielectric loss, dielectric strength, and stability, all fall noticeably below those of samples prepared in the laboratory and generally are not subject to all the disturbing conditions mentioned above.

The uncertainties arising in the presence of these disturbing conditions and the inability to determine their relative importance has meant that most of the improvement in the quality of cables in recent years has resulted from empirical development and experiments on the finished cable. Cable engineers have been slow to adopt the results of laboratory research on controlled specimens, except perhaps in the clear-cut results of studies of such fundamental matters as drying and evacuation as related to the impregnation process, the purification of oil and paper, and the like. They have feared the effect of a change in a known variable on those which are still unknown.

The experimental studies described in this series of papers fall definitely in the controlled laboratory class. Effort has been made to eliminate the influence of all those disturbing elements in cable insulation except a particular variable under study. For example, the specimens tested are assembled and impregnated, cable fashion on rigid smooth conductors; they suffer no mechanical deformation, they are tested at one temperature, and in particular, they contain no free gas. On the other hand, the type of specimen and mode of testing permit the study of many variables in paper, oil, and mode of assembly of the usual type of cable insulation.

It will be evident that great care and perhaps reserve should be exercised in applying the results of these studies to the design and construction of finished cables. From what has been said, for example, there is an important condition obtaining in the usual solid type of cable, namely, free gas and gaseous ionization, which has been carefully eliminated in the present tests. It is most important, therefore, in such cables to consider the possible influence of the variations shown in these experiments in a number of other variables, on the volume and extent of gaseous ionization. On the other hand, it appears that many of the results of the present studies should be immediately applicable to the so-called oil-filled type of cable in that both in finished cable and laboratory specimens the conditions are closely the same. Even in this case, however, it is necessary to bear in mind the difference between a relatively short-life test in the laboratory and the long-time performance of finished cable.

Cable engineers are nevertheless deeply interested in these research programs and the results therefrom. They have shown this interest by suggestion, discussion, and other cordial support and co-operation. The researches have been supported by grants from The Engineering Foundation with the sponsorship of the American Institute of Electrical Engineers and have enjoyed the hearty co-operation of an advisory committee of manufacturers' and utilities' engineers as appointed by the latter body.

Scope of the Work

The first paper of this series is devoted to a study of the influence of the density of the paper on dielectric strength and life, the outstanding result being a noticeable decrease of dielectric strength with increasing value of paper density. The second paper reports studies of the influence of the thickness of paper on dielectric strength. The earlier studies on density occasioned some surprise and were contrary to the expectations of a number of cable engineers. Consequently the present paper describes primarily further experiments on the influence of the density of the paper, particularly in the use of a different oil, and also studies on the influence of oil viscosity, all directed to a possible explanation of the unexpected results on paper density. In addition, results of a study of the influence of the width of oil channels between convolutions of paper tape on dielectric strength are described. In all these experiments a very sensitive and rapid method of circuit interruption has been used, resulting in the great majority of cases in partial failures without burning. Followed by careful examination, dissection, oil extraction, and magenta staining, this has resulted in a very intimate picture as to the probable causes of failure in each case.

The Test Specimens, the Paper, and the Oils

The Test Specimens

The specimens were wrapped on brass tubes 48 inches long and one inch in diameter. The central or measuring electrode was of lead foil 16.5 inches long. At each end it was overlapped by a lead foil guard electrode 9.5 inches long, separated therefrom by one layer of paper. Beyond the guards the specimen was equipped with narrow angle conical ends of impregnated paper designed for uniform stress distribution.

The Paper

The cellulose wood-pulp paper was supplied by a well-known manufacturer in four values of specific gravity 0.703, 0.896, 1.136, 1.144, all of approximately 0.005 inch in thickness, and here designated as papers A, B, C, and D in the order of increasing density. The paper tapes were in all cases one inch wide.

Certain observations were also made on a fifth grade of paper (E), of 0.004 inch in thickness remaining from foregoing studies and manufactured five years earlier.

The test specimens were made by wrapping the paper tapes on one-inch-diameter smooth brass tubes, normally with $33^1/_3$ per cent and $66^2/_3$ per cent

Paper 42-92, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted February 13, 1942; made available for printing April 20, 1942.

J. B. Whitehead is director of the school of engineering, The Johns Hopkins University, Baltimore, Md.

Acknowledgment is made to the AIEE, The Engineering Foundation, and to various manufacturers and utility companies for their sponsorship and support of the work reported in this paper. Special acknowledgment is made to research assistants C. Oakford Newman, H. M. Ogle, J. M. Kopper, and J. B. Adams, Jr., for their skill, resourcefulness, and enthusiasm in the conduct of the experiments.

overlay with a butt spacing of tapes of between $^{1}/_{64}$ inch and $^{3}/_{64}$ inch. The normal thickness of the insulation wall was 0.080 inch, that is, 16 layers of 0.005 inch paper. Studies of different channel widths up to $^{1}/_{8}$ inch were made with 0.005 inch *B* paper.

Nine identical specimens were constructed for each value of density, thickness of paper, for each value of channel width, or other variable studied. In a few cases the number of identical specimens tested was reduced to six.

For details as to the construction of the specimen, methods of test, experimental data, accuracy, and so forth, the earlier papers may be consulted.[1]

The Oils

Two high-grade insulating oils having commercial numbers 5,314 and 5,317 were each tested over the entire range of paper variables as described above. Number 5,314 is a thin oil as used in oil-filled cables. Its values of viscosity at 40 degrees, 60 degrees, and 100 degrees centigrade are 17, 8.2 and 3 centipoises respectively. Oil 5,317 is a heavier oil somewhat darker in color and prepared for use in solid-type cables. Its values of viscosity at 40 degrees, 60 degrees, and 100 degrees are 480, 120, 18.3 centipoises respectively.

The specimens were impregnated in groups of three, normally at 60 degrees centigrade. In certain studies of the influence of viscosity on impregnation, the impregnating temperature of 5,314 was reduced to 40 degrees and that of 5,317 raised to 100 degrees, these temperatures giving the same value of viscosity for the two oils.

Breakdown and Stability Tests

The accelerated step-up life tests started at 400 volts per mil. The voltage was increased by 3.12 per cent every four hours, thus giving a geometric increase to 700 volts per mil in three days. The continuous application of voltage was interrupted at intervals (usually every four hours) for tests of power factor, capacitance, and internal gaseous ionization.[2] In this program the average life of a specimen was from two to five days. It has been assumed that this brief duration eliminates the influence of chemical change. Long experience has shown that there is no free gas in these specimens. Consequently the results appear to isolate definitely the influence of each of the several variables studied, that is, paper density, paper thickness, oil viscosity, and so forth. The design of the specimen and close attention to uniformity of construction have ensured that the failures have occurred almost invariably under the central electrode of the specimen.

Results of Tests

Density of Paper

The results of the tests on four values of paper density using 5,314 oil have been published in an earlier paper.[3] For convenience some of them are reproduced in Figures 1 and 2. In the same figures will be found the results of later studies on the same papers as impregnated with 5,317 oil, and under the same conditions as to impregnation, test program, degree of accuracy, and so forth.

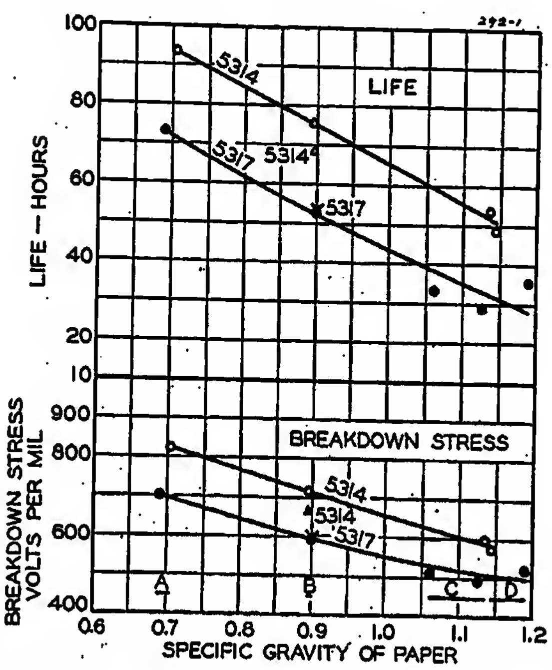

Figure 1. Stability of oil-impregnated-paper insulation—life and breakdown stress

Impregnation at a pressure of 2.0 millimeters of mercury

Δ—40 degrees centigrade
x—100 degrees centigrade
All others—60 degrees centigrade

Two noteworthy features are indicated:

1. The decrease of dielectric strength and life with increasing paper density, already reported for 5,314 oil, is also found to obtain with close parallelism for 5,317 oil.

2. Values of dielectric strength and of life using 5,317 are uniformly lower than those for 5,314.

The impregnating oil content is somewhat higher for 5,314, particularly at the low values of paper density. The power factor for 5,314 is also higher. The trend of these curves has been discussed in the earlier papers.

Paper Thickness

The studies of the influence of paper thickness with 5,314 oil only have been reported in an earlier paper.[4] Figure 3 is reproduced therefrom. It will be noted that there is a pronounced and uniform decrease of breakdown strength with increasing thickness of paper ($21^{1}/_{2}$ per cent decrease from 0.003 inch to 0.008 inch thickness).

Saturation Studies

For each group of tests the percentage of oil content by volume was determined for one or more specimens. Thus in Figure 2 the decrease of percentage of oil with increasing paper density is readily noted It is also noticed that specimens impregnated with 5,314 oil contain a higher percentage of oil, other things being equal, and that this is accompanied by higher dielectric strength. The same parallelism has been observed in other tests. In order to determine whether viscosity of the oil had any bearing on these differences, six specimens of *B* paper were impregnated with 5,314 oil at 40 degrees, and six others with 5,317 oil at 100 degrees, the viscosities of the two oils having the same value at these temperatures. All twelve specimens were subjected to life test at 40 degrees centigrade, in accordance with the standard program.

Results of these comparative studies are indicated as single points giving the average values in Figures 1 and 2. The

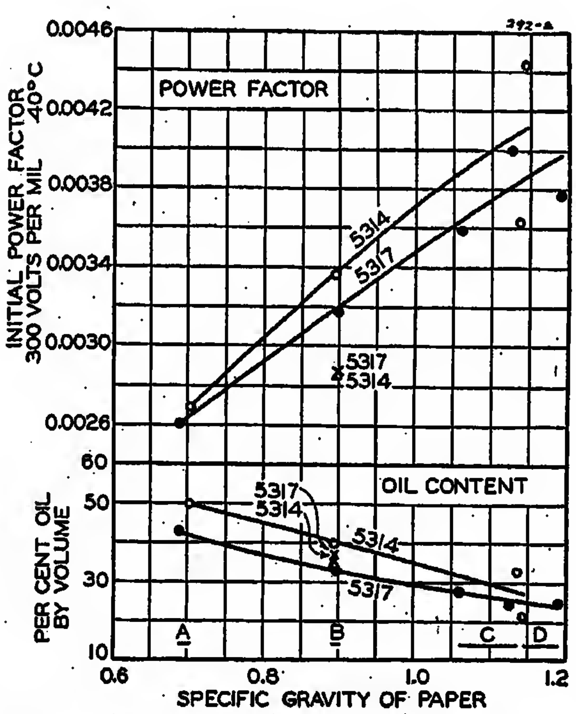

Figure 2. Stability of oil-impregnated-paper insulation—power factor and oil content

Impregnation at a pressure of 2.0 millimeters of mercury

Δ—40 degrees centigrade
x—100 degrees centigrade
All others—60 degrees centigrade

order of accuracy is about the same as that in the paper-density studies (plus or minus deviation five to ten per cent). It will be noticed that the change of viscosity of 5,317 oil results in no appreciable change in either dielectric strength or life, notwithstanding a rather wide variation

in the value of viscosity (480–120 centipoises). On the other hand, impregnation with 5,314 oil with a considerably smaller variation of viscosity results in a slight lowering of both dielectric strength and life, although the values are still substantially higher than those for 5,317.

As to oil content, in the case of number 5,317, large decrease in viscosity between 60 degrees and 100 degrees results in the small increase of oil content of from 33 per cent to 37 per cent. In the case of 5,314 oil the increase of viscosity between 60 degrees and 40 degrees in these comparative studies results in a reduction from 40 per cent to 34 per cent. When the viscosities are the same, the oil content and power factor are about the same.

Width of Channel

The influence of the width of channel on breakdown strength and accelerated life was studied between the limits of a close butt joint and a maximum channel width of $^1/_8$ inch, observations being taken at one intermediate thickness, $^3/_{64}$ inch. Observations were also made on six specimens having a $^1/_{64}$-inch overlap, for one of the oils. Otherwise nine speci-

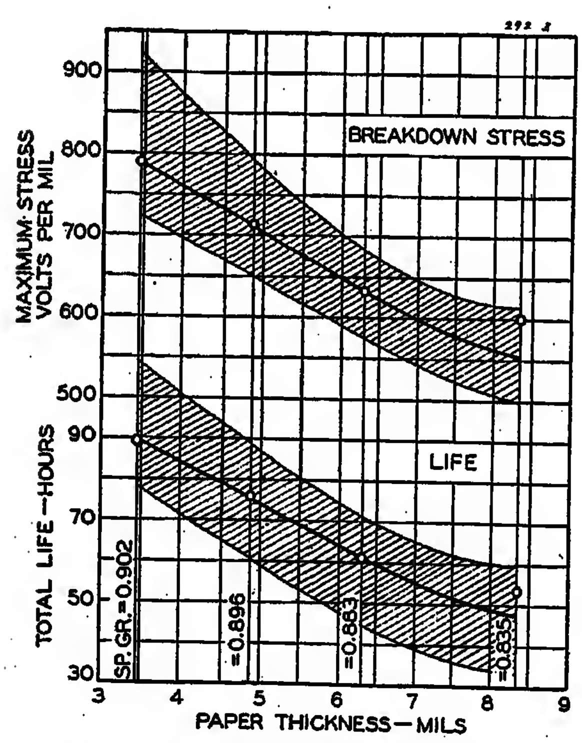

Figure 3. Stability of oil-impregnated-paper insulation—breakdown stress and life

mens were tested at each channel width and for each of the two oils, 5,314 and 5,317.

The results of these studies are plotted in Figure 4, in which the average spread of the nine specimens represented by each point is indicated in vertical lines.

It will be noted that the decrease of dielectric strength with increasing width of oil channel is practically linear for oil 5,314, the percentage decrease from a close butt joint to a channel width of $^1/_8$ inch being 9.5 per cent. A similar over-all decrease is seen for oil 5,317, although the rate of decrease with channel width is less regular. The over-all decrease in this case is roughly six per cent. No great accuracy may be claimed for numerical values in these results, principally because it is difficult to maintain a uniform channel width of low value. Thus in the close butt experiments, the results on two specimens have been omitted, because on dissection it was found that the joints between tapes were slightly open in the region of failure. The closest butt joint that can be wound seems to have here and there a slight opening. With this in mind a set of specimens was wound with a $^1/_{64}$-inch overlap,

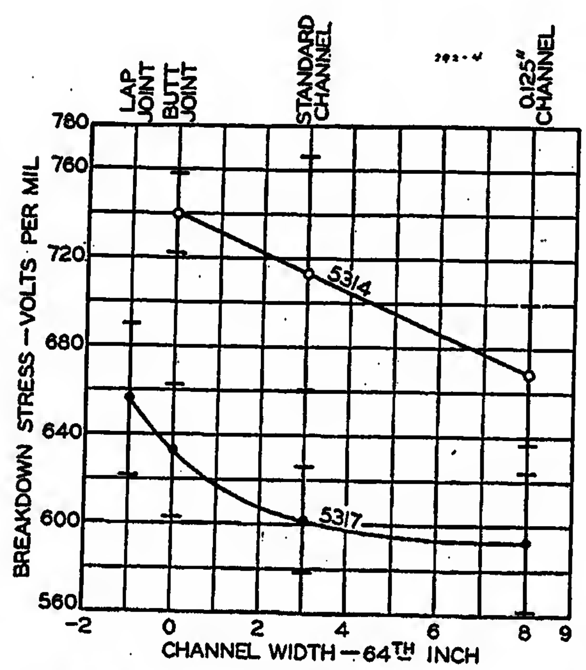

Figure 4. Stability of oil-impregnated-paper insulation—breakdown stress versus channel width

and it may be seen from the curve for oil 5,317 that this resulted in a still further slight increase of dielectric strength.

It is to be noted that the higher dielectric strength of oil 5,314 over 5,317 noted in the other experiments, appears also in the experiments on channel width.

Types of Failure

Initial and Partial Failures

An early method of interrupting the circuit following breakdown of the specimens, using a very light fuse in the primary circuit of the testing transformer, resulted uniformly in through failures with considerable burning. Later, use was made of a thyratron tube, operated from the voltage over a resistance in series with the connection of the low-voltage electrode to ground, and operating a fast-moving relay and circuit breaker in the primary circuit. This resulted in early interruption of failure and indeed enabled us to remove and examine a great many specimens in which partial failures only had occurred. These partial failures consisted of the burning, or break through, or other evidence of trouble, in from one layer of paper or channel of oil, to an increased number of layers up to but short of the full insulation wall. The amount of burning in a failed specimen of this type is very greatly reduced, and a much better idea of the origin, causes, and succeeding progress of the failure has been obtained.

The failures may be roughly divided into four groups based on careful dissection followed in many cases by oil extraction and staining with magenta:

A. Through radial failures.

B. Partial failures involving one half of the total thickness of the insulating wall or less, and all terminating on the high-voltage conductor, or on the outer lead sheath.

C. Partial failures within the insulating wall, but not reaching either conductor or sheath.

D. Failures with no outward evidence of burning, but with subsequent evidence of wax formation.

Out of a total of 117 specimens tested, 46 had complete through failures and 66 had partial failures of one type or another.

Class A—Through Radial Failures. In these cases the burning is greater than in the partial failures, but in general the evidence is that there is little departure from an approximately straight radial failure ending in an oil channel near the outer layers and the first adjacent layers. Tree patterns and tracking are often evident, but only to the extent of reaching one adjacent oil channel. Puncturing through the tape of four consecutive layers was not uncommon.

Class B—Partial Failures Ending on Inner or on Outer Conductor. The characteristic of most of these failures is an area of blackened or burned oil film, never greater than one inch in diameter, towards the center of the insulating wall. Beyond the burned spot, evidence of trouble diminishes rapidly within one or two layers, then disappears. In the other direction burning also decreases, the puncture taking the form of short lengths of blackened oil in the channels and puncture through tapes, becoming smaller and cleaner towards the electrodes. The first, second, or third oil channel from the high-voltage conductor is usually involved. An exceptional case in this group consisted of four tiny punctures of four outside layers, originating in the oil adjacent to a corner of reinforcing paper at the end of the specimen and with no evidence of burning.

Of a total of 66 partial failures, 11 terminated on the outer electrode and 49 on the inner electrode. In one case there was a partial failure to each electrode, the two being well separated longitudinally, and apparently not related.

Class C—Partial Failures Not Reaching Either Electrode. Only three failures of this type were noticed, but they were quite definite. They were characterized by iso-

lated black regions in an oil channel. Two were within four layers of an electrode. In one case the trouble was confined to only two layers.

In addition to these clearly marked local failures, there were ten cases in which this type of trouble was found to be coexistent with a failure either "through" or "partial" ending on an electrode, although definitely separated from it.

Class D—Failures With No Outward Evidence of Burning. In two cases first examination of the specimen failed to reveal any trouble other than a slight smell of burned oil. After subsequent oil extraction and staining with magenta dye, there was evidence in each case of initial wax formation at various places.

In considering these results, it should be borne in mind that in our specimens the insulation wall was relatively thin (0.08 inch), and the diameter of the smooth high-voltage conductor was relatively large (one inch). The excess of stress at the conductor surface over that at the outer electrode is of the order of 16 per cent, which is not much greater than the values of the average spread of our experimental breakdown results; thus partial failures originating on the outer electrode may be due to normal variations in the paper or oil. The smooth high-voltage conductor is perhaps an advantage in that it eliminates the common type of oil pocket in stranded conductors and confines the experimental results more definitely to the impregnated wall.

Throughout the careful examinations of the failed specimens, constant evidence has been found that the initial trouble arises in an oil space. In the cases of partial failures, either the first or the second oil channel was always involved. In all cases involving one, two, or three layers only, punctures were rarely found, the trouble being of the nature of oil blackening and surface tracking. Also in all cases without exception it was found that the oil in the channel next to the high-voltage conductor was more or less blackened, in many cases the blackening being limited to the edges of the paper and revealed by fine black lines on the polished conductor.

Discussion

It is believed that the outstanding results of this and the foregoing papers may be explained qualitatively in terms of the characteristics of the impregnating oil.

All refined degassed insulating oils apparently have the following characteristics in greater or less degree:

(*a*). A relatively low long-time conductivity, that is, as measured after a long application of continuous electric stress. This conductivity is partly electronic, but largely due to an inherent electrolytic dissociation arising in the complex molecular structure.

(*b*). An initial or short-time conductivity persisting for, say from one-tenth to one second, which may be many times as great as the short-time conductivity. This conductivity is due to an accumulation of relatively large and heavy ions or clusters of neutral molecules about a central ion. It is the motion of these large ions back and forth under alternating stress which causes the greater part of the dielectric loss in such oils.

(*c*). Both types of conductivity are increased by contact with paper and metals, due to added electrolytic impurities, and also to increased electrolytic dissociation.

(*d*). Application of continuous stress causes the large heavy ions to move to the electrodes or limits of an oil space, where, owing to their envelopes of neutral molecules, not all of them are discharged, and space charges accumulate close to the electrodes or other limiting surfaces, for example, paper tapes. Under alternating stress a similar action goes on resulting in maximum space charge accumulations at the crest of each half cycle. Studies of the mobility of these ions indicate that at 60 cycles there is sufficient time during a half cycle for some at least of these ions to pass completely across the oil channels occurring between paper tapes in impregnated-paper cable insulation.

The mass of evidence from the failures studied in this series of papers is that failure begins in an oil channel between paper tapes and probably at the contact surface between paper and oil. The failure is caused by a layer of high stress between the paper and a space charge layer immediately adjacent. Witness for example the spiral marking on the high-voltage conductor immediately under the edges of the paper tapes and over the full length of the specimen; also the isolated cases of partial failure in which the only evidence of failure is blackening in the channels, with carbonized channels through paper tapes spreading therefrom.

The ultimate cause of failure is a stress sufficiently high to ionize a molecule with the liberation of gas. The tiny bubble of gas may be reabsorbed before the next voltage crest in which case increasing carbonization may result before final failure. With further increase of stress, however, the gas bubble becomes larger, continues through the cycle, and is the seat of gaseous ionization. This latter attacks the adjacent paper much more aggressively, leading ultimately to puncture, to the extension of the oil breakdown in the next oil film, and to surface spreading to the adjacent oil channel of the next layer.

Failures here described, in outward appearance are often similar to those described by Robinson.[5] However, there is much indication in this work that the "coring" in the paper tapes occurs at the end rather than at the beginning of the process of failure. Coring has been noticed frequently at both conductor and sheath, but in these cases the complete absence of burning, as compared with conditions in the oil channels of deeper lying layers indicates strongly that the initial trouble originates in the channels then extending to puncture of the paper by the coring process. In our case we picture the oil as breaking down with the liberation of gas, subsequent gaseous ionization attacking the paper wall, perhaps in the manner suggested by Robinson. However, Robinson postulates a free gas bubble originally present near the high-voltage conductor, gaseous ionization in this bubble, and coring as the first stage of failure in the insulation wall itself. We believe our specimens to be originally entirely free of such gas bubbles and that the first gas that appears is due to oil failures. We do not find that coring is limited to the inside layers, due to the small difference in radial stress between outer and inner layers in our specimen. However, in the cases discussed by Robinson the higher stresses on the inside layers would tend to give first oil failures and subsequent coring in those layers.

The decrease of dielectric strength with increasing density of the paper tapes has already been ascribed to the increasing value of the stress in the oil channels due to the increasing value of dielectric constant of the impregnated paper. Approximate computation of the breakdown stress in the oil indicates a slight decrease in the critical stress with increasing paper density.[3] It is suggested that this is explained by the fact that the oil in contact with papers of increasing density takes on a greater number of adsorbed ions from the paper. There is a resulting increase in the density of the space charge layers, and an increase in stress between this layer and the adjacent surface. Thus the critical or breakdown stress in the oil is reached at a lower voltage or lower average stress.

Some cable engineers have been loth to accept this evidence that the dielectric strength of impregnated paper decreases with increasing paper density. It is stated that in manufacture, cables containing high-density paper give a higher dielectric strength than those using paper of a lower density. In one case it is stated that it has certain other advantageous physical properties. There are, however, no published data clearly showing these advantages of high-density paper in comparative life tests under sustained stress.

One possible explanation is that there

may be a difference in behavior under impulse or short-time tests and under sustained voltage tests. Here too experimental data is very meager. Del Mar and Works have recently presented data indicating that under short-time tests for certain values of overlap of paper tape, the breakdown strength of high-density paper may rise above that of low-density paper. However, as emphasized elsewhere in this paper, a time element undoubtedly is present in failures under sustained high stress. It is possible, therefore, that under impulse or short-time tests the inherent high dielectric strength of the high-density paper might play a more important part than the delayed breakdown of oil in the oil channels, in which the stress is much higher than the over-all average stress, due to the difference in the dielectric constants of the impregnated paper and the oil in the channels.

A pronounced decrease in dielectric strength with increasing paper thickness has been found.[4] This result may be attributed to the well-known fact that the breakdown strength of thin oil films decreases with increasing thickness. However, in this case also, approximate computations of the values of stress in the oil films at breakdown decrease with increasing thickness, again giving a first indication that the breakdown stress of the oil does not have a constant value. The same explanation may be offered here, namely, that with increasing paper and channel thickness, more ions are present in the oil film, greater values of space charge accumulate, and a critical breakdown strength of the oil is reached at a lower value of over-all stress.

Conclusions

1. Laboratory studies in accelerated life tests of the influence of the density of the paper on the breakdown strength of impregnated-paper insulation have been continued. When impregnated with a heavier oil, as used in solid-type cables, there is a marked decrease of dielectric strength with increasing paper density. Results are closely similar to those already found using a thin oil as impregnant.

2. Raising the viscosity of the thin oil and lowering the viscosity of the heavy oil so that both have the same value during impregnation has little effect on the breakdown strength. Specimens impregnated with the heavy oil show no change in behavior. Raising the viscosity of the thin oil results in a slightly lower dielectric strength. When the two oils have the same viscosity, the values of power factor and of oil content are approximately the same.

3. The dielectric strength of impregnated paper decreases with increasing oil-channel width between successive convolutions of tape. When the thin oil is used the decrease is about 9 per cent; when the heavy oil is used, the decrease is about $6^1/_2$ per cent, as the channel width increases from zero (close butt joint) to $^1/_8$ inch.

4. In all the foregoing experiments the dielectric strength and stability when using the thin oil as impregnant were noticeably higher than when using the heavy oil.

5. Close examination of all failures leads to the conclusion that in the accelerated life or stability tests lasting two days or more, failure always begins in an oil space.

6. Qualitative explanations are offered for results in this and two preceding papers of this series.

Frequency Control of Load Swings

J. E. McCORMACK
MEMBER AIEE

R. J. LOMBARD
NONMEMBER AIEE

Synopsis: The Consolidated Edison Company made a series of tests to determine the cause and extent of system load swings on generators and tie feeders. The results were reported in detail in a previous paper.[1] An analysis of these tests indicated ways in which our load dispatching methods could be improved. This paper reports the effect of the changes in the method. Our experience indicates that the operators may reduce tie and generator load swings to negligible values by using frequency to control manual adjustments of generator output, provided that an accurate frequency indication is available at each generating station.

SEVERAL of the principles reported in the previous paper[1] have been applied to our method of load dispatching to reduce the load swings on the tie feeders and generators. These principles are:

1. Major load swings are caused by manual operation of governor valves in one or more stations during periods of load change.

2. Governors or supplementary controllers do not contribute to load swings but operate continuously to check them.

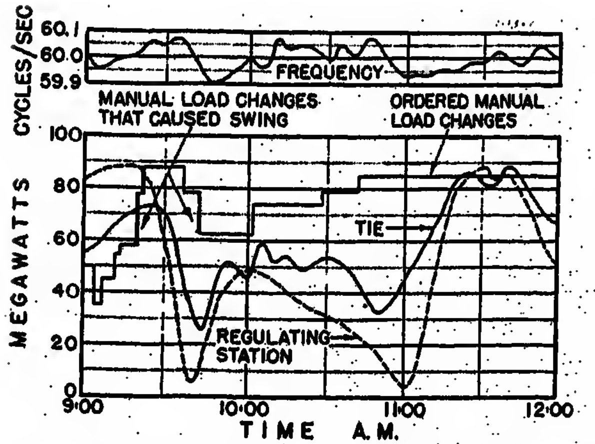

Figure 1. Load swing caused by load changes ordered by the system operator

The load changes were made when they drove the frequency away from normal

3. A change in voltage will result in a change in both real and reactive load demand, but a change in frequency within reasonable limits and with constant voltage does not result in an appreciable change in system demand.

4. The instantaneous relations between load, voltage, and frequency serve to indicate the initiating cause of a load change. An initial change in any one of these quantities will affect the other as shown in Table I.

Table I

Initiating Change	Effect on Voltage	Effect on Load	Effect on Frequency
Voltage			
Increase	—	Increase	Decrease
Decrease	—	Decrease	Increase
Load			
Increase	Decrease	—	Decrease
Decrease	Increase	—	Increase
Frequency			
Increase	Increase	Increase	—
Decrease	Decrease	Decrease	—

Effect of Manual Adjustments of Generator Output

On a system supplied from one turbogenerator, a manual adjustment of the steam input would be readily discernible in the speed and voltage. This effect is not so apparent on a large system, because there are many governors and controllers operating to compensate the change. A change in steam input in excess of the load requirement on the one unit system results in a relatively large speed change, while on the large system, it results in a load swing over the connections between generators. On a large system the generator on which a manual load adjustment is made will have a simultaneous change of speed and load in the same direction, while all other units, under the influence of their respective governors, will change load in a direction opposite to the frequency.

If the generator ouput at one station is increased by manual adjustment when the frequency is at or above normal, the governors at the other stations will reduce the generated load by an equal amount. If these other stations are operating on scheduled loads the station operators will make manual adjustments to restore their stations to schedule, thus driving frequency still higher. This jockeying of load between stations results in load swings on the tie feeders, as well as on the stations, and imposes an unnecessary burden on a station assigned to regulation of frequency.

An example of load swing caused by manual adjustments without regard to instantaneous frequency is shown in Figure 1. This type of load swing can be avoided if the system frequency is used as a control in making manual adjustments.

Load-Dispatching Methods

It was the practice of the system operator to assign blocks of load to each station from time to time on the basis of an advanced estimate of the load requirements. Past experience with the hour-to-hour changes in total system demand was used in making the estimate. The station operators made the load changes when ordered, regardless of the frequency at that time. If the system demand did not change exactly as anticipated, the ordered changes would cause the frequency to depart from normal, and a

Paper 42-113, recommended by the AIEE committee on power generation for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 7, 1942; made available for printing May 19, 1942.

J. E. McCormack and R. J. Lombard are both with Consolidated Edison Company of New York, Inc., where Mr. McCormack is assistant outside plant engineer.

system-wide load swing would result as the governors and controllers operated to compensate for the excess change. Where the tie feeders are relatively small in capacity, or where for contractual reasons the tie feeder interchange is to be maintained at a fixed value, it is then necessary to make additional adjustments to restore the tie-feeder load to normal.

In order to minimize these load swings, the following changes were made in our load-dispatching methods. The system operator now estimates the load in advance but assigns load to each station in larger blocks and at less frequent intervals. When the station operator receives a load-change order, he executes the order only at an instant when the change will tend to restore the frequency to normal. In other words, the station operator increases load only with low or dropping frequency and decreases load only with high or rising frequency. Thus, errors in load anticipation which could cause load swings are automatically eliminated.

The system operator has authority to make load changes, regardless of frequency, should changes be necessary, but he must specifically state that this shall be done.

We would like to point out that these measures are not intended to maintain closer frequency or to keep the accumulated time error within narrow limits, but are for the purpose of reducing, by the use of indicated frequency, the unnecessary load swings on generating facilities and tie feeders.

Figure 2 shows the extent that load swings have been reduced by the present method of load dispatching.

Need for Accurate Frequency Indication

Frequency indication as a control in making manual load adjustments requires that each station have a suitable frequency indicator. Since the normal frequency band on the system is about 0.1 cycle per second, an instrument for this purpose would have to be accurate within a fractional part of this normal band. This accuracy should be in the neighborhood of one part in 50,000, which is beyond the capability of the conventional frequency meter. A meter of normal accuracy could be used if one meter sent impulses to all stations indicating whether the frequency was high or low. Another way would be by transmitting a standard frequency voltage and comparing it differentially with another voltage at system frequency at each station.

On our system a standard frequency accurate to better than one part in a million is available.[2] This standard frequency is transmitted to each major station and compared with the system frequency by means of a synchroscope. The synchroscope gives one revolution for each cycle of slip frequency between the standard and system frequencies. The direction of rotation indicates whether the system frequency is high or low, and the rate of rotation is a measure of the amount of departures from standard frequency. Each station operator therefore has the same indication of system frequency.

This method of transmitting a frequency standard has been practical on the Consolidated Edison Company system because of the relatively few large stations and the short distances between them. In order to use a similar scheme over a widespread system, we have developed a frequency indicator operating from a frequency standard received by radio. Figure 3 shows the schematic diagram of this device. This scheme is based upon sending a standard frequency by a radio transmitter which has sufficient signal strength to cover the area of the system.

The radio signal is amplified by a radio receiver at each station, and the amplified standard-frequency voltage output is impressed on a step-up transformer. The transformer supplies a neon tube which is circular in shape and is covered by a disc having a single slot. The disc is driven by a synchronous motor from the power system. The standard frequency in cycles per second must be exactly divisible by the motor synchronous speed in revolutions per second. When the device is in operation, and the neon tube is viewed through the slotted disc, a series of light spots evenly spaced in a circle will be seen. If these spots remain stationary, the system frequency at that time is correct. If the spots rotate, the system frequency is incorrect. The direction of rotation indicates whether the system frequency is above or below the standard frequency.

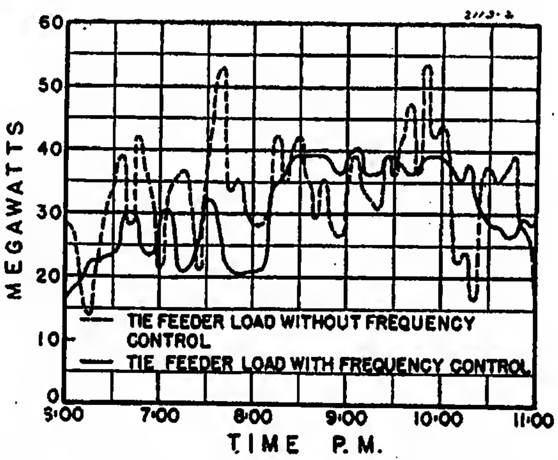

Figure 2. Effect of frequency control of manual load changes on tie-feeder loads

When load changes are made independent of system frequency, the tie-line loads vary considerably. When the load changes are made so that they restore frequency to normal, the large rapid load changes are not experienced

A few trial installations of this device are in service using an existing standard-frequency broadcast by the Bureau of Standards in Washington. This signal is broadcast on a carrier frequency of five megacycles and modulated by a 440-cycle tone. A 1,200-rpm synchronous motor is used to drive the slotted disc. The experience with this device has been very satisfactory.

Conclusion

The results of a year's experience using frequency as a control in making manual load changes on the Consolidated Edison Company system have led us to the following conclusions:

1. Generating-station and tie-feeder load swings can be reduced to a point where load swings are no longer a problem.

2. The need for accurate load anticipation becomes less important.

3. Tie feeders can be loaded safely to their thermal or stability limits.

4. Interchange energy between parts of the system may be controlled within closer limits. For contractual reasons this is often important.

5. Boiler-room maintenance costs can be decreased by reducing the load swings on the boilers.

6. Manual load adjustments by the station operator can be normally made in a direction to aid the automatic governors or controllers.

The Effect of Initial Conditions on Subharmonic Currents in a Nonlinear Series Circuit

STEPHEN J. ANGELLO
ASSOCIATE AIEE

Synopsis: This paper shows the importance of switching time as an initial condition for the current in a simple nonlinear series circuit with a saturable inductor. It is also shown that initial flux linkages in the inductor have an important effect on the current response during the first few cycles after closing the switch. It is emphasized that all experimental work was done with voltages below the critical ferroresonant voltage.

It is the purpose of this paper to report the results of a study of the effect of switching time on the current response in a series R, L, C circuit containing a saturable inductor. In previous experimental work no attempt has been made to control the initial angle of the sinusoidal applied voltage.

This series nonlinear circuit has been the subject of considerable investigation. Its importance was recognized in this country when outages caused by abnormally high currents were experienced in transmission lines equipped with series capacitors. It was found that the observed abnormal currents had a frequency lower than the system frequency. The frequency was a submultiple of the fundamental; hence, they were called "subharmonic" currents. Concordia[1] and Butler solved the equations of the circuit for the parameters of interest in their transmission-line problem by employing a differential analyzer. Following this work Travis[2] and Weygandt approached the problem analytically with the method of matching boundary conditions. They were forced to make many simplifying assumptions, but the solutions they obtained give an insight into the mechanism of the production of subharmonic currents in this circuit. One of the most serious assumptions, namely, that of neglecting capacitance in the circuit when the inductor is saturated, was removed by I. Travis[3] in a later paper. The theoretical investigation has reached a point where a great amount of computation must be done to obtain a small amount of information. To study the performance of this circuit further J. D. McCrumm[4] has employed an experimental method which consists of a systematic variation of circuit parameters, and recording of wave forms on oscillograms. The currents in his circuit were initiated by the random closing of a knife switch.

Experimental Procedure

The circuit studied is shown in Figure 1. The timed switch is constructed so that it can be closed at any point of the 60-cycle sine wave. After closure, it remains closed for the duration of four cycles, and then opens. Two cycles later it closes again at the same switching angle as before. This repetitive closing and opening enables the experimenter to view the first four cycles of the current as a steady image on an oscilloscope screen. During the two cycles that no voltage is applied, the capacitors are short-circuited to insure that the initial charge is zero. With this timed switch it is possible to watch the change of wave form as the switching angle is varied and also while various circuit parameters are varied. Provision was made to keep the switch closed after one of its periodic closures. This enables the experimenter to make oscillograms of the current from the time of initiation. Details of the timed switch are given in the appendix.

Results

The effect of initial voltage phase angle on the circuit response is best shown by

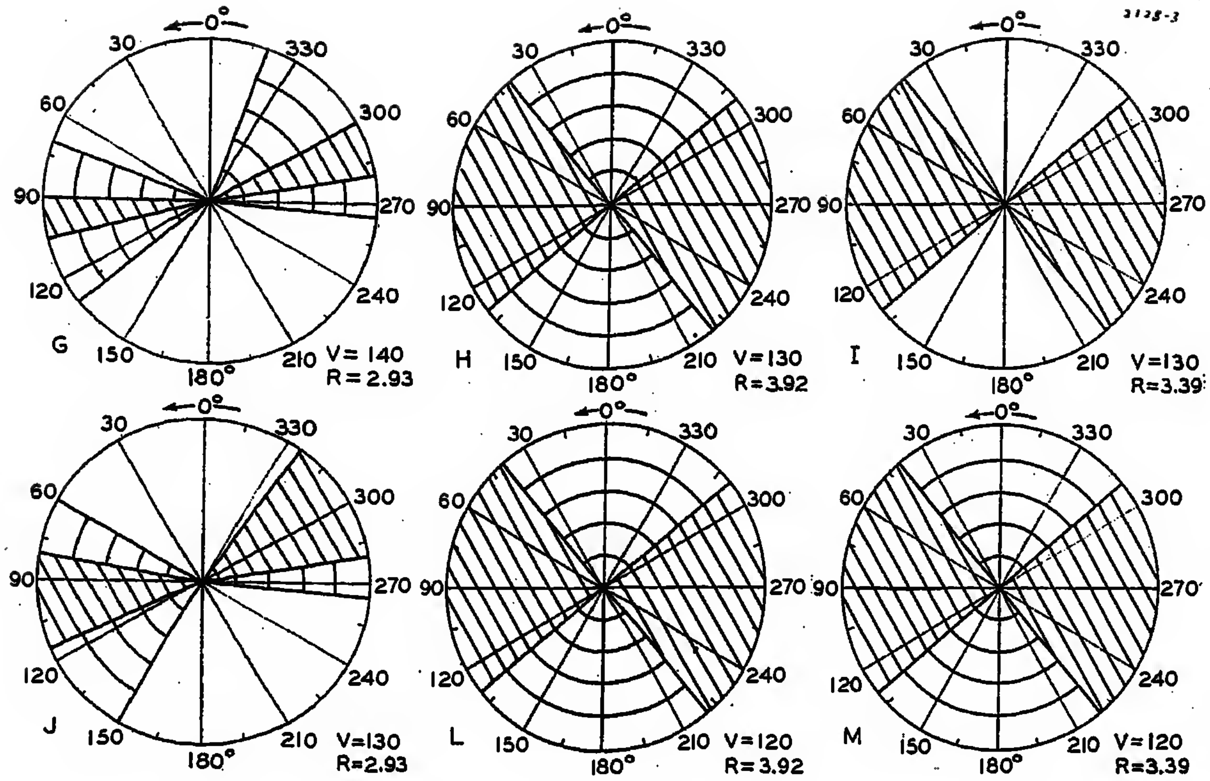
Paper 42-128, recommended by the AIEE committee on basic sciences for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted February 26, 1942; made available for printing May 19, 1942.

Stephen J. Angello is with the research laboratories of Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

The author wishes to express appreciation to his adviser, C. N. Weygandt, for help, and to the General Electric Company for plans of the relay employed in the experiment. This work was done at the Moore School of electrical engineering, University of Pennsylvania, Philadelphia, Pa., during the term 1939–40. Financial assistance was given by a Moore School fellowship.



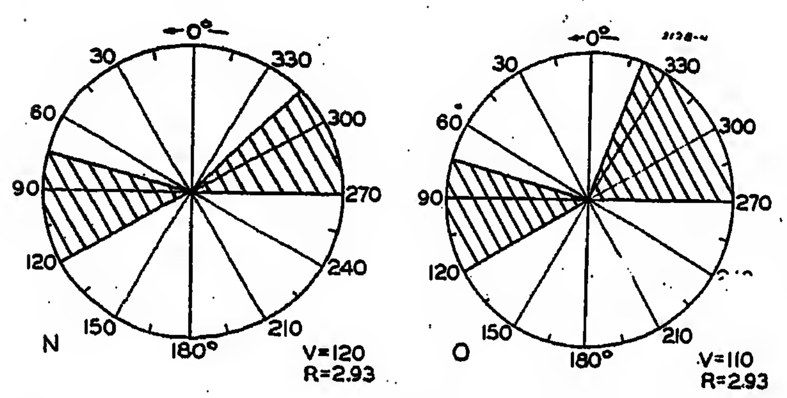


Figure 3 (above)

Figure 4 (left)

the polar diagrams of Figures 2, 3, and 4. The zero of angle was arbitrarily chosen as the zero on an oscillogram before the negative half-cycle.

The response of the circuit may be divided into three types, namely:

1. Exciting current.
2. Stable subharmonics.
3. Unstable subharmonics.

Exciting current is the normal current in a transformer primary for no load on the secondary. Stable subharmonics are abnormally high currents having a frequency which is an integral submultiple of the frequency of the applied voltage. The currents are said to be stable if they persist as long as voltage is applied to the circuit and they maintain a repetitive wave form. Unstable subharmonics are abnormally high currents having a nonrepetitive wave form. According to the theory of Travis and Weygandt, these currents have imperfectly matched boundary conditions, and therefore they cannot repeat each cycle exactly. It is common for such currents to continue in a "jittery" state for many minutes and suddenly disappear not to reappear until the circuit is again closed with the proper initial conditions.

The wave forms of the subharmonics are not given here, since many have already been published.[4] The initial voltage phase angle has no effect on the wave form of the subharmonic current in the region where these currents are possible. Switching angles of 90 degrees and 270 degrees generally give an exciting-current response, and the unstable subharmonics are situated on the border line between exciting current and stable subharmonics.

The diagrams of Figures 2, 3, and 4 show also that the subharmonic region is smaller for high values of circuit resistance. In the circuit of Figure 1, subharmonics could not be initiated at any angle when the resistance R was greater than approximately seven ohms. The extent of the subharmonic region also decreases as the applied voltage decreases. This is to be expected, because the lower the voltage, the more difficult it is to saturate the core of the inductor.

The boundary lines between current regions are drawn sharply but actually it is difficult to tell within plus or minus five degrees where one region ends and another begins. These graphs then have only a semiquantitative value. Each diagram is the result of observations taken at least two complete cycles of 360 degrees to be certain that the results are reproducible.

Another possible initial condition which has not been previously investigated either theoretically or experimentally is the initial flux in the inductor core. Oscillograms were taken with the transformer winding flashed with d-c before the switch was closed. Figure 5 shows two oscillograms taken of current initiated with identical initial conditions, except that the inductor was flashed in one direction for one oscillogram, and in the reverse direction for the other. It can be seen that the first few cycles are very different, but the wave forms after a short time has elapsed are identical. Figure 6 shows a repetition of the experiment for a different set of initial conditions.

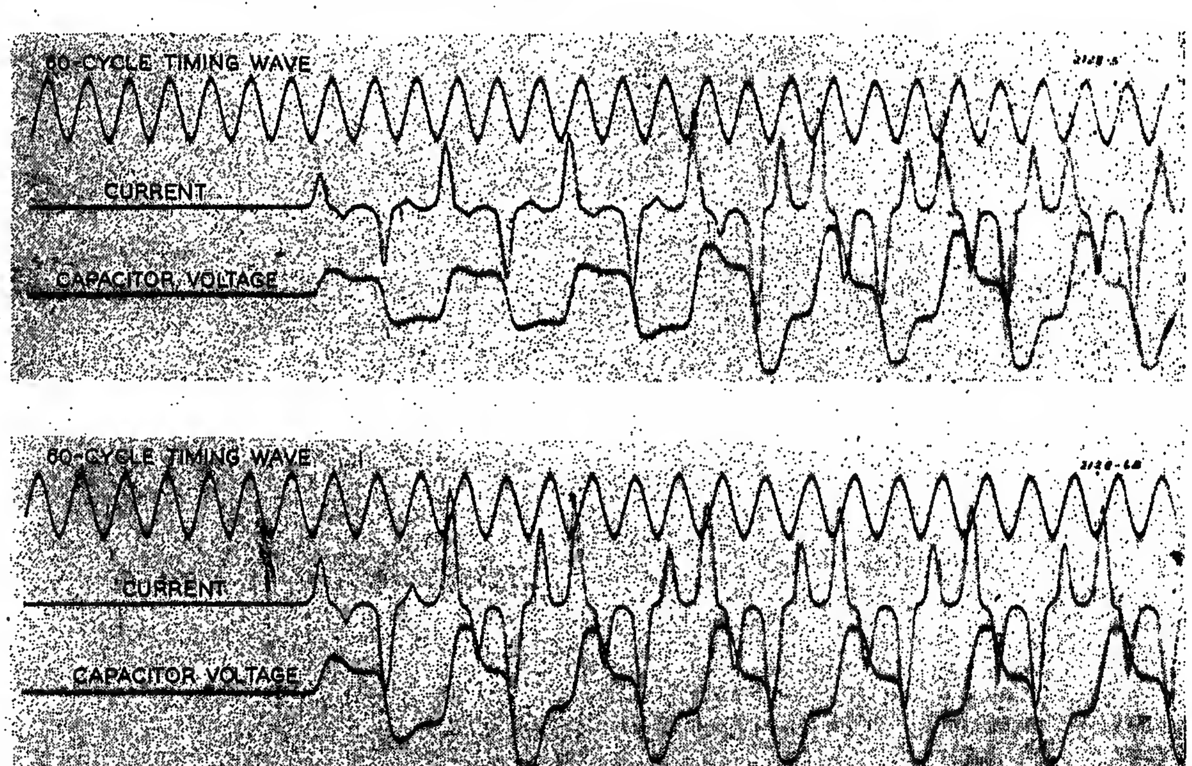
Conclusions

The results of this study may be summarized as follows:

(a). The current response in this circuit is dependent on the initial voltage phase angle.

Figure 5. Oscillograms showing the current response of the circuit for identical initial conditions except that the initial flux in the inductor core was reversed

The initial voltage angle was 31 degrees. Other data are R=2.93 ohms, V=120 volts, and q_0=zero



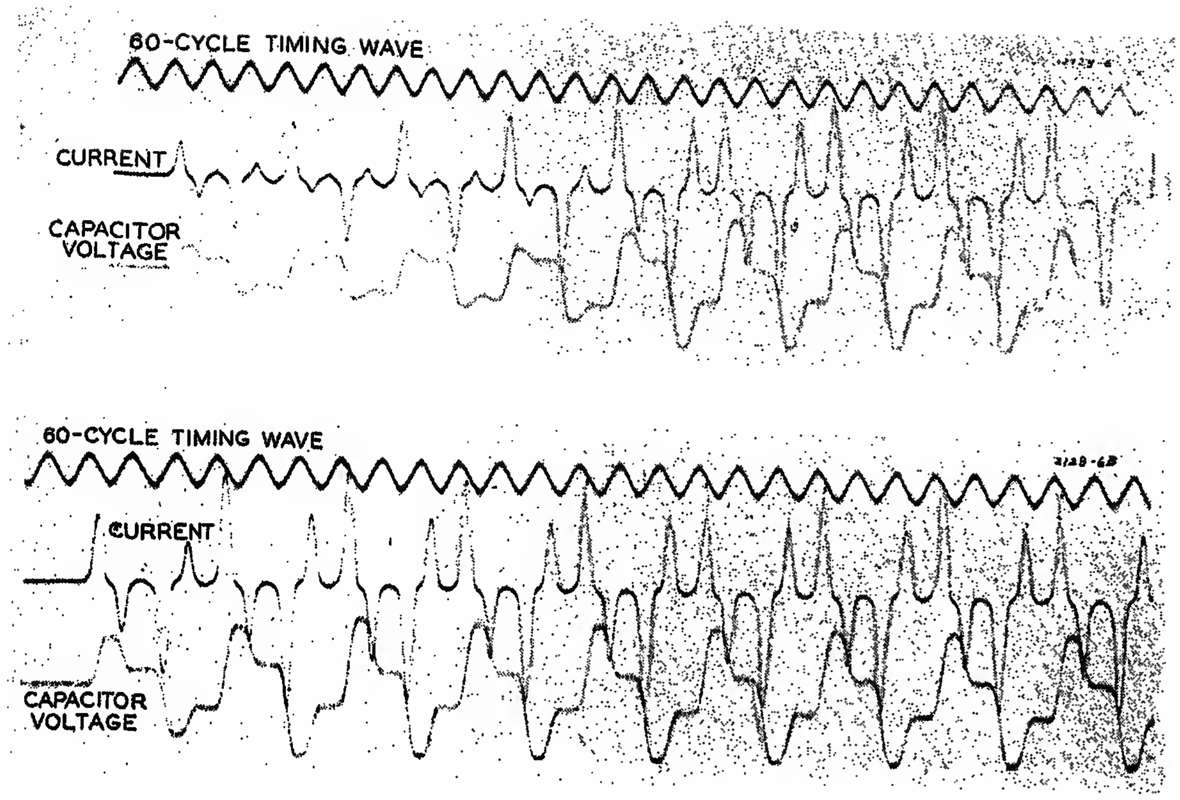


Figure 6. Oscillograms made in a manner similar to those of Figure 5

In this case the initial phase angle was 266 degrees. Other data are R=2.93 ohms, V=140 volts, and q_{0}=zero

(*b*). The wave form of stable subharmonics is independent of initial phase angle.

(*c*). The wave form of the first few cycles of a subharmonic current is dependent on the value of initial flux linkages in the inductor.

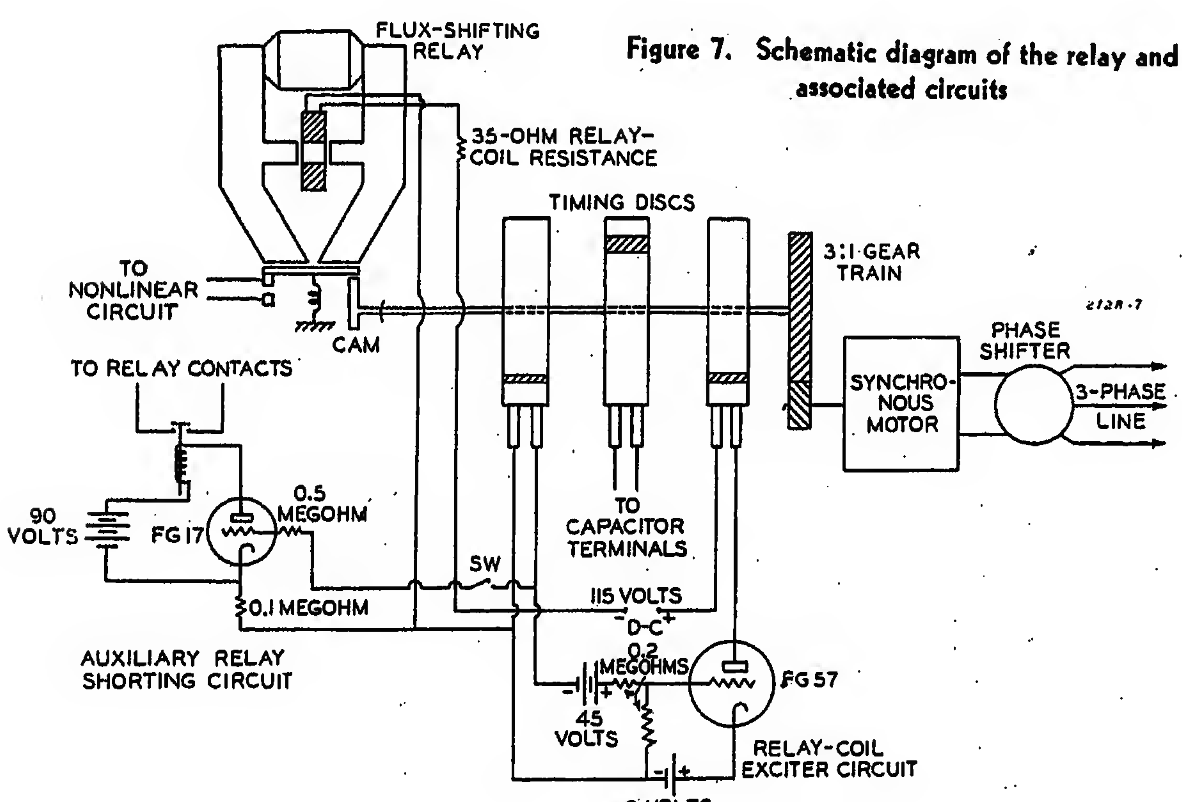

Figure 7. Schematic diagram of the relay and associated circuits

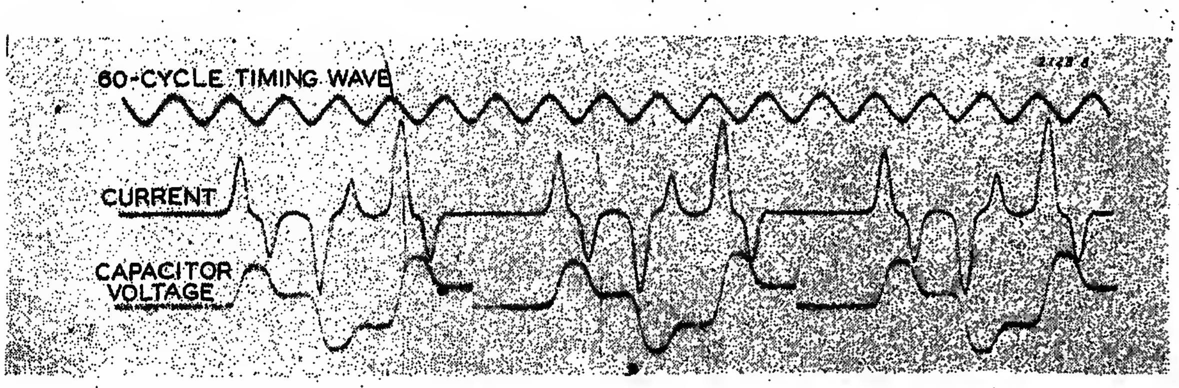
Figure 8. An oscillogram illustrating the performance of the timed switch

Note that the wave forms are repeated in detail. Note also that the capacitor voltage is reduced to zero after the switch opens so that q_{0}=zero for the next closure

It should be noted that nothing has yet been said about ferroresonance. The impressed voltages employed in this work were lower than the critical voltage for ferroresonance in all cases. All statements concerning initial conditions, therefore, apply only to subharmonic currents. It is certain that the currents of ferroresonance are abnormally high, but the frequency is that of the applied voltage. This point is stressed, because some confusion is apparent in the discussions of other papers.



Appendix

The timed switch discussed under experimental procedure was a mechanical flux-shifting relay. A mechanical relay was employed, because it is necessary to have the circuit resistance very low. This eliminates the possibility of using electronic switches, because they have a high internal resistance, and furthermore this resistance is a function of the current.

Figure 7 shows a schematic diagram of the relay and the associated circuits. The purpose of the circuits is to excite the flux-shifting coil on the relay at the proper time. The timing is effected as follows:

(*a*). A synchronous motor running at 1,800 rpm turns three coaxial disks at 600 rpm through a 3 to 1 gear train.

(*b*). One disk has a shorting bar on the periphery which closes the bias circuit of the *FG* 17 thyratron. The thyratron plate current excites the flux-shifting coil on the relay, causing it to close. This coil excitation occurs once every six cycles. The part of the 60-cycle wave at which it occurs is determined by the space angle of the synchronous motor rotor. This space angle can be varied through 360 degrees by means of the phase shifter on the input.

(*c*). A cam is set on the end of the synchronous motor shaft so that it opens the relay about four cycles ($^1/_{15}$ second) after the closing instant.

(*d*). Another disk on the motor shaft is arranged to break the thyratron plate circuit after the arc in the tube has been initiated. This is necessary to make the tube ready for the next closure.

(*e*). A third disk on the motor shaft has a shorting bar on the periphery. This is oriented so that during the two cycles after the cam opens the relay, the charge on the capacitors in the circuit may be reduced to zero.

The oscillogram, Figure 8, shows the performance of the timed switch. Note that each cycle of operation is repeated in every detail. The result is a steady image of the first four cycles of current in the circuit on an oscilloscope screen.

The *FG* 17 circuit is switched in if it is desired to keep the circuit closed after a given closure. This circuit is used in conjunction with an oscillograph to get photographs of the current, and capacitor voltage wave forms from the time of closure until the steady state is reached.

Study of Driven Rods and Counterpoise Wires in High-Resistance Soil on Consumers Power Company 140-Kv System

J. G. HEMSTREET
ASSOCIATE AIEE

W. W. LEWIS
FELLOW AIEE

C. M. FOUST
MEMBER AIEE

THE Consumers Power Company operates an extensive 140-kv system in eastern, southern, and western Michigan. In parts the top soil is sand, sometimes extending to a considerable depth, and tower footings in this soil have very high resistance compared with resistance encountered in other soils.

In 1936 the Consumers Power Company and the General Electric Company began a joint investigation of the ground-circuit arrangement best suited to carry the lightning current with a minimum potential across the line insulators. The test setup was arranged to study the relative merits of the driven rod, the continuous-parallel counterpoise, and the radial counterpoise, as well as to investigate the current and voltage conditions near the surface of the earth in the vicinity of the lightning stroke.

Methods of Grounding

To study various methods of grounding, a portion of the *N*-14 line between Croton and Muskegon was divided into three sections, and each section was equipped with special earth connections as follows:

Section *A*. Towers 7,659 to 7,682, parallel continuous counterpoise and right-angle counterpoise.

Section *B*. Towers 7,683 to 7,708, parallel continuous counterpoise and driven rods.

Section *C*. Towers 7,711 to 7,723, right-angle counterpoise and driven rods. (Tower 7,709 has been removed. Tower 7,710 is equipped with ground rods, but not with right-angle counterpoise because of deep gully and road.)

Figures 1a, 1b, and 1c show the three arrangements. The length of each section is approximately two miles. The counterpoise wire consists of seven-strand $^3/_8$-inch galvanized-steel cable buried to a depth of approximately 18 inches. The parallel wire extends continuously between towers, passing directly beneath the towers and connecting to the middle leg. The right-angle counterpoise wires extend 250 feet each side of the line and are attached to the side legs of the towers. The total length for each tower approximates the length of one span.

The rods were driven as deep as necessary to secure a resistance of between 10 and 20 ohms. In some cases one rod was sufficient and in other cases two rods were necessary. The rods were made of $^5/_8$-inch copper bearing steel, 8 feet long, the lengths being joined together by pressed fit couplings and driven into the ground by gasoline hammers.[1,2] Rods were driven to all depths, up to 150 feet in some cases.

In addition to the counterpoise wires and driven rods connected to the towers, 10 isolated probe wires approximately 100 feet long were buried in the ground, beginning approximately 300 feet from the line and extending at right angles to the line. These were spaced approximately uniformly throughout the experimental region between towers 7,659 and 7,723.

The *N*-14 line for the greater part of its length is a single-circuit line on steel towers. The conductors are arranged in a triangle, two on one side of the tower and one on the other, the equivalent delta spacing being approximately 15.6 feet. The total length of the line between Croton and Muskegon is 37.4 miles, of which 35.4 miles is 3/0 steel-reinforced aluminum cable and two miles 4/0 steel-reinforced aluminum cable. There is a ground wire at the peak of the towers made of three strands of number 7 Copperweld. The line is insulated with 9 disks spaced $5^3/_4$ inches on suspension and 11 disks on dead ends.

The towers are of the three-legged type and each leg was equipped with one

Paper 42-107, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 7, 1942; made available for printing April 24, 1942.

J. G. HEMSTREET, is superintendent of operation, Consumer's Power Company, Jackson, Mich.; W. W. LEWIS is with the central-station engineering department, and C. M. FOUST with the general engineering laboratory, both of the General Electric Company, Schenectady, N. Y.

The authors acknowledge the assistance of many people in this investigation, especially J. R. Eaton, now of Purdue University, who had active charge for Consumers Power Company of the installation of the driven rods, counterpoise wires, and measuring equipment; Carl C. Tanner, who carried on the field work after Mr. Eaton left the company; and R. F. McAtee of the general engineering laboratory, General Electric Company, who helped in the calibration work and in analyzing the data.

There is no tower 7,709.

* Tower 7,710 has two driven rods, but no counterpoise connected to it.

bracket for magnetic links. After the 1937 season, brackets were installed on the overhead ground wire on each side of every tower, about 3 feet away from the tower. The continuous counterpoise wires were equipped with brackets on each side of each tower, about 4 feet from the center tower leg, and also at the middle of each span. The right-angle counterpoise wires on each side of the tower were equipped with one bracket at 4 feet from the tower leg, and on only the south side one at 125 feet and one at 225 feet. Each separate probe wire had a bracket at approximately the middle of its length. Each driven rod was equipped with one bracket. In all cases each bracket was equipped with two magnetic links in order to obtain a current range and to make use of the oscillatory calibration.[3]

The entire test portion of the *N*-14 line extends over a very uniform flat sandy plain. Table I gives the resistance measured by ground megger of the footing of each tower of the *N*-14 line included in this investigation. These resistances are of the footings alone and were measured before counterpoise wires and driven rods were installed. The table also gives for sections *B* and *C* the lengths of the driven rods and the final combined resistance of tower footing and driven rods.

During the years 1937 to 1941 inclusive, six strokes were experienced on the experimental part of the *N*-14 line. Of these one was in section *A*, two in section *B*, and three in section *C*. Following is a brief analysis of the important features of these strokes:

Stroke 1

On October 19, 1937, there was a stroke to the overhead ground wire of the *N*-14 line, between towers 7,764 and 7,765, in section *A*, equipped with parallel counterpoise and right-angle counterpoise. Current records were obtained at 14 towers, 7,659 to 7,672 inclusive. The stroke was negative, that is, all tower currents flowed upward and all parallel counterpoise currents toward tower 7,665 and all right-angle counterpoise currents toward the towers. An idea of the comparative ability of the two types of counterpoise to pick up current may be gained from the following:

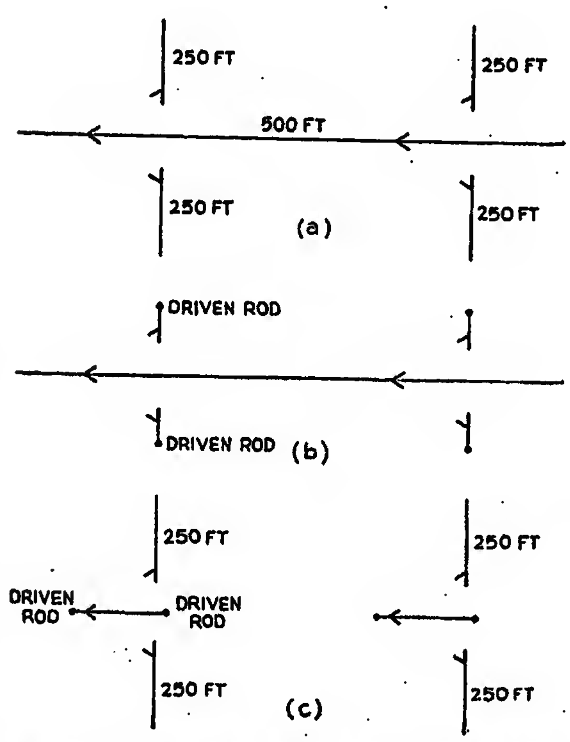

Figure 1. Experimental installation of parallel continuous counterpoise, right-angle counterpoise, and driven rods

For the parallel counterpoise, the difference between the current in a span approaching the tower and the current in the same span leaving the preceding tower is taken as the current collection or pickup in that span. For the right-angle counterpoise, the currents approaching the tower at each side at the magnet station nearest the tower are added up to give the pickup for that tower. Table III shows the parallel counterpoise pickup and Table IV the right-angle counterpoise pickup for this stroke. It will be noted that these currents are nearly equal, 23,000 amperes total in the parallel counterpoise and 25,700 amperes in the right-angle counterpoise.

At the first tower at which readings were obtained, tower 7,659, there were 2,800 amperes in the parallel counterpoise at the stroke side of the tower and no current was read in the counterpoise on the other side of the tower, in the tower legs, or in the right-angle counterpoise. Likewise, at the extreme end, tower 7,672, there were 1,800 amperes in the parallel counterpoise on the stroke side and no current was read elsewhere. The origin of this current is unknown.

It is interesting to note that current flowed in the parallel counterpoise for about six spans on each side of the point of stroke, while the right-angle counterpoise carried readable current at only three towers adjacent to the stroke, and the tower members themselves showed current in only two towers. This wide extent of current pickup on the parallel continuous counterpoise is common on this line, and also has been observed on other lines.[4,5]

Total counterpoise pickup			23,000

Table IV. Right-Angle Counterpoise Current, Stroke 1

Tower No.	Direction of Counterpoise Wire	Amperes
7,664	North	2,500
	South	2,500
7,665	North	8,000
	South	8,300
7,666	North	2,200
	South	2,200
Total		25,700

Isolated probe conductors were installed in the ground opposite towers 7,660 and 7,667, but no current was measured in these wires. However, neither was any current measured in the right-angle counterpoise wires extending out toward the probe conductors at these towers.

It is interesting to obtain an idea of the comparative ability for collecting current of the shallow buried counterpoise wires

and the short tower footings, extending perhaps eight feet below the ground surface. This may be done as follows:

Table V shows the total current picked up by the ground system, exclusive of the tower footings, which could not be measured in these tests.

Current was measured in only two towers, 7,664 and 7,665, as shown in Table VI. The difference between the total tower current of 58,400 amperes and the total counterpoise pickup current 53,300 amperes is 5,100 amperes, which is assumed to be the tower-footing pickup current.

If the current of 2,800 amperes in counterpoise at tower 7,659 and 1,800 amperes in counterpoise at tower 7,672 is prorated to the parallel and right-angle counterpoise in the ratio 23,000 to 25,700, we can sum up the distribution of currents between counterpoise and tower footings and evaluate the counterpoise resistance.

Table V. Measured Current Picked up by Counterpoise System, Stroke 1

	Amperes
Parallel counterpoise	23,000
Right-angle counterpoise	25,700
Current in counterpoise at tower 7,659	2,800
Current in counter poise at tower 7,672	1,800
Total	53,300

The multiple resistance of the 14 towers, 7,659 to 7,672, from Table I, is 42.7 ohms. The counterpoise resistance is then assumed to be inversely proportional to the current pickup, as shown in Table VII.

This comparison indicates that the counterpoise wires are very efficient compared with the natural tower footings which penetrate only a short distance below the ground in the same top soil occupied by the counterpoise wires.

STROKE 2

On August 20, 1938, there was a stroke to the overhead ground wire on the *N*-14 line between towers 7,708 and 7,710. Tower 7,709 had been removed prior to this time, so that towers 7,708 and 7,710 were adjacent. The stroke was negative, that is, cloud negative and earth positive, all tower currents flowing upward and all counterpoise currents flowing inward toward the point of stroke.

Table VI. Tower Current, Stroke 1

Tower No.	Amperes Leg 1	Leg 2	Leg 3	Total Current (Amperes)
7,664	8,000	1,600	1,600	11,200
7,665	11,700	8,500	4,000	24,200
				35,400
Estimated cross-member current 65 per cent				23,000
Total				58,400

Table VII. Counterpoise and Tower-Footing Current and Resistance, Stroke 1

	Current Amperes	Per Cent	Resistance (Ohms)
Parallel counterpoise	25,170	43.2	8.66
Right-angle counterpoise	28,130	48.3	7.75
Tower footings	5,100	8.5	42.7
Total	58,400	100.0	

Tower 7,708 was at one end of section *B*, equipped with parallel counterpoise and driven ground rods. Tower 7,711 was at the beginning of section *C*, equipped with right-angle counterpoise and driven ground rods, but tower 7,710 had only two driven rods and no counterpoise connected. The span between towers 7,708 and 7,710 was long and ran across a gully.

Table VIII summarizes the pickup in the counterpoise wires and driven rods. Approximately one half of the total current picked up by the driven rods was collected by the single driven rod at tower 7,708. This rod was 92 feet deep and had a measured resistance of approximately 11 ohms. Tower 7,710 had two driven rods, one 121 feet deep and one 92 feet deep, with a combined measured resistance of about 13 ohms. These two rods, however, picked up only 4,200 amperes total. It appears that ground currents flowing in the gully at right angles to the line were tapped more readily by the single rod at tower 7,708, possibly because of soil resistance in the vicinity and also possibly because the cloud may have been centered more to the north of the gully (toward tower 7,705).

The set of readings in the parallel-counterpoise and driven-rod section, towers 7,705 to 7,708 inclusive, lends itself to a determination of the equivalent resistance of the counterpoise, on the assumption that the resistances are inversely as the currents carried. The tower-footing resistance for towers 7,705 to 7,708 inclusive, in multiple, is found to be 179 ohms, from Table I, the combination tower and driven-rod resistance is found to be 2.89 ohms, and by calculation the driven-rod resistance alone is 2.93 ohms. Table IX shows that the driven rods carried about 81 per cent of the total current and the parallel continuous counterpoise about 17 per cent, with the tower-footing current negligible. The equivalent resistance of the parallel counterpoise is 13.7 ohms, compared with 2.9 ohms for the driven rods.

A buried probe conductor opposite tower 7,707 carried no measurable current, while the driven rods at this tower picked up 4,400 amperes.

Table VIII. Counterpoise and Driven-Rod Current, Stroke 2

Tower No.	Counterpoise Type	Counterpoise Amperes	Driven Rod (Amperes)
7,705	Parallel	1,000	1,000

Total	25,840	100.0	

STROKE 3

This stroke took place on July 30, 1940, to the overhead ground wire between towers 7,714 and 7,715, in section *C*, equipped with right-angle counterpoise and driven rods. The stroke was negative. A l tower currents flowed upward and all rod and counterpoise currents flowed toward the towers. Table X summarizes the current collection by right-angle counterpoise and driven rods.

The multiple footing resistance of the 12 towers, 7,712 to 7,723 inclusive, from

Total	45,900	67,100

Table XI. Driven-Rod, Counterpoise, and Tower-Footing Current and Resistance, Stroke 3

	Current: Amperes	Current: Per Cent	Resistance (Ohms)
Driven rods	67,100	59.0	0.86
Right-angle counterpoise	45,900	40.3	1.26
Tower footings	900	0.7	64.0
Total	113,900	100.0	

Table I, is 64 ohms, while the multiple resistance of the combined footings and ground rods is 0.85 ohm. From these figures the driven-rod resistance alone calculates 0 86 ohm.

Table XI shows the division of current and the equivalent resistance of the driven rods, right-angle counterpoise, and tower footings, on the assumption that the resistances are inversely proportional to the currents. From Table XI it will be seen that the driven rods carry about 59 per cent of the current and the right-angle counterpoise wires about 40 per cent, the tower-footing current being negligible.

From Table XI the summation of the currents picked up by the driven rods, right-angle counterpoise wires, and tower footings is about 114,000 amperes. The sum of all tower currents involved in the stroke, towers 7,712 to 7,723 inclusive, is 60,700 amperes, which increased by 65 per cent for estimated cross member currents, would give 100,000 amperes. This should be increased by 3,300 amperes coming in on the overhead ground wire from beyond tower 7,712. Thus there is good agreement between the current of about 114,000 amperes collected from the ground and the tower current of about 103,000 amperes. However, the current in the overhead ground wire at the two ends of the span that was struck totaled only 57,300 amperes. This current is undoubtedly too low. A saturated inner link at the Croton side, at tower 7,715, permitted the use of the outer link only, with the unidirectional calibration curve. This value is therefore a minimum. This discrepancy might indicate that the counterpoise and ground-rod current crests are not coincident. The currents in the counterpoise in the ground surface might rise to crest value more quickly than the currents in the ground rods, which are draining a charge from 100 feet below the surface, including the ground charge extending well out beyond the surface counterpoise wires.

It will be noted from Table X that, in the towers near the lightning stroke, the driven-rod currents are much greater than the counterpoise currents, while at the more remote towers the pickup is more nearly equal, if not greater in the counterpoise. This might be expected if the major portion of the ground charge is located deeply and flows through a conducting layer radially to the driven rods near the lightning stroke.

Summation of the counterpoise currents to the north of the line gave 30,000 amperes, while those to the south of the line totaled 15,900 amperes. This would suggest that the cloud charge participating in the lightning stroke was more to the north of the line.

A reading of 5,000 amperes was obtained in a buried probe conductor opposite tower 7,715, while in the three stations on the right-angle counterpoise wire, extending in the same direction, readings were obtained of 1,000, 2,500, and 3,400 amperes, going progressively toward the tower. Also a reading of 1,800 amperes was obtained in a probe conductor opposite tower 7,722, while a reading of 1,000 amperes was obtained in the right-angle counterpoise extending in the same direction at the magnet station nearest the tower.

Stroke 4

This stroke took place July 30, 1940, to the overhead ground wire of the *N*-14 line between towers 7,702 and 7,703, in section *B*, with parallel continuous counterpoise and driven rods.

The current collection for the parallel counterpoise and driven rods is shown in Table XII. The stroke was negative.

The resistance of the footings of towers 7,700 to 7,706 inclusive, in multiple, is 93.7 ohms from Table I. The combined resistance of tower footings and driven rods is 1.74 ohms and the calculated resistance of the driven rods alone is 1.77 ohms.

Table XIII shows the distribution of current among the driven rods, parallel counterpoise, and tower footings, and the equivalent resistance on the basis that the current divides inversely as the resistance. It will be noted that the driven rods carry 88 per cent of the total current, as against 10 per cent for the parallel counterpoise wires.

Table XII. Parallel-Counterpoise and Driven-Rod Current, Stroke 4

Counterpoise: Tower No.	Counterpoise: Amperes	Driven Rods: Tower No.	Driven Rods: Amperes

		7,704	7,100
		7,705	1,000
		7,706	2,000
Total	5,000		42,200

Table XIII. Driven-Rod, Counterpoise, and Tower-Footing Current and Resistance, Stroke 4

	Current: Amperes	Current: Per Cent	Resistance (Ohms)
Driven rods	42,200	88.0	1.77
Parallel counterpoise	5,000	10.4	15.0
Tower footings	800	1.6	93.7
Total	48,000	100.0	

Buried probe conductors opposite towers 7,700 and 7,707 showed no readable current. The driven rods at tower 7,700 picked up 1,900 amperes and there were readings in the parallel counterpoise wire and in the tower legs at this tower. However, at tower 7,707 no readings were obtained in the driven rods, counterpoise wire, or tower legs.

Strokes 5 and 6

These strokes occurred on October 2 1941, to the overhead ground wire between towers 7,715 and 7,716, and between towers 7,720 and 7,721. This is the section of line equipped with right-angle counterpoise and driven rods (section *C*). Subsequent inspection showed flash marks on all three insulator assemblies at tower 7,721, but there was no tripout on this date. Both strokes were negative.

The current collection for the right-angle counterpoise and driven rods is shown in Table XIV.

The multiple resistance of the footings of the ten towers, 7,714 to 7,723 inclusive, from Table I is 76 ohms, and the multiple resistance of the combined driven rods and tower footings is 0.976 ohm. From these figures the resistance of the driven rods alone is 0.99 ohm. The distribution of current and the equivalent resistances are shown in Table XV. It will be noted that the driven rods carry

Table XIV. Right-Angle Counterpoise and Driven-Rod Current, Strokes 5 and 6

7,723	0	6,000
Total	27,700	124,500

Table XV. Driven-Rod, Counterpoise, and Tower-Footing Current and Resistance, Strokes 5 and 6

	Current		Resistance (Ohms)
	Amperes	Per Cent	
Driven rods	124,500	81	0.99
Right-angle counterpoise	27,700	18	4.45
Tower footings	1,620	1	76.0
Total	153,820	100	

about 81 per cent of the current, as against 18 per cent for the right-angle counterpoise.

No readable current was measured in buried probe conductors opposite towers 7,715 and 7,721. In the right-angle counterpoise wire, extending toward the probe wire at tower 7,715, 6,400 amperes were measured at the magnet station adjacent to the tower. In the right-angle counterpoise wire, extending toward the probe wire from tower 7,721, currents of 800, 3,600, and 5,800 amperes were read progressively toward the tower.

Voltage Gradient in Vicinity of Towers

For the purpose of indicating the voltage conditions in the vicinity of the tower during lightning strokes, a portion of the T-20 line was selected. This line runs between Croton and Grand Rapids, a distance of approximately 39.2 miles. The line has four-legged double-circuit steel towers, with the conductors arranged vertically on one side of the tower only for 32 of the 39.2 miles. The conductors are 110,000-circular-mil copper, with 15.1-feet equivalent delta spacing. One overhead ground wire, consisting of three strands of number 8 Copperweld, is installed at the peak. The line is insulated with ten disks, spaced $4^3/_4$ inches on suspension, and 12 units on dead ends. A section of this line from towers 4,387 to 4,417 inclusive, 31 towers, was selected for this investigation.

About two thirds of this test section traversed a sandy plain where tower-footing resistance was very high, while the remainder passed over low ground composed of muck and sand where footing resistances were comparatively low. Ten consecutive towers in the high-resistance section, 4,387 to 4,396 inclusive, were equipped with deep-driven rods to reduce the tower-footing resistance. In two cases there was one rod per tower, in five cases two rods per tower, and in three cases four rods per tower. The resistances of all the towers in the experimental section are given in Table II.

At one side of each tower, and about six feet from the tower legs, a probe rod was driven into the ground about five feet deep, and between the tower and the probe rod was introduced a lightning-stroke recorder.[6] The purpose of this recorder was to measure the voltage drop between the tower and the probe rod during lightning strokes.

Each tower leg was equipped with a bracket, and after 1937 a bracket was installed on the overhead ground wire on each side of each tower. Each deep-driven rod was also equipped with a bracket. In all cases each bracket was equipped with two magnetic links.

Eight strokes occurred on the T-20 line during the period of this investigation (1936 to 1941 inclusive). Six strokes in which there was good correlation between the tower current and the potential between tower and probe rod are summarized in Table XVI.

The stroke on September 15, 1936 (stroke 7) made contact with the overhead ground wire between towers 4,404 and 4,405. Measurements were obtained at 31 towers extending from 4,387 to 4,417 inclusive. At 29 towers, records were obtained on the lightning-stroke recorders connected between the tower leg and the five-foot probe rod. These readings ranged from 5 to about 50 kv, the external flashover value of the recorder. There were 3 cases of external flashover and 13 cases of film flashover. As a result of this experience, capacitance dividers with ratios of 2 to 1 were installed at all tower probe-rod stations.

On June 24, 1937, a stroke occurred to tower 4,408 (stroke 8). Records were obtained at 19 towers, 4,395 to 4,413 inclusive. In 7 cases the lightning-stroke recorder flashed over. For the other 12 cases, the readings ranged from 9 to about 100 kv, which was the flashover of the recorder and voltage-divider combination. It was therefore necessary again to increase the voltage-divider ratio and a 6 to 1 ratio was installed. This ratio proved sufficient, as no more flashovers were experienced.

All the strokes of which there were good records were negative. Stroke 12 is worthy of mention. This stroke (not listed in Table XVI) took place to the top of tower 4,389. About 6,300 amperes flowed upward in this tower, and a total of 6,300 amperes was measured in the two deep-driven rods connected to this tower, flowing upwards. In the adjacent tower 4,388, no current was measured, but in the second tower to the north, 4,387, about 13,200 amperes flowed downward and 6,000 amperes was measured flowing downward in the single deep-driven rod connected to this tower. Currents from the overhead ground wire flowed toward the stroke from beyond tower 4,387 and from beyond tower 4,391 to the south.

Surge Resistance of Tower Footings Under Natural Lightning Conditions

The potentials measured on the probe rods driven five feet deep at a distance six feet from the tower footings have been correlated with the tower-structure currents as shown in columns 4 and 6 of Table XVI. These tower-to-probe voltage measurements of column 6 are less than true tower potential by the earth potential differences beyond the probe rods. An approximation of the relation between measured tower-to-probe-rod voltage and actual tower potential is found as follows:

The current from the earth to the tower footing is assumed to be distributed uniformly in the earth, its density being the same at identical distances from the tower footing and inversely proportional to the square of the distance from the footing. The earth's resistance, being proportional to cross section, also is de-

† Total tower current (column 4) assumed 1.5 times measured current in tower legs, to take care of cross member current.

creasing as the square of the distance from the tower footing.

The voltage gradient at ground points of differing distances from the footing will be inversely as the square of the tower to point distance. The potential at a ground point is the integrated voltage gradient and is therefore inversely proportional to distance.

Accordingly, with an assumed tower-base spread of 18 feet and a probe point 6 feet farther out, the probe potential will be to the tower potential as 9 is to 15, or the tower potential will be 15/9 times the probe potential. The tower potential less the measured tower-to-probe voltage will be the probe potential. Therefore, the measured tower-to-probe potential must be multiplied by 2.5 to give tower potential. Values of true tower potential calculated on this basis are given in column 7.

To show the relation between the surge resistance and the normal footing resistance, the values of column 9 were calculated by dividing values in column 8 by those in column 3. These figures show the surge resistance to range from some 4 to 90 per cent of normal resistance values. These values are somewhat lower than those reported from artificial surge measurements.[7,8] In this connection, however, it should be observed that the range of normal resistances, from 13 to 1,300 ohms, is wider than is ordinarily investigated, and the range of currents, 6,000 to 45,000 amperes, is also very wide. In general in these measurements we are dealing with high resistances and large currents.

The resistance ratio of column 9 was shown, by plotting, to decrease very definitely with increasing currents and with increasing resistances. Accordingly, this ratio was plotted against a composite factor the product of up-tower current and normal footing resistance shown in column 5. In Figure 2 the ratio of surge resistance to normal resistance of column 9 is plotted as ordinate against the product of current and normal footing resistance of column 5. The points, while somewhat scattered, nevertheless show very clearly the trend indicated by the solid line. This is borne out by plotting on log-log paper, which shows a relation between ratio and product as follows:

$$\frac{R_S}{R_N}=\frac{14}{(R_N I_T+80)^{0.6}}$$

in which R_S=surge resistance, R_N=normal or megger tower-footing resistance, and I_T=total tower current.

For practical purposes these curves might be utilized somewhat as follows: Assume that it is desired to evaluate the surge resistance of a certain tower under a lightning current of 10,000 amperes, where a normal tower-footing resistance of 100 ohms has been measured. The product of tower current and footing resistance is $1{,}000 \times 10^3$, which referred to the curve gives a ratio of 0.22. This ratio applied to the 100-ohms footing resistance gives a surge resistance of 22 ohms. The resultant tower potential would be 220,000 volts, which is substantially below flashover.

The flashover of this line is taken as 700 kv on a 1.5x40-microsecond wave and on this basis it is interesting to examine actual field operating records as to insulator-assembly flashovers that might coordinate with the derived tower potential of column 7. Flashover occurred at tower 4,400 for stroke 10, for which the derived tower potential is just 700 kv. All three phases flashed over. No other flashovers are correlated with tower-to-probe measurements for the records shown in this table. Accordingly, on the basis of this flashover it is indicated that the ratio between true tower potential and measured tower-to-probe potential could not be lower than the 2.5 figure derived from the assumption outlined above. Also for tower 4,412, stroke 13, the tower potential is 555 kv, as the last item in column 7. In this case there was no flashover and the tower-to-probe potential was 222 kv. The ratio of 700 to 222 kv, or slightly over 3 to 1, is therefore indicated as the upper limit by these data. It is therefore concluded that the true ratio is between 2.5 and 3 to 1 and the use of the curve for interpreting true surge resistances from tower currents and normal ground-resistance measurements is seen to be reasonable.

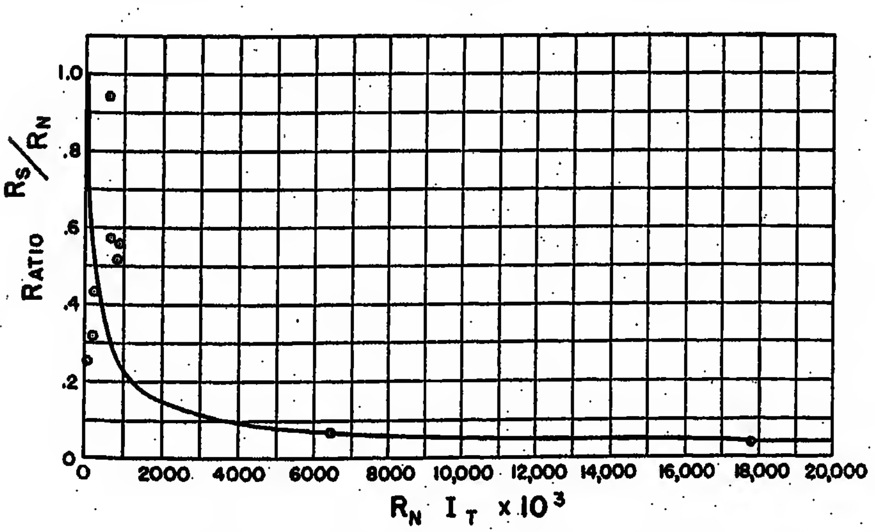

Figure 2. Ratio of surge resistance to normal tower-footing resistance, plotted against product of current and normal footing resistance during natural lightning strokes

Conclusions

In field lightning research, the investigators are often disappointed at the few direct strokes in the experimental section, even after a period of several years. The present investigation is no exception. However, it is believed that the preceding analysis and the following conclusions represent a fair interpretation of the limited data available. It should be understood that the conclusions apply specifically to the conditions prevailing on this particular transmission line.

1. Parallel continuous counterpoise wires and right-angle counterpoise wires of equal total length have approximately equal current-collecting ability. Direction of counterpoise apparently is not a governing factor, but only resistance to ground. In comparison with the normal tower footings the counterpoise wires are very effective in picking up lightning current.

2. In sandy high-resistance soil, rods driven deep enough to penetrate the clay or loam beneath the sand serve to reduce the tower-footing resistance from 500–1,400 ohms to 7–25 ohms. These rods, in comparison with counterpoise wires in the high-resistance surface soil, are much more effective in picking up lightning current.

3. There is some indication that the current pickup in the counterpoise wire near the ground surface and in the deep-driven rods is not coincident. Possibly the ground rod requires more time to discharge the surrounding earth on account of its deep penetration into the earth.

4. Data seem to indicate that the ratio of surge tower-footing resistance to normal tower-footing resistance decreases definitely with increasing currents and with increasing resistances. For example, at 10,000 amperes and 100 ohms the surge resistance decreases to approximately 22 ohms. This may account for frequent failure to flash over when the product of current and normal resistance indicated that flashover should take place.

5. The ratio of surge resistance to normal footing resistance is shown under natural lightning conditions to be as low as 0.04 for sandy soil, where normal resistance ranges up to 1,000 ohms or more and tower current up to approximately 50,000 amperes.

Precision Speed Control for World's Largest Induction Motor

ROBERT R. LONGWELL
NONMEMBER AIEE

M. E. REAGAN
FELLOW AIEE

A RECENT paper by Dickey, Kilgore, and Laffoon described an installation consisting of a 40,000-horsepower wound rotor induction motor and the necessary auxiliary equipment required to provide for variable speed operation.[1]

To meet the many requirements of control, imposed by this application, it was necessary to devise new methods for insuring smooth acceleration of auxiliaries and main motor, for limiting the change in power required from the supply system to a definite maximum value, to provide precision regulation of speed, as well as means for control for the main motor from either of two points. In addition, power-factor regulation and means for emergency quick stopping was provided. These and many other features were incorporated in the automatic control, the functions of which are briefly outlined in the following paragraphs.

In order that the auxiliary motor generator sets and main motor may be supplied with adequate bearing lubrication and ventilation at all speeds, it is necessary to start the oil circulating pump and ventilating fans prior to placing those units in service. In addition, the seven-unit exciter set, which supplies d-c energy to the fields of the machines comprising the auxiliary motor-generator sets, must be started. After these preliminary operations are complete, the starting indication is given the automatic control by manual operation of the starting control switch which energizes the master relay. Starting and acceleration of the auxiliary motor-generator sets and connection of the main motor to the 6,900-volt bus is accomplished in the following sequence:

1. Closing of d-c machine field breakers.
2. Closing of high-voltage breaker for constant speed motor-generator set, energizing motor through starting reactor.
3. Closing of starting reactor short-circuiting breaker.
4. Energizing of fields of a-c machines.
5. Connection of speed matcher to bus and primary of main motor.
6. Acceleration of variable speed motor-generator set under control of constant current regulator for d-c machine fields and master speed-control rheostat operated by speed matcher contacts.
7. Energizing of voltage-balancing relay and automatic synchronizer.
8. Closing of main motor primary breaker.

At this point the main auxiliaries are operating at synchronous speed and the main motor is at rest but connected to the 6,900-volt three-phase bus. To start the main motor the operator, at one of the two suitably interlocked control points, turns the pointer on the speed-control dial to a definite speed position. Following that manual operation the automatic control completes the following operations:

1. Starts rotor-lift oil pumps for main motor.
2. Causes the variable speed set to slowly decrease in speed.
3. Main motor begins to rotate and gradually approach the desired speed.
4. Acceleration stops and main motor speed is maintained constant by means of the electronic speed regulator, controlled from a pilot generator on main motor. This regulator provides energy for speed-regulating field windings on d-c machines of constant speed motor-generator set.

In stopping the main and auxiliary units, the automatic operations take place in the reverse order to those performed when starting. The same smooth operation is afforded, as in starting, with power being fed back into the system as a means of decelerating the machines.

All of the recent developments in switching equipment were employed to provide utility, flexibility, and compactness of design. The 6,900-volt switchgear is of the metal-clad type, using oil circuit breakers having a suitable interrupting capacity; all low-voltage circuits are protected with metal-enclosed air circuit breakers, and the main control switchboard is of duplex construction. In addition to all those features, the latest innovation in relay construction was employed by the use of plug-in devices for both protection and automatic control.

Starting of Auxiliaries

All of the power and switching equipment, consisting of the following apparatus, is located in the power building (Figure 2).

1. 40,000-horsepower main motor.
2. 6,250-kva constant-speed motor-generator set.
3. 38,000-horsepower variable-speed motor-generator set.
4. 400-horsepower seven-unit exciter set.
5. 6,900-volt metal-clad high-voltage switchgear.
6. 460-volt metal-enclosed switchgear.
7. Seven-panel main duplex control switchboard.
8. Ventilation blowers for main motor and each motor-generator set.
9. Lubricating-oil circulating equipment.

Apparatus for remote control of the main-motor speed and for emergency quick stopping is installed on a control desk in the control room of the test chamber, Figure 3. The test chamber is an integral part of the wind tunnel.

If it is assumed that test operations are to be conducted, the first requirement is that the operator in the power building start all equipment necessary for supplying energy to the wind tunnel. This operation is initiated from the main control switchboard by first starting the exciter set, the ventilating fans, and lubricating equipment by remote manual push-button control. When these auxiliaries are in service, the main auxiliaries may be

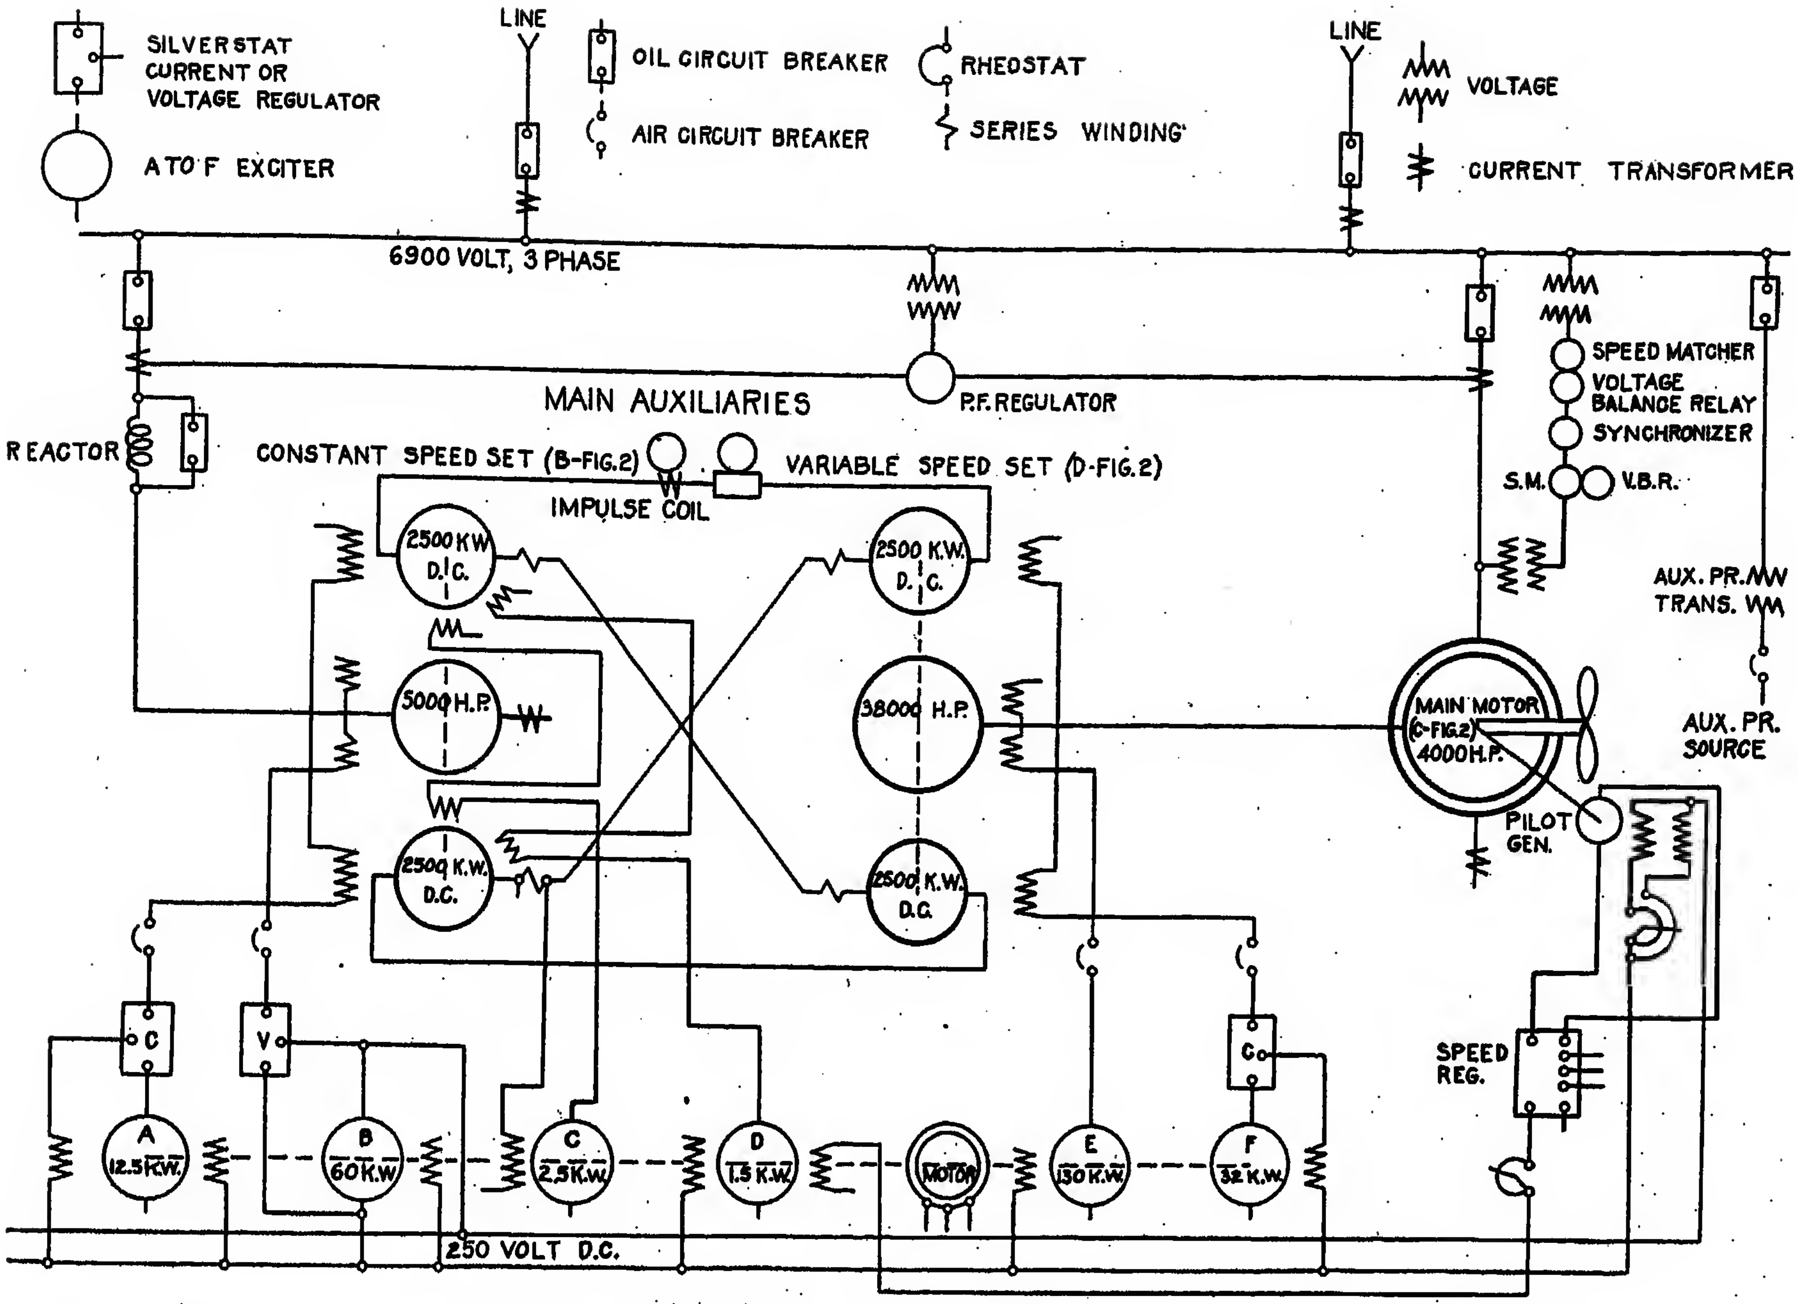

Figure 1. Schematic connection diagram for 40,000-horsepower motor and auxiliaries

started by means of a control switch on the main control switchboard. This switch energizes the master relay of the automatic control and all further starting operations are accomplished under the supervision of that equipment.

Starting of Constant-Speed Motor-Generator Set

The constant-speed motor-generator set consists of a 6,250-kva a-c machine and two 2,500-kw 750-volt d-c machines. During the starting operation of both main auxiliary sets, the a-c machine functions as a synchronous motor, and the d-c machines as generators. After the 40,000-horsepower motor is in service, the d-c machines operate as motors driving the a-c machine as a synchronous generator supplying power to the a-c system. Because of the dual function of these machines and to avoid confusion, they are referred to simply as a-c and d-c machines rather than as motors or generators.

Each operation, in the starting scheme, follows a planned automatic sequence which insures correct and positive functioning of the equipment being controlled. Following energizing of the master relay, the automatic control closes the field breakers for the fields of the d-c machines of both main auxiliary sets. Completion of this operation, as indicated by interlocks on the field breakers and a contact on the field relay for the d-c machines of the variable-speed set, the a-c machine of the constant-speed set is connected to the 6,900-volt bus through a starting reactor.

During the time that the constant-speed motor-generator set is accelerating, excitation on the exciter for the d-c machines of this set is held at zero. After sufficient time has elapsed for the set to reach approximately synchronous speed, a reactor short-circuiting breaker is closed connecting the a-c machine directly to the bus. This operation is followed by application of field energy, and the motor-generator set then pulls into synchronism and is ready to assume the load required for starting the variable-speed unit.

Master Speed-Control Rheostat

Because of the necessity for simultaneous control of all d-c-machine fields when initiating speed changes, it was necessary to combine all field rheostats in a motor-driven master speed-control assembly. This master rheostat is comprised not only of rheostats for exciter field control, but rheostats for recalibrating the Silverstat constant current regulators used in the fields of the d-c machines of the main auxiliary sets. In order to assure correct commutation on the d-c machines of the variable-speed set at all loads, shunt rheostats connected across those commutating fields are included in the master assembly. Also, this assembly contains a recalibrating rheostat for the electronic speed regulator, as well as one for controlling the field current to the driving motor of the master speed-control rheostat. This latter rheostat is used to provide for slow operation of the entire assembly when the variable-speed set or main motor is being accelerated, or decelerated, thereby assuring a slow and uniform change in power on the system.

Starting of Variable-Speed Motor-Generator Set

The variable-speed motor-generator set consists of a 38,000-horsepower synchronous machine and two 4,000-horse-

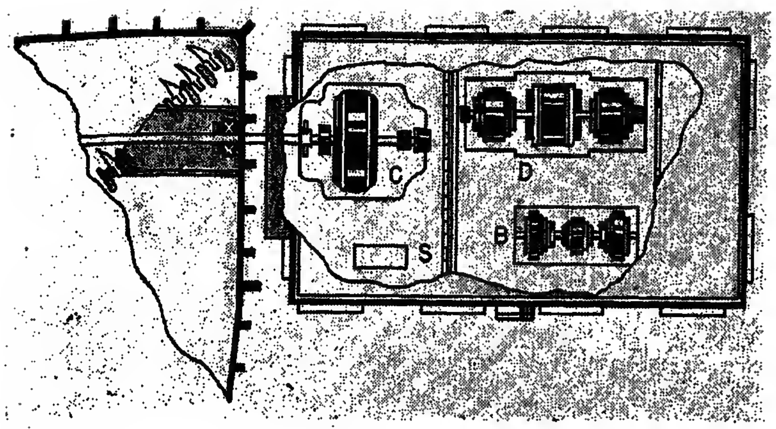

Figure 2. Automatic-control switchboard "S", main motor "C", variable-speed set "D", and constant-speed set "B"

power 750-volt d-c ma chines. The a-c machine is designed for a stator current of approximately 5,000 amperes at 5.5 cycles frequency when operating at approximately 48 rpm. This machine will also operate at a stator voltage of 4,800 volts at 60 cycles frequency and when rotating at 514 rpm. During the starting period the a-c machine operates as a synchronous generator supplying exciting current to the windings of the 40,000-horsepower main-motor rotor to which it 's connected. When the main motor is in service, the a-c machine of the variable-speed set functions as a synchronous motor driven by the power generated in the rotor of the main motor—due to the slip frequency when the motor is rotating at other than synchronous speed. When the variable-speed set is being started, the d-c machines act as motors driven by energy from the d-c machines on the constant-speed set. After the main motor is in operation, these same d-c machines function as generators, driven mechanically by the a-c machine, and supply power to drive the constant-speed motor-generator set which feeds power into the a-c system. Had the conventional means of speed control been used, this power would have been dissipated as heat and been lost.

During the starting operation of the variable-speed set, the master speed-control rheostat is under control of a balanced torque-type speed matcher. The elements of the speed matcher are connected to potential transformers on either side of the open contacts of the main-motor primary breaker. Initially with the variable-speed set at rest, there is no voltage on the stator or primary terminals of the main motor, and the speed-matcher element connected to the bus side of the breaker operates to close a contact to cause the master speed-control rheostat to operate. The rheostat will function to permit excitation of the fields of the d-c machines of the constant-speed set, and those machines will deliver energy to the d-c machines on the variable-speed set. As this set begins to rotate, the a-c machine will generate a voltage and frequency proportional to the speed. An equivalent voltage at equal frequency will appear on the stator terminals of the main motor, due to the transformer action of the motor windings. So long as the frequency of the voltage on the motor terminals is below that of the voltage on the bus, the speed matcher, operating through the speed-control rheostat, will cause the variable-speed set to accelerate. Acceleration is accomplished first, by increasing the field strength on the d-c machines of the constant-speed set to a maximum and, finally, by decreasing the field current in the d-c machines of the variable-speed set until synchronous speed is reached.

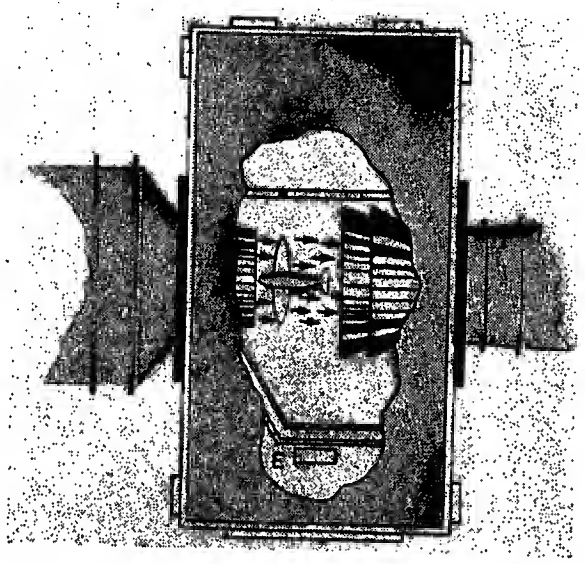

Figure 3. Remote-control desk "E"

Connection of Main, 40,000-Horsepower Motor to Bus

In order that power drawn from the power-supply system may be a minimum when the main motor is connected to the bus, the voltage on the stator windings is synchronized with the bus voltage before the oil circuit breaker is closed. This synchronizing operation is accomplished by means of an electronic-type automatic synchronizer operating in conjunction with the speed matcher and a voltage-balancing relay. At the instant that synchronism is accomplished, the oil circuit breaker is closed automatically.

All operations of the speed matcher, synchronizer, and voltage-balancing relay cease with closing of the main-motor breaker, and these devices are automatically removed from the circuit. However, a power-factor regulator takes over control of the excitation of the a-c machine of the variable-speed set, and through operation of a motor-operated shunt field rheostat functions to maintain practically unit power factor during the time the main motor is connected to the bus. Except for power-factor control the automatic equipment performs no further operations until the indication is given manually to start the main motor. Both auxiliary motor-generator sets continue to rotate at synchronous speed, since no device is yet in operation to change the position of the master speed-control rheostat, and the main motor remains at rest while the frequency of the rotor voltage is in synchronism with that applied to the stator.

Starting of Main Motor

Normally, control of the main motor speed is the duty of the operator in the test chamber, and for this reason, a speed-control dial, Figure 4, equipped with contacts and a synchro-tie motor, is mounted on the test-chamber control desk. A similar dial is located on the main switchboard, but it may be assumed that speed control from that point will be an emergency operation in the event that a fault occurs in the control cable between the power building and the test chamber. Control assignment switches are located beside each control dial for the purpose of assigning control to either, but not both, locations. Assignment of the point of control is accomplished by both assignment switches being in agreement, and, after once being assigned, cannot be changed by either one of the operators

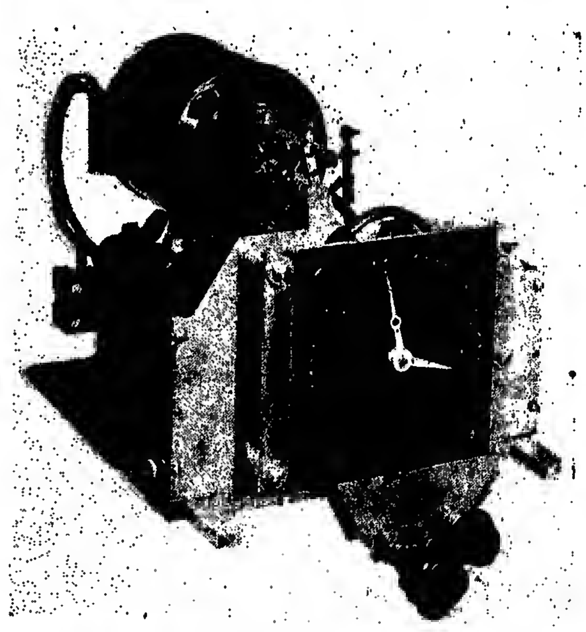

Figure 4. Speed-control dial, contact mechanism, and Synchro-tie

changing the position of his switch. A set of indicating lamp signals, coupled with the assignment switches, indicate the point to which the control has been assigned, and also indicate when the assignment switches are not in agreement.

With the main motor connected to the bus, but at rest, the operator to whom control is assigned may cause the motor to start and assume a certain definite speed by merely turning the knob on the control dial until the pointer reaches the desired speed position. It is well to note that the automatic control is provided with a position indicating relay, so that if the speed-control dial is not at the zero speed position when the main motor is connected to the bus, it will be necessary for the operator to return the pointer to zero and then to the desired speed setting before the motor will start. This insures that the motor will remain at reset after being connected to the bus during the starting operation, even though the control dial is at other than the zero speed position. Movement of the pointer off the "zero" speed position will cause the starting of rotor-lift oil pumps which will raise the main-motor rotor off the bearings, and when this is accomplished, the speed control equipment will operate to start the motor.

Acceleration of the main motor is accomplished by gradually slowing down the variable-speed set by first strengthening the field of the d-c machines on that set, and, as the speed decreases, by weakening the fields of the d-c machines on the constant-speed set. These field changes are accomplished by means of the master speed-control rheostat. This rheostat is equipped with a synchro-tie motor which is coupled electrically to a similar motor on the speed-control dial mechanism. When rheostat and dial mechanism are in the same relative position, with respect to main-motor speed setting, contacts on the dial mechanism are closed, short-circuiting the operating coils of the polarized "raise–lower" relay which is a part of the speed-control apparatus. Moving the dial mechanism to some fixed speed position opens these contacts, and the polarized control relay operates to cause the master rheostat to operate in a direction which will increase or decrease the main-motor speed, depending upon which way the dial pointer is turned. As the rheostat moves to accomplish the desired speed change, the synchro-tie moves a contact on the dial mechanism. When the rheostat reaches the position which will cause the motor to operate at the new speed setting, the control contacts will again close, and the rheostat will stop.

Control of Motor Speed

After the master speed-control rheostat comes to rest, the control for constant speed of the main motor is taken over by an electronic speed regulator which receives control energy from a pilot generator geared to the motor shaft. This speed regulator is recalibrated for any new speed setting by means of a rheostat on the master speed-control rheostat assembly. The regulator energizes the field of a small 1.5 kw speed-control exciter which supplies energy to field windings on the constant-speed machine. By increasing or decreasing the shunt field strength of this machine, the speed of the main motor is held constant by varying the torque through control of the power taken from the rotor and fed back into the a-c system.

By varying the speed of the speed-control rheostat automatically, smooth acceleration and deceleration of the main motor is possible. Also, by this means, the amount of power drawn from the bus during acceleration may be held to a steadily increasing value not exceeding a fixed increase per minute at any point on the speed range between 0 and 295 rpm. When the desired speed is reached, the electronic regulator maintains that speed constant within a range of 0.5 per cent for speeds from 37.5 rpm to 150 rpm and 0.3 per cent between 150 and 295 rpm.

Stopping of Main Motor and Motor-Generator Sets

The normal method for stopping the main motor and auxiliaries is first to reduce the main-motor speed to zero, then trip the motor breaker by turning the "start–stop" control switch to the "stop" position. Tripping of this breaker will disconnect the motor from the bus, and the automatic control will operate to decelerate the variable-speed set and cause it to come to rest. When this set is at rest, the high-voltage breaker for the power supply to the constant speed a-c machine will be tripped, and all automatic equipment will assume a normally de-energized position in readiness to again start the units at the will of the operator.

Emergency Quick Stopping

Means is provided for rapid deceleration of the main motor in case of emergency and, under such conditions, the motor is decelerated at the most rapid possible rate permitted by the power company. Rapid deceleration will cause power to be fed into the power company's system by regeneration through the main auxiliary motor-generator sets. Means is also provided for emergency shutdown and disconnection of all units from the bus should the necessity arise. Under this condition, all high-voltage and field circuit breakers are tripped simultaneously, and the main motor and motor-generator sets drift to standstill with friction and windage losses being the only decelerating forces.

Protective Devices

A complete complement of protective relays is provided with the automatic control. Those devices which prevent starting or operate an annunciator and sound an alarm are as follows:

1. Failure of bearing oil flow.
2. Failure of ventilation air.
3. Low lubricating oil pressure.
4. Low a-c voltage.

Those devices which merely annunciate and sound an alarm are:

1. High machine winding temperature; all machines.
2. High lubricating oil temperature.
3. Low lubricating oil temperature.
4. High bearing temperature.
5. Basement air temperature.
6. Low lubricating oil level.
7. Ground on auxiliary power circuits.

Devices which operate a lockout relay, drop an annunciator, sound an alarm, and cause all machines to be immediately removed from service are:

1. Overspeeding of either main auxiliary motor-generator set.
2. Unbalanced phase current on constant-speed a-c machine or main motor.
3. Differential protection on constant speed a-c machine or main motor.
4. A-c overcurrent in constant speed a-c machine or main motor.
5. Low a-c voltage on the bus.
6. Failure of unit to complete automatic starting sequence.
7. Overcurrent on d-c machines of main auxiliaries.
8. Short circuit on d-c machines of main auxiliaries.
9. Manual operation of emergency stopping switch.

The more serious of these faults, as indicated, cause immediate disconnection of the units from the bus while others merely sound an alarm and warn the operator that continued operation is undesirable, at which time provisions can be made to complete the test in as short a time as

Electrical Features of Design and Operation of the Plantation Pipe Line

M. A. HYDE
ASSOCIATE AIEE

H. B. BRITTON
NONMEMBER AIEE

PLANTATION Pipe Line Company's new 1,254-mile pipe line system is the largest ever built for the handling of refined petroleum products and is the largest all-electric-powered pipe line in existence. First full-length delivery was made early in February 1942, and immediately the line became an important factor in the transportation of gasoline and fuel oils to a large area in the southeastern states. Compared to the usual pipe line, this system operates under highly exacting conditions, and in its design the electrical and associated control features are of prime importance. The major electrification problems were:

1. To design for economical future increase in line capacity.

2. To provide flexibility in operation to meet varied schedule requirements.

3. To co-ordinate pumps, motors, and control, so as to accomplish the starting of units reliably and with reasonable demand on the station power service.

4. To design stations for safe handling of petroleum products.

5. To develop a station control system, co-ordinating the electric and hydraulic-control devices and meeting the requirements of single-attendant operation.

Paper 42-143, recommended by the AIEE committee on industrial power applications for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 13, 1942; made available for printing June 1, 1942.

M. A. Hyde is industry engineer of the petroleum and chemical section, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa. H. B. Britton is chief engineer of the Plantation Pipe Line Company, Atlanta, Ga.

The authors wish to acknowledge the collaboration of R. A. Rockwell, engineer, Mason Neilan Regulator Company, and of A. Hollander, consulting engineer, Byron Jackson Company, in the development of the hydraulic control system discussed in a portion of this paper.

General Conditions of Operation

The statements made in this report regarding the capacities, pressures, and horsepowers, both for present operation and future installation possibilities, do not necessarily represent actual conditions, but do indicate the general principles involved.

The system comprises an unloading dock at the supply terminal with a short line of four parallel 12-inch pipes to a storage tank farm and the initial station of the pipe line proper, a section of 12-inch line, followed by a section of 10-inch line extending to the delivery terminal. Four branch lines serve areas to the north and south of the main line. The tankage at the supply terminal main line station is used to store incoming shipments, and to make up pipe-line shipments (known as tenders) according to the system schedule. Smaller storage facilities are located at the branch line origins.

Approximately 30 delivery terminals are situated at various points along the system, each with facilities for handling several products. The handling of multiple products to 30 delivery points creates a scheduling and dispatching problem probably far more complex than on any existing line.

The capacity of the line as initially equipped is 60,000 barrels per day of gasoline through the 12-inch section and 42,000 barrels per day through the 10-inch section. This requires two 600-horsepower motor-driven main-line pumps for each of the seven stations on the 12-inch line, and two 450-horsepower units in each of the seven stations on the 10-inch line. Each of three branch lines is served by a single 150-horsepower unit. A 450-horsepower unit is required at the origin of the fourth branch line, plus an additional booster station requiring a single 450-horsepower unit. The unloading station at the supply terminal dock contains five 600-horsepower units, providing ample capacity for rapidly unloading two tankers simultaneously. The initial mainline station at the supply terminal tank farm contains a complete spare pump unit to insure the availability of two units at all times. The system comprises 16 stations with a total of 39 centrifugal pumping units exclusive of tankage pumps and auxiliary pumps.

Provisions for Future Increase in Capacity

The present installation is designed as a long-term project to cover the commer-

---

possible. All of the above protective features may be incorporated in the control of different types of machines but, never before, have all been included in the protection of a single assembly of machines.

Switchgear

The high-voltage metal-clad switchgear is equipped with lift-type oil circuit breakers which may be easily removed for inspection and service. Low-voltage metal-enclosed switchgear makes use of drawout-type air circuit breakers of suitable interrupting capacity for the circuits involved. The control switchboard is of the duplex type with meters and control switches on the front panels and all automatic and protective relays on the rear panels. Meters are semiflush, and all relays are semiflush of the plug-in type, equipped with stab contacts which permit easy removal from the panel for inspection and calibration. The entire assembly is easily accessible for maintenance and service, and all parts are of most advanced design with formed steel switchboard panels assembled in a complete self-supporting structure.

Conclusion

The automatic control provides reliable means, by use of proved apparatus, for performing all of the necessary starting, stopping, speed control, and protective functions for equipment of the type and size employed. The various switchgear assemblies are compact and well adapted to the service.

Many new switching problems were encountered in designing the complete control, and their solution opens up new fields of application to other apparatus. In addition, different types of standard equipment were employed to provide a complete and modern design which can be easily duplicated and one in which spare or renewal parts are readily obtainable.

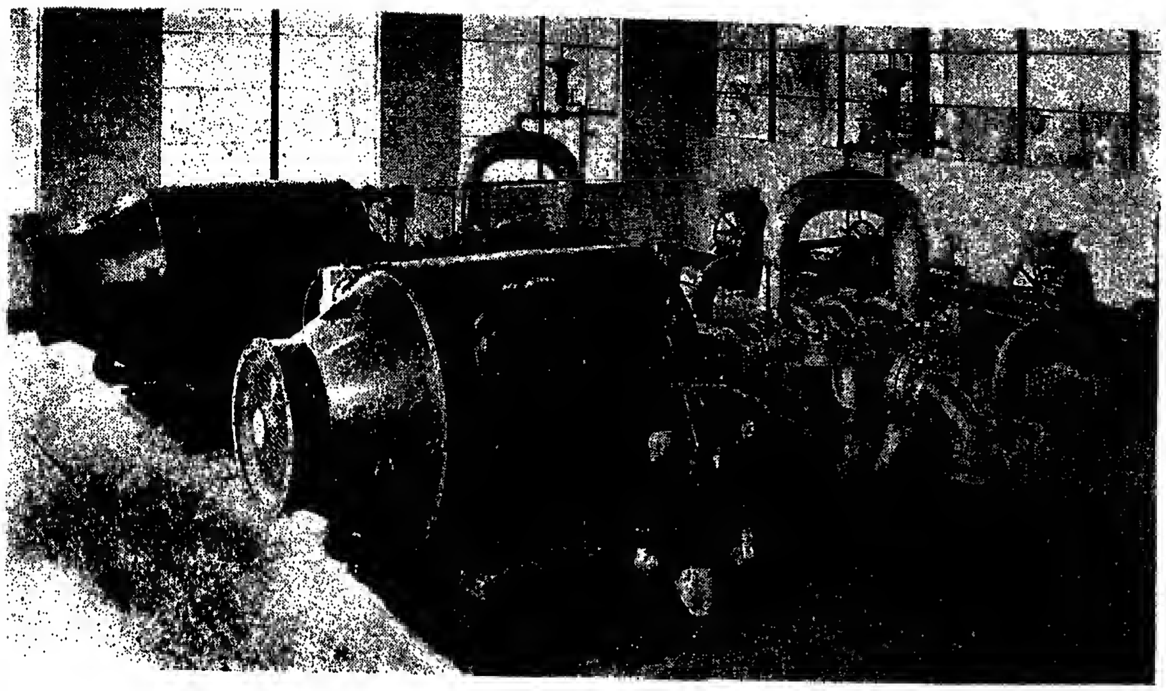

Figure 1. Pump room of typical main-line station on Plantation Pipe Line system

cial needs of the territory served and to operate economically on that basis. At the same time provision is made for possible future operation at increased capacity.

The maximum pressure at which the line will be operated is approximately 900 pounds per square inch in the 12-inch section and 975 pounds per square inch in the remaining sections. These values are determined by the allowable unit stress in the pipe walls, which in turn is a matter of economics in the design of the line. It is necessary in centrifugal pump operation that positive suction pressure be maintained at each pump, and if the minimum allowable suction pressure at the initial pump is established as, say, 40 pounds per square inch, then with a maximum allowable station discharge pressure of 900 pounds per square inch, the pressure increment introduced into the line at any station is 860 pounds per square inch, plus the pressure loss through the station piping. The stations are so spaced, then, that the pressure drop between stations due to fluid friction at rated line throughput, plus the static pressure differential totals approximately 860 pounds per square inch. Between the discharge of one station and the suction of the next, with uniform pipe, there is a uniform decrease in the component of total pressure due to line friction, this pressure drop being directly proportional to the distance from the upstream station. Referring to Figure 2, which represents a level section of 12-inch line, *SA* represents the suction pressure at initial station *A*, *DA* the discharge pressure at this station, and line *DA-SB* the pressure gradient along some 60 miles of line from station *A* to station *B*, for a flow rate of 60,000 barrels of gasoline per day. This is the flow that can be carried by the line under the conditions prescribed. If station *B* is at an elevation higher than station *A*, the distance between stations must be decreased by an amount that will reduce the friction drop sufficiently to provide the pressure differential necessary to balance the positive static head, and if station *B* is lower than station *A*, the distance between them will be increased to compensate for the negative static head.

To increase the capacity of the line without exceeding the maximum allowable working pressure, a second series of intermediate pressure increments may be added, one of which is represented by intermediate station *M*. If this station is placed at the hydraulic mid-point between stations *A* and *B*, the same pressure increment may be introduced at station *M* as at station *A*. The flow rate then will increase to a value such that the pressure drop between stations *M* and *B* will be the same as existed between stations *A* and *B* before adding the pressure increment at *M*. For the line in question this flow rate for gasoline is calculated at approximately 90,000 barrels per day.

When this higher flow rate is established, obviously the horsepower input per station must be increased in both the initial and added stations. Whereas the initial stations are equipped with two 600-horsepower units for 60,000 barrels per day throughput, operation at 90,000 barrels per day will require two 900-horsepower units in all stations.

All stations on the main line are arranged for future change-over to higher capacity by initially installing pumps of such design that new impellers can be readily substituted, and motors designed for ultimate operation at the increased horsepower. These motors are of the totally enclosed fan-cooled type, and in order to secure efficient operation of the 12-inch line motors at 600 horsepower, they are equipped initially with a ventilating fan designed to deliver only the amount of ventilating air required by the motor operating at this capacity; when the change-over to 900 horsepower is made, no electrical or mechanical changes are involved except replacement of this one fan on the front shaft extension. Similarly, on the 10-inch section of the line, motors of ultimate 600 horsepower capacity are installed with initial fan capacity for operation at 450 horsepower. The motor-control and power-supply equipment in all the main-line booster stations are designed for operation at the ultimate ratings.

Operating Flexibility

All motors 75 horsepower and above are 2,300 volt. All motors above 150 horsepower are 3,600 rpm. All motors 450 horsepower and above are mechanically interchangeable, simplifying the problem of spare equipment, because a spare motor of 600/900-horsepower design can be installed on any line pump unit in the system except the 150-horsepower branch-line units. This feature also provides maximum utility of the equipment under unpredictable future alterations, due to changed operating conditions.

While the line is designed for a certain rated capacity, consideration must be given also to its flexible and economical operation at reduced throughputs. Contrary to practice on lines handling one uniform type of tender, the throughput of this line must be held above a certain minimum rate, to prevent excessive contamination between adjoining tenders

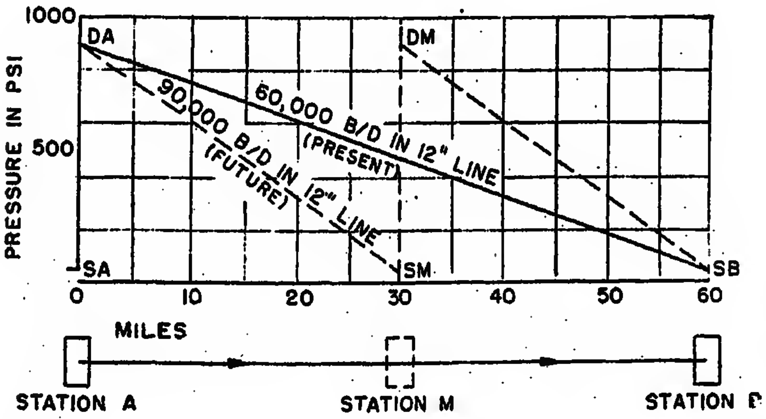

Figure 2. Pipe-line pressure gradients for flows of 60,000 barrels per day and 90,000 barrels per day

passing through the line. Between this rate and the full capacity of the line it is desirable, from the standpoint of power consumption, to operate at a rate as low as will suffice to meet the transportation schedules.

Motors of the constant-speed type are preferred because of their simplicity and their adaptability to construction suitable for hazardous atmospheres. Installation of two units per station, operated at constant speed, with the pumps connected in series, provides the required degree of flexibility. With this arrangement, and with all stations along the line having piping installed to permit by-passing any unused unit or station, changes in throughput in steps of a few per cent can be made by operating 2, 1, or 0 units in properly selected stations.

Motor-Starting Conditions

With the station locations determined solely by the hydraulics of the line and, therefore, without regard to existing power facilities, it was necessary to consider carefully the method of starting the units, from the standpoint of voltage conditions on the electric service.

Most stations contain two main pumps comprising 95 per cent of the station load. From the standpoint of starting conditions the 12-inch line motors are 900 horsepower, and the 10-inch line motors 600 horsepower. The motors are of low-starting torque design in order to minimize rotor resistance and attain high operating efficiency, important in view of the high load factor at which the system will operate. To minimize current peaks during starting, motor starters for all units 450 horsepower and above are of the autotransformer type, with closed-circuit transition. During the brief interval when the motor is transferred to full voltage with its terminals still connected to the starting tap, a reactor is inserted between the autotransformer tap and the motor to limit the current in the autotransformer circuit. By suitable control this reactor also provides an additional reduced-voltage starting step when power is first applied to the motor.

During starting, the discharge valve of the centrifugal pump is closed which minimizes the required motor torque. After the unit is up to speed the discharge valve is opened slowly so that the change in direction of flow through the station piping will be gradual, for well-known hydraulic reasons. Speed-torque curves for the pump with closed discharge, and for the motor with various applied voltages, are shown in Figure 3. These curves apply to the 12-inch line pumps when equipped with impellers for 900-horsepower operation, representing the most difficult conditions that must be met. The speed-torque requirements of the pumps are shown as a band curve, the upper limit applying to the pump when operating on fuel oil of specific gravity 0.83 and the lower limit for gasoline of 0.73 specific gravity.

Motor speed-torque curves and line current-torque curves are shown for full voltage, also for 80 per cent voltage applied by autotransformer. Also shown are speed-current curves for three-step starting with the reactor initially connected between the autotransformer tap and the motor. With the reactor in circuit approximately 85 per cent of the tap voltage appears at the motor terminals during the first portion of the initial starting step.

During starting, the voltage actually applied to the motor terminals should be of sufficient value to enable the motor to develop the torque necessary to reliably accelerate the unit to a speed above pull-out on the starting tap; when this speed is exceeded, the current decreases rapidly, and transfer to full voltage can be made on a low-current portion of the motor current-torque curve. Acceleration occurs directly as the excess of motor torque beyond pump input torque and inversely as the total inertia of the unit. Starting must be accomplished within a reasonable time, a limit in the order of 30 seconds being established as desirable by considerations of heating of the fluid within the pump casing. To perform the accelerating duty within this time limit it is found that the speed-torque curve of the motor when operating from the autotransformer tap should not fall below the curve corresponding to an applied voltage of about 1,630 volts. This means, when accelerating with the motor on tap giving a voltage of 80 per cent of line voltage, and with the reactor shunted, the voltage supply to high-voltage side of the starting autotransformer must be not less than:

1,630 volts ÷ 0.80 = 2,038 volts, or 88.6 per cent of normal 2,300 volts

Using a starting tap giving 85 per cent of line voltage, the voltage supply to the starting equipment must be not less than:

1,630 volts ÷ 0.85 = 1,918 volts or 83.4 per cent of normal 2,300 volts

To accommodate both present and future pump requirements, as well as variations in voltage conditions encountered at the several stations, the starters for the 600/900-horsepower motors were equipped with autotransformers having taps to deliver, under starting load, 80, 85, or 90 per cent of line voltage. In the first portion of the initial starting step, when the reactor is inserted into the tap circuit, the voltage at the motor terminals for these three tap connections is respec-

tively, about 68, 72, or 76 per cent of normal line voltage.

Station Design as Affected by Hazardous Nature of Tenders

Safety problems introduced by the handling of petroleum hydrocarbon products of volatile and inflammable nature required special consideration throughout the design of the stations.

The areas subject to the occurrence of hazardous atmospheres (class *I*, group *D* as defined in the National Electrical Code) are the pump room and adjoining piping platform. The pump room contains the pumps with associated valves, hydraulic control devices, and piping. On the piping platform are situated the incoming and outgoing line piping and all necessary station and auxiliary piping with associated scraper traps, strainers, filters, valves, a sump tank with motor-driven pump for its service, and in many stations pressure-reducing valves and fluid meter and meter calibration facilities for delivery of product from the line to the distribution terminals.

The pump room is ventilated by a flow of incoming fresh air through glass-wool filters below the windows in the front wall of the station and directly opposite the motor air intakes. This air is forced through the motors by the motor blowers and discharged toward the rear wall of the pump room. In the rear wall just below the ceiling are mounted one or more motor-driven exhaust fans which discharge the air from the pump room and onto the piping platform. The piping platform is open on three sides with a flat roof for weather shelter, a construction affording maximum natural ventilation. The piping platform and pump room are at ground level, and in their design trenches and other depressions favorable to accumulating hydrocarbon vapors were avoided.

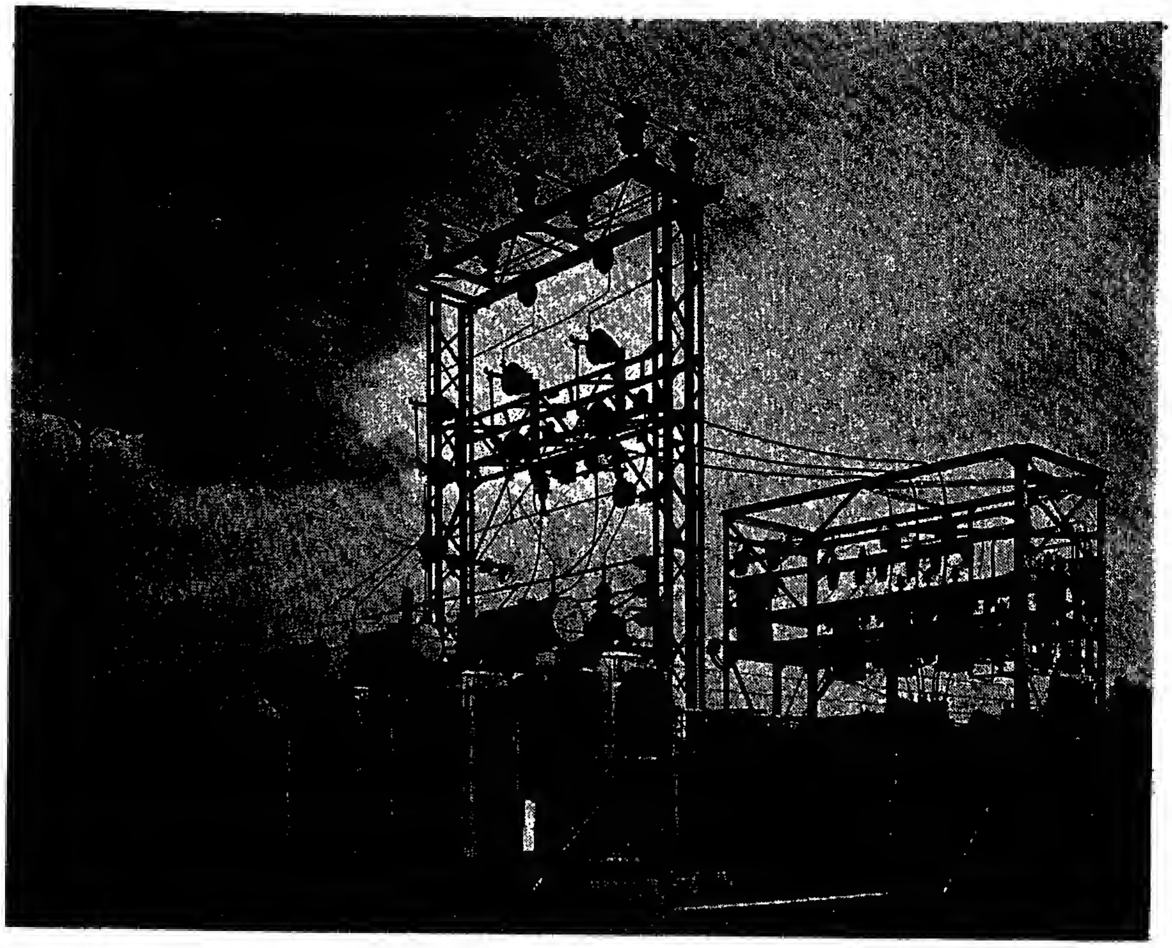

Figure 5. Outdoor substation for pumping station serving main and two branch lines

44- to 2.3-kv transformer bank consists of three 833-kva units. At right is the outdoor breaker controlling the 2,300-volt underground circuit to the pumping station bus. Structure at right mounts transformers for lighting, outside auxiliaries, and metering, as well as low-voltage breakers for lighting and outside auxiliary circuits

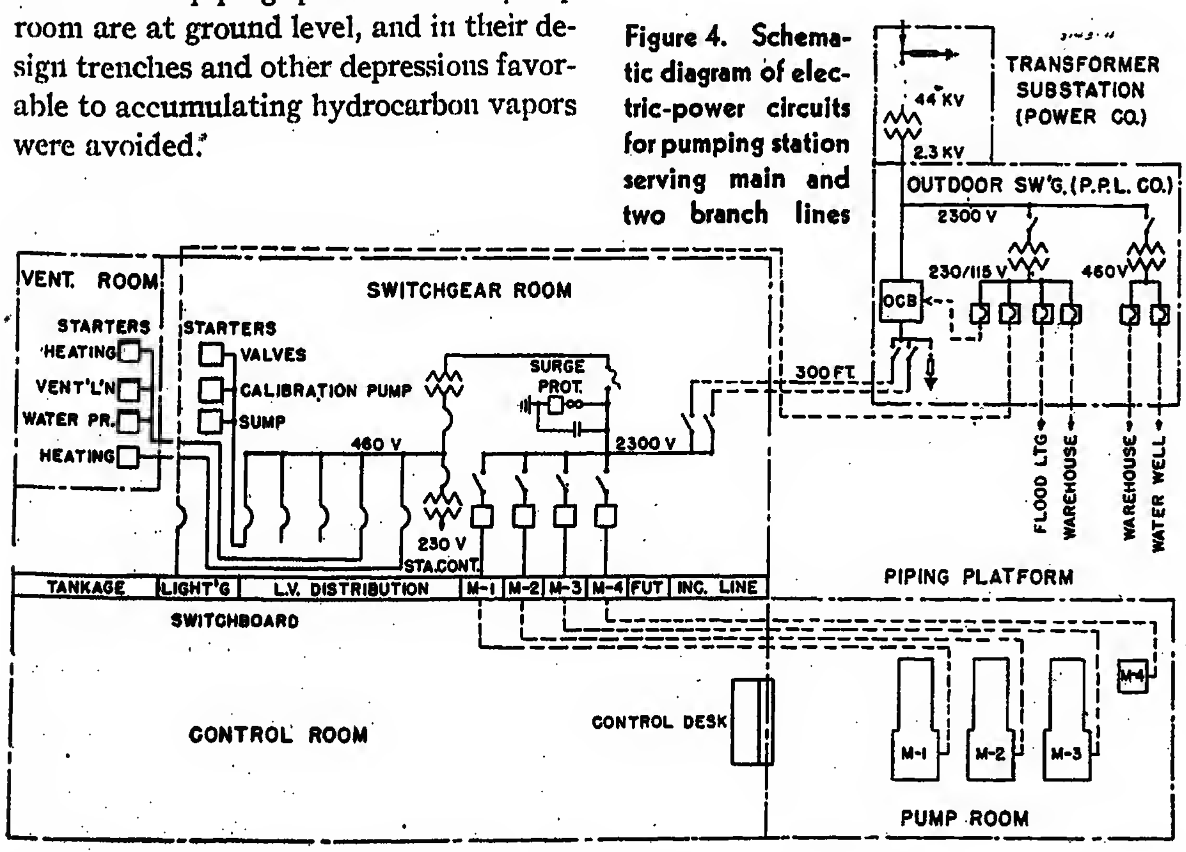
All electric motors, control, signal devices, motor-operated valves, lighting fixtures, and wiring installation in this area are specifically designed for service in class *I* group *D* hazardous atmospheres.

The 600/900-horsepower motors on the 12-inch line pumps are believed to be the largest, explosion-resisting motors ever built. Attainment of this rating in a relatively compact construction—an important consideration in explosion-resisting design—is accomplished by the circulation of large volumes of cooling air through the motor frame and by the use of class *B* insulation with the motor rating based on 75 degrees centigrade rise. All main-line pump motors have sleeve bearings, oil-ring lubricated and cooled by air blast from the motor ventilating fan. These bearings require no oil circulating system; consequently each motor is an entirely self-contained unit without external accessories.

Control apparatus is of dead-front construction. With appropriate measures taken for safety, experience in products' pipe-line operation indicates that provision of a nonhazardous location and installation therein of switchgear and control apparatus of open design are preferable to the use of special forms of switchgear and control in explosion-resisting or oil-immersed enclosures designed for class *I* group *D* location. This is true from both cost and operating standpoints. The importance of accessibility hardly can be overemphasized; since the several stations on a pipe line operate in series and interdependently, it is imperative that during operation of the line any inspection and maintenance work on electrical equipment be performed without shutdown or in emergency with the very minimum of shutdown time.

Nonhazardous conditions are maintained in all parts of the pumping station

Figure 4. Schematic diagram of electric-power circuits for pumping station serving main and two branch lines



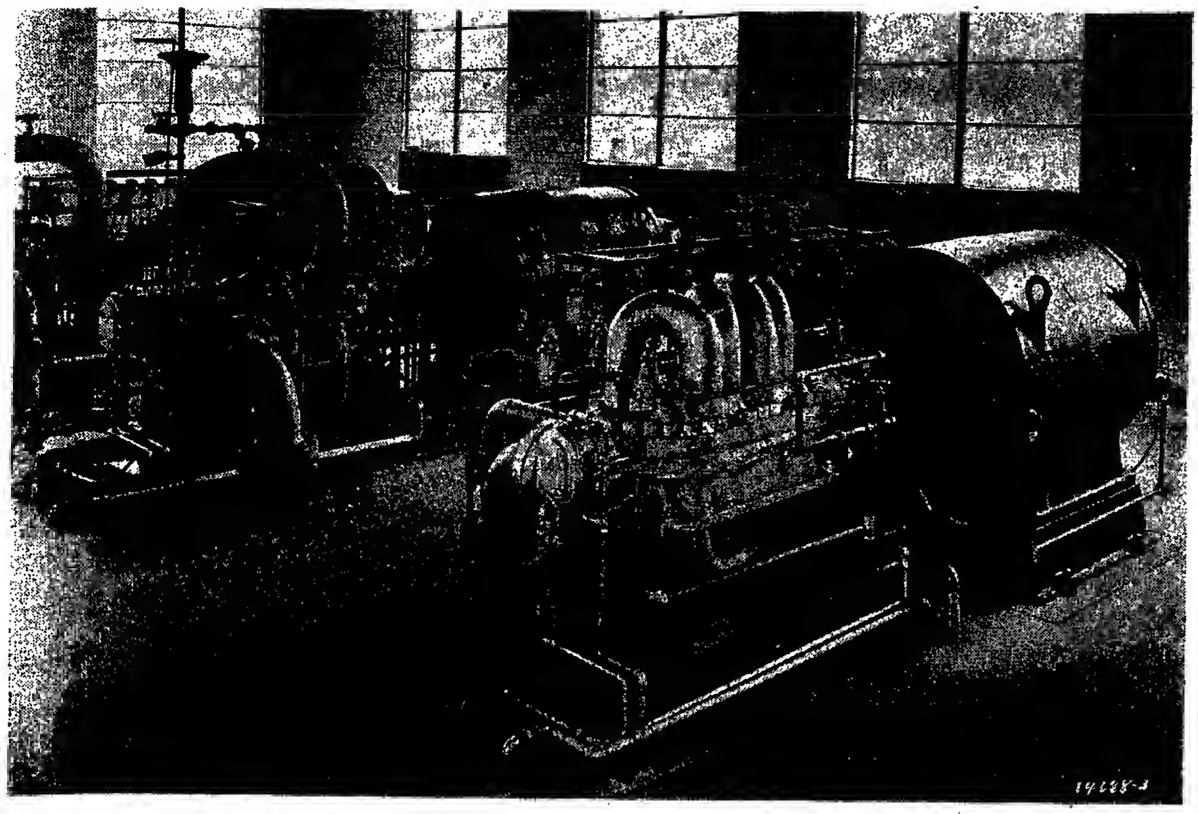


Figure 6. General view of pump room showing two main-line pumps (left) and branch-line pump (right) driven by 450/600-horsepower explosion-resisting motors

building, except the pump room and piping platform. The nonhazardous portion of the building, designated as the operating section, has a floor level about three feet higher than the pump-room floor and is completely separated by wall from the pump room and piping platform. No direct connection is provided between these areas, it being necessary to pass through outside entrances in going from one to the other. The atmosphere in the operating section is maintained in safe condition by outside air drawn into the building at the end opposite the pump room, maintained at a pressure a few inches above the outside air and above the atmosphere in the pump room. This insures that any air seepage through the wall, separating the operation section from the pump room or piping platform, will be in the direction to prevent entrance of hazardous atmosphere to the operating section.

The operating section of the station comprises a control room, switchgear room, ventilating and auxiliary room, lavatory, and in three of the stations a division superintendent's office.

The wall between the control room and the pump room consists of a vapor-tight, wire-glassed observation window. Into the center section of this window is sealed a vapor-tight steel gauge board, on which are mounted hydraulic recording and control devices and indicating pressure gauges as will be discussed later. These devices are gasketed to prevent passage of vapor through the mounting openings.

To provide for safely shutting down the station in case the control room should become hazardous due to an equipment failure, an explosion-resisting "emergency" pushbutton is mounted on the control desk contiguous to the gauge board. By pushing this button the attendant will trip the circuit breaker at the origin of the incoming power feeder.

This breaker, normally controlled from the incoming line panel in the station, is located at the transformer substation approximately 300 feet from the pumping station. From the outdoor breaker, an underground circuit runs to a 2,300-volt bus in the switchgear room, which in turn feeds the main pump starters as well as a 2,300-to-460-volt transformer bank serving all the station auxiliaries. Energy for the control circuits of the motor starters and for signal lights and alarms is furnished at 230 volts through a transformer from the station auxiliary supply. A single-phase transformer connected to the 2,300-volt service ahead of the station power breaker supplies station lighting and outdoor lighting at 115/230 volts through separate low-voltage outdoor breakers. At some of the stations there are loads outside the station proper, such as fire pumps, water well pumps, and warehouse, which must be operable even when the pumping station is shut down. To carry these loads, as well as the lighting load, a 2,300-volt bus is provided on the outdoor structure, connected to the power service ahead of the station power breaker. To this outdoor 2,300-volt bus are connected the station bus breaker, the lighting transformer, a 2,300-to-460-volt transformer bank for outside auxiliaries and a 2,300-volt fire pump circuit.

With this arrangement of circuits, shown schematically in Figure 4, the station operator can clear all power circuits within the station proper by opening the 2,300-volt outdoor circuit breaker. This he can do either from within the station or at the substation. At the same time he can leave the station lights and outside auxiliaries in operation if required, since these circuits are not affected by tripping the outdoor breaker.

Control System

A fundamental consideration in establishing the control system was that of station attendance; it was decided at the start that:

1. In the interest of safeguarding property, each station must have attendance at all times.

2. During the tour of duty the attendant may be at any part of the station property, subject to prompt arrival at the control room upon signal.

3. In the simple booster stations the at-

Figure 7. Control desk set into vaportight wire-glassed partition, through which the pump room is clearly visible

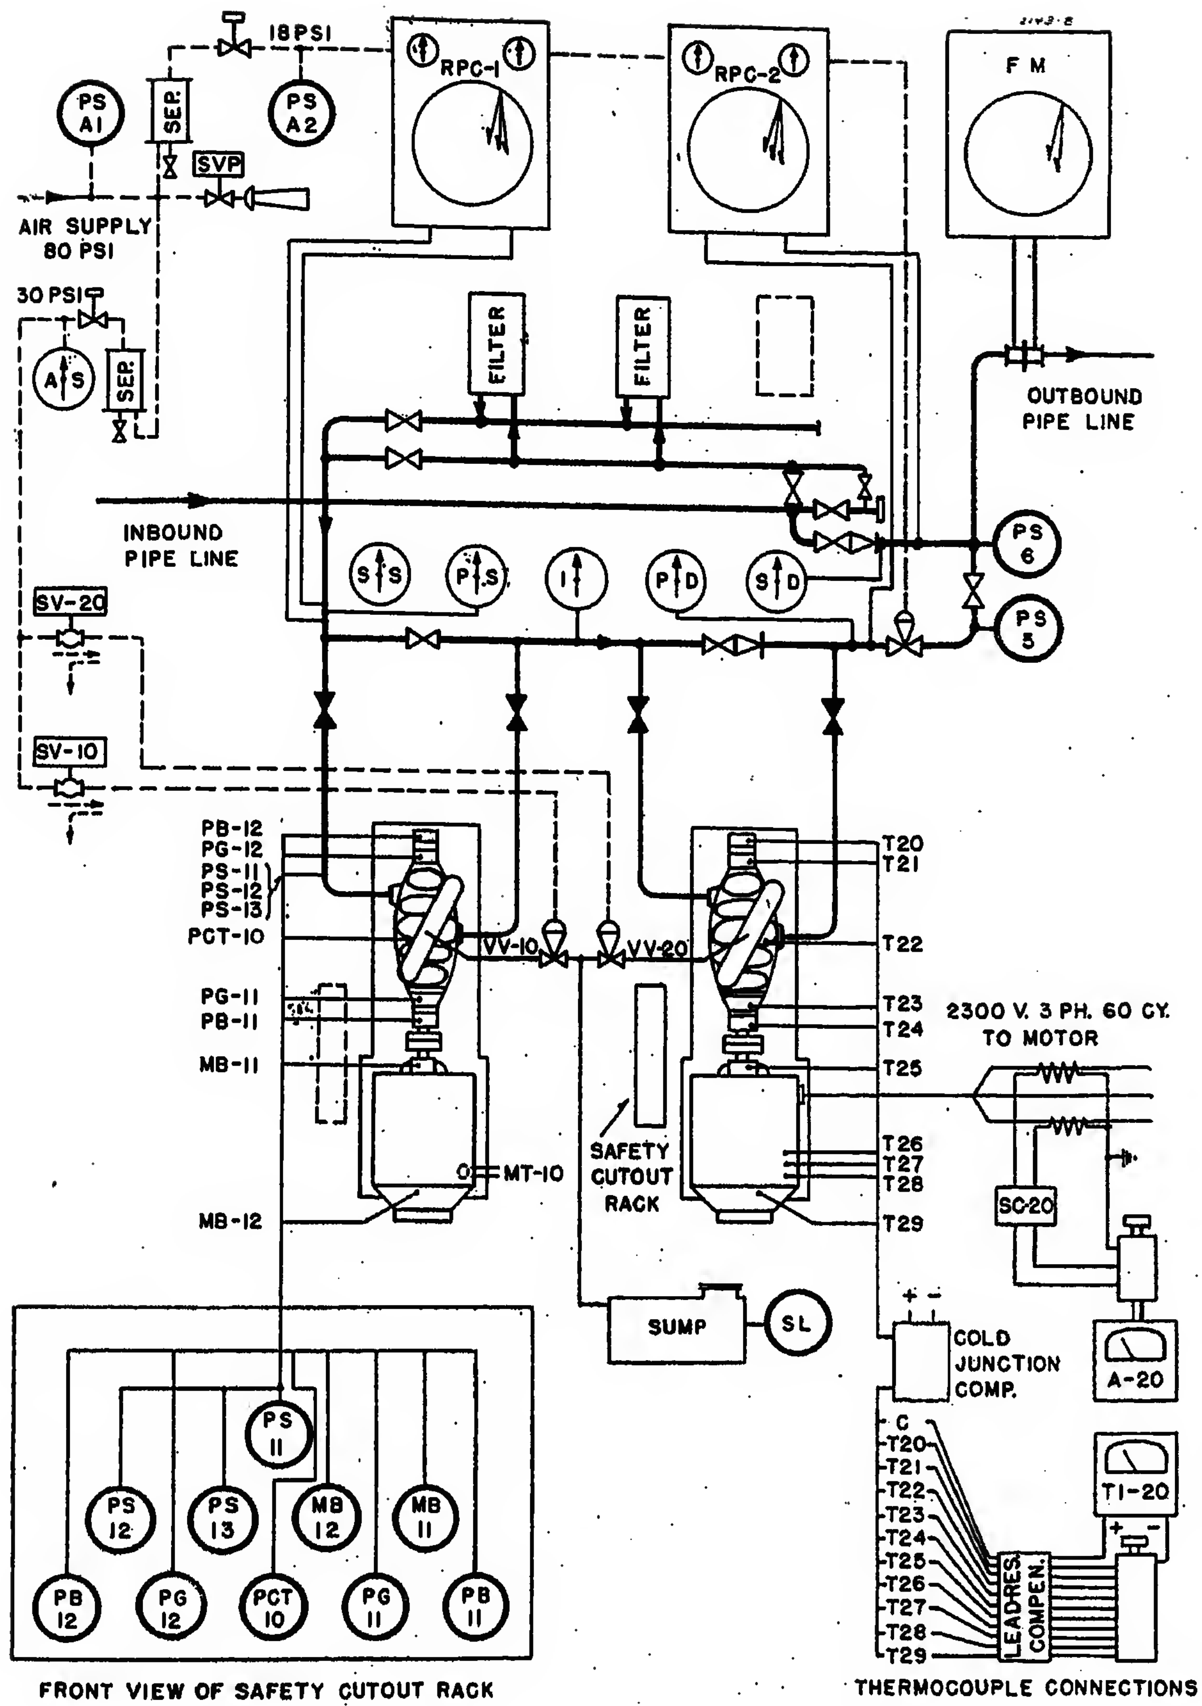

Figure 8. Schematic diagram of station control system for typical two-unit station

tendant will perform singly all operating duties incidental to starting, running, and stopping units, as required by the central dispatching office.

4. Maintenance work except of minor nature is to be handled by established maintenance personnel, progressing from station to station. In case of difficulty or failure in the operation of equipment, specialized repair personnel will be available on call to the superintendent of the division.

These operating conditions determine the following essential features of the system of control:

(*a*). Starting and normal stopping of the stations and of units within each station shall be controlled by the station attendant.

(*b*). Protective shutdown of units and stations must be instituted automatically when conditions arise that exceed predetermined limits of safe operation.

(*c*). In case of automatic protective shutdown, a signal must be given to inform the attendant that shutdown has occurred, and indication must be given of the specific protective function that caused shutdown.

(*d*). In the starting and stopping of main-line units, it is desirable to simplify the duties of the attendant by providing automatic operation in proper sequence for the valves, motor control, and pressure devices concerned. The operator, thus relieved from performing a routine of manual operations at different points in the station, can devote his attention to the over-all process and to the results obtained.

(*e*). For continuous operation of the line it is, of course, necessary to maintain pressure conditions within the limits predetermined for protective shutdown, and this should be accomplished by automatic means.

Design of Station Control

The control system developed to meet these requirements embodies the co-ordinated application of pressure, temperature, and electrical control and indicating devices.

Each pump unit normally is controlled from an individual "start–stop" push-button, the control system providing a predetermined sequence of operations. Considering a typical two-unit booster station, this control system provides automatic means for:

1. Venting the pump casings during shutdown to prevent building up of pressure within them by leakage past suction or discharge valves.

2. Permitting the starting of a unit only upon existence of a predetermined minimum suction pressure.

3. Operating in correct sequence a motor-driven suction valve and a motor-driven discharge valve for each unit.

4. Venting vapor from the pump casing and circulating liquid through the pump during starting.

5. Adjusting the station capacity to the line throughput while the station is on the line.

6. Limiting the minimum value of station suction pressure to a value safe for pump operation.

7. Limiting the maximum value of the station discharge pressure to a value safe from the standpoint of pipe-line stress.

8. Safety shutdown, sounding the station alarm and lighting an individual indicating light, in case of:

	See Figure 8 Symbol
Excessive duration of high motor starting current	*SC*-20

3 Motor-winding thermocouples	*T*-27,-28,-29

The gauge panel mounts a flowmeter (*FM*) for indicating and recording the rate of flow at or by the station, also two pressure controllers (*RPC*-1, *RPC*-2) whose function will be discussed below, and six gauges indicating pressure at the following points:

	See Figure 8 Symbol
Station suction	*SS*
Pump suction	*PS*
Interpump	*IP*
Pump discharge	*PD*
Station discharge	*SD*
Air supply to air operated vent valves	*AS*

Pump Venting

Each pump has a connection from the top of its casing through a vent valve to the station sump. The vent valve (*VV*-10, *VV*-20) is spring-opened, air-closed, the air supply being controlled by a three-way solenoid valve (*SV*-10, *SV*-20). This valve is so connected in the motor-control sequence that the vent valve is open while the pump unit is down and remains open during the starting cycle until the pump discharge valve is fully open, whereupon the solenoid valve is energized to close the vent valve. In a shutting-down cycle, when the pump discharge valve leaves its open position, the solenoid valve is de-energized to open the vent valve. At the conclusion of the shutting-down cycle both the discharge valve and the suction valve are closed, and flow through the pump-venting system ceases.

Station Pressure Control

The regulation of station pressure is accomplished by air-actuated instruments such that the station suction and discharge pressures can be automatically maintained at any predetermined values. The control valve which is actuated from these instruments is normally automatically controlled, but is equipped for manual operation in the event of air failure or interruption of electric service at the stations. All the stations operating in a continuous section of line are affected by any change in flow rate that may occur. There are many changes in flow rate throughout the entire system. These are occasioned by the existence of the large number of delivery points or terminals, which may be utilized for multiple deliveries or for single full-line capacity deliveries. The station pressure controls are so designed as to immediately adjust each station to these varying flow conditions and thereby maintain uninterrupted operation. The previously mentioned automatic shutdown features are co-ordinated with the regulating equipment, so as to permit operation of the control system over its full range, and only to prevent operation of one or two units in the station in case the pressures exceed pre-established limits.

Figure 9. Control desk, gauge board, teletype and telephone facilities, and panels for incoming line, motor starters, and low-voltage power distribution, in a typical two-unit station

Control Desk

Physically, the control for each station centers in a control desk in the control room, where also is situated the gauge board previously mentioned, the attendant's working desk, and a teletype operating over a circuit serving the system dispatcher's office and all pumping stations.

Red indicating lights on the control desk identify the functioning of each of the protective shutdown and alarm switches already mentioned. Amber and green indicating lights show respectively the open and closed positions of the motor-operated suction and discharge valves and of the principal manually operated valves in the station piping.

To clarify the function of each device the desk top bears a schematic layout of the principal piping for the particular station, and in this piping diagram the indicating lights, temperature indicator, ammeters, selector switches, and push-buttons are all mounted in appropriate position. An accompanying illustration shows how conveniently the control desk and gauge board in one of the stations serves as the central point for indication and control of all principal station functions.

Conclusion

As evident from this discussion, the electrification of the Plantation system was designed to meet the practical requirements of products-line operation. That it adequately serves these needs is indicated by operating experience with the system to date, which has verified all fundamental features of its design.

Protection of Pilot-Wire Circuits

E. L. HARDER
MEMBER AIEE

M. A. BOSTWICK
ASSOCIATE AIEE

THIS paper reviews the problem of protecting pilot-wire circuits, briefly discusses the sources of disturbing voltages, describes two types of neutralizing transformers, and illustrates how they are used to distribute the disturbing voltage most favorably throughout the pilot-wire circuit. The recent increase in use of high-speed pilot-wire relays for the protection of important power circuits has accentuated the need of better understanding of the pilot-wire protection problem. Therefore, a review of this general subject and a description of a new type of neutralizing transformer with mathematical formulas to determine its effectiveness, is considered timely.

Three principal objectives to be attained when applying pilot-wire protective apparatus are:

1. To assure correct operation of the protective relays or other apparatus at all times.
2. To protect operating personnel.
3. To protect the apparatus.

Pilot circuits for protective relaying must be operative at all times, especially at times of system disturbances. Thus, simple protective gaps which provide adequate protection for many other pilot services cannot be used to protect against voltages induced by the power-system currents, as this would render the circuit inoperative when most needed. Certain supervisory control and other functions are also required to be operative during power-system faults, and this discussion applies equally well to pilot circuits for these purposes. The principles and methods will also be found useful in applying protection to those telemetering and supervisory control circuits which are not required to be operative during power-system faults.

A pilot circuit may be exposed to disturbing voltages of several sorts, which will be discussed subsequently. Briefly, these are:

(*a*). Lightning and other surges.

(*b*). Induction from power lines.

(*c*). Elevation of station ground potential.

(*d*). Direct crosses with power circuits.

If these voltages are not to disrupt the proper operation of the circuit, they must be disposed of by some combination of the following measures.

(*a*). By insulating the circuit to stand them.

(*b*). By distributing them through design of the circuit impedances and grounds.

(*c*). By the use of gaps or arresters to prevent surge voltages from reaching excessive values.

(*d*). By drainage—dissipating the disturbing voltages as impedance drops in the circuits.

(*e*). By shielding the wires or so locating them that the disturbing voltages are lessened.

(*f*). By using insulating transformers or neutralizing transformers to take up longitudinal voltages as will be explained.

In many cases no specific protective measures are required. This is frequently the case when rubber-lead-covered control cable is used in relatively unexposed locations. However, a consideration of the magnitudes of disturbing voltages is worth-while in any case, to insure that the pilot circuit, through its insulation, arrangement, and protective features, provides adequately for the voltages to be encountered.

Pilot-wire circuits that are totally enclosed in a frequently grounded sheath are inherently provided with a high degree of protection against lightning. Circuits of this kind, that are not exposed to induction from transmission lines and that enter stations in which only small ground potentials can occur, require no special protective measures. The auxiliary equipment that will be discussed is needed only when calculation or measurements indicate voltages in excess of the normal insulation strength.

The general problem is very much as follows: Assume that lightning strikes the power line and causes a phase-to-ground fault at the far end of the line section that is protected with pilot-wire relays. Assume also that the pilot circuit is exposed to the effects of the same lightning stroke. Arresters on the pilot wires must operate to protect the relays and associated equipment. However, the arresters must immediately seal off and interrupt any power follow, so as to make the pilot circuit operable. The seal-off voltage of the arresters must be above the maximum voltage that can be impressed on them by induction in the pilot wires or by a combination of a rise in ground potential and induction which can be caused by the flow of transmission-line fault currents. If the arresters should fail to seal off, they would effectively short-circuit the pilot wires and block operation of the protective relays. Similarly, provision must be made to guard against the accidental operation of pilot-wire relays which may be caused by unsymmetrical operation of the arresters. This may be accomplished, for example, by connecting a low-voltage protector tube between the pilot wires, as shown in Figure 4 and by distributing fundamental frequency-disturbing voltages so

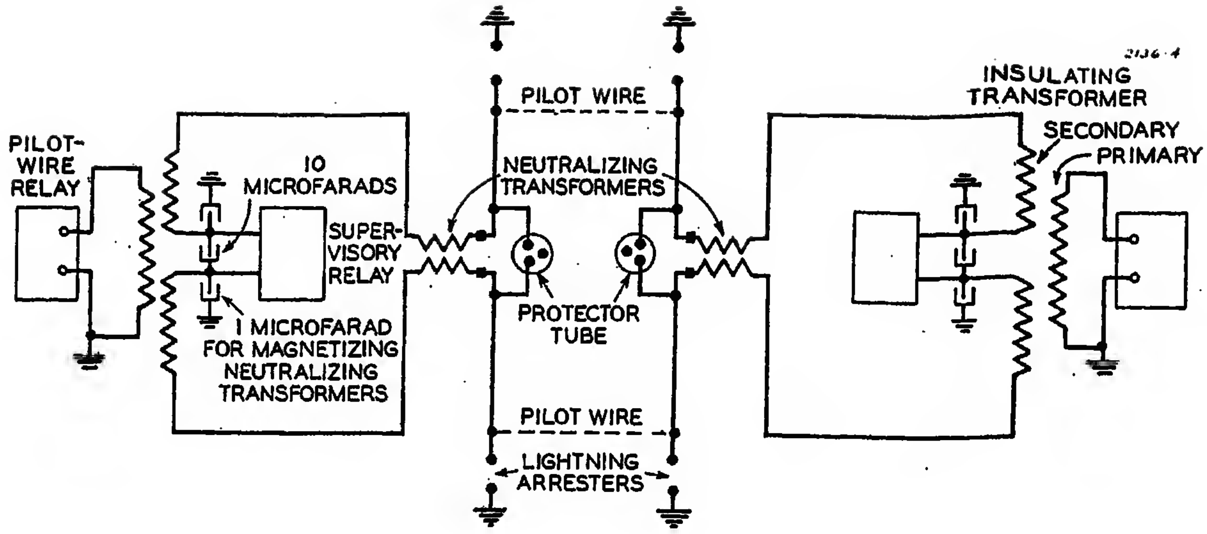

Figure 4. Protective apparatus

as to avoid operating the lightning arresters.

To aid in visualizing the manner in which these disturbing voltages may be impressed on the pilot-wire circuits by transmission line faults, consider the circuit that is illustrated in Figure 1. Inasmuch as these disturbances are most severe when one phase of the transmission line is grounded, only a single-phase system is drawn. As shown in Figure 1, assume that the faulted power system consists of a single-phase generator, a grounded transformer, a section of line, and equivalent ground-fault resistance. The pilot-wire circuit is spaced from the power-line conductor, a distance of S feet.

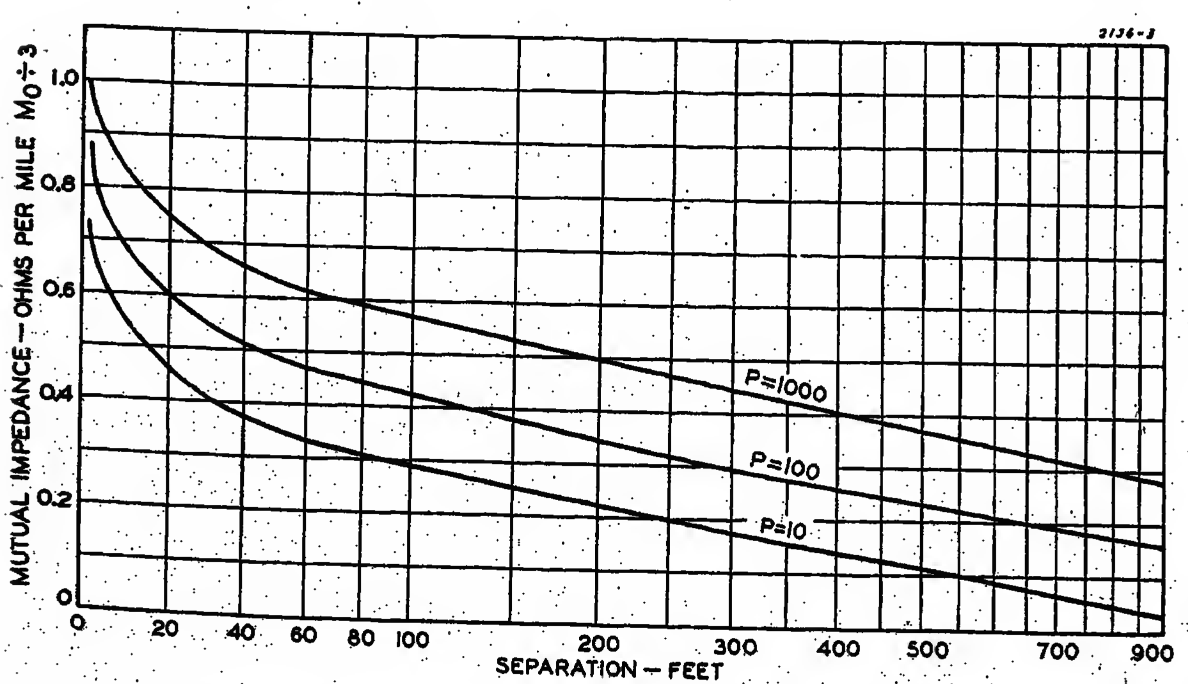
When the ground fault occurs, current will flow out through the transmission line and return through the ground. The generated voltage is used up in a series of voltage drops in the generator and transformer, line, ground-fault resistance, and the effective resistance that can be measured between the station ground bus and true ground. This resistance, indicated in Figures 1 and 2, varies from a fraction of an ohm in well-grounded stations to several ohms in stations that are not so well grounded. The value may be high or low, depending upon the earth resistivity in that vicinity. Ground potential rises of 1,000 to 3,000 volts are not uncommon, while values up to 15,000 volts are sometimes encountered.

The manner in which voltage is induced in the pilot-wire circuit is indicated in Figure 1. Fields of flux are set up by the flow of current in the transmission line and in the earth return. These fluxes link both pilot wires and induce voltages along the length of the exposed portion of the pilot-wire circuit in proportion to the magnitude of the flux linkages. If a twisted or spiraled pair of wires is used for the pilot circuit, no appreciable voltage difference will appear between the pilot wires. This is important, for the voltage difference that appears between the pilot wires must be limited to avoid operating the protective relay, or associated apparatus that is connected to the pilot circuit. Because of this, only longitudinally induced voltages, which are equal and in the same direction in both wires, will be discussed.

It will be noted that the flux which links the pilot wires from the ground current is 180 degrees out of phase with respect to that set up by the transmission-line current. Consequently, these two fields tend to cancel, or it may be said that the ground current tends to "shield" the pilot wires from induction. This effect becomes quite appreciable when ground wires carry a large portion of the ground-fault current.[1]

Figure 3 illustrates how the mutual impedance between the transmission line and pilot wires varies with the separation between the two circuits. Three different curves are drawn to illustrate how this quantity is affected by extreme variations in the resistance of the earth-return circuit or how the earth currents "shield" the pilot circuit from induction. When the earth resistivity is high, current returns deep in the ground and produces less shielding. The ground-fault current multiplied by the proper mutual impedance equals the magnitude of voltage that will be induced in the pilot-wire circuit. Note that this quantity can never exceed the magnitude of the transmission-line reactance drop. A voltage equal to that magnitude can be obtained only when the transmission line and pilot wires occupy the same space or have 100 per cent coupling. It should also be remembered that ground wires and return circuits that are provided by cable sheaths all tend to reduce the magnitude of the induced voltage. In general, the shielding that is obtained from a full-sized, lead-covered telephone cable will reduce the voltage that would be induced in an open-wire circuit by approximately 50 per cent.[1]

Figure 3. Approximate variation in mutual impedance between transmission circuit and pilot wires



Protective Measures

Disturbing voltages can be impressed on the pilot-wire circuits by lightning, electrostatic and electromagnetic induction, station ground potentials, and actual contact with power circuits. The damage which results from crosses with power circuits can be limited by solidly grounding and isolating portions of the circuit through action of arrester blocks and fuses. Frequently this will cause

relay operations that cannot be prevented. Voltages impressed on the circuit by lightning, induction, and ground potentials can be dissipated, distributed, or isolated with insulation in a manner that will not cause relay operation. This is accomplished by use of lightning arresters (which must be chosen so that they cannot be operated by system disturbances), by draining appreciable amounts of currents from the circuit through mid-tapped

transformers or similar balanced impedances, by altering the natural distribution of voltage stresses with neutralizing transformers or grounding impedances, and by insulating the apparatus or isolating it with insulating transformers so that it will withstand the applied voltage.

Insulating transformers have long been used to insulate the terminal equipment from disturbing voltages in pilot-wire circuits. They are also used to keep station ground potentials off the pilot wires. Insulation built directly into the relay can be used in a similar manner. This action is illustrated with typical graphical solutions in the latter part of this paper. The effects of electrostatic and electromagnetic induction can be counteracted directly in the pilot wires by current drainage, as by grounding the mid-points of the insulating transformers at both ends of the line. When this is done, it is necessary to consider thermal capacities of the equipment and inequalities in voltage drop in the individual pilot wires as any lack of symmetry in the circuit tends to insert an extraneous (unbalanced) voltage in the pilot loop and may affect the associated relay operation. Neutralizing transformers are used in circuits of this kind to reduce the circulating current to an absolute minimum and to provide a control means that can be used in d-c circuits.

To study the action of neutralizing transformers and determine the distribution of the disturbing voltages, pilot-wire equipment should be classified into groups at different potentials somewhat as follows:

1. Terminal equipment at station ground potential. In Figure 1 this includes the current transformers and relay parts up to and including the primary of the insulating transformer.

2. Terminal equipment on the station side of a neutralizing transformer. As neutralization is not perfect, this equipment operates at the remnant or unneutralized voltage to ground. In Figure 4 this includes the supervisory relay, secondary winding of the insulating transformer, and the capacitor between the two center taps of the insulating transformer.

3. The incoming pilot wires, any equipment connected thereto, and their potential with respect to ground.

4. The cable sheath, usually at true ground potential if insulated, or at station ground if connected thereto.

5. Other wires in the cables, and their potential to ground.

Figure 5b. Three-winding neutralizing transformer neutralizing longitudinally induced voltage

Z = Impedance of ground return circuit, *a* to *b*

E = Longitudinal voltage induced equally in pilot and neutralizing wires

m = Mutual impedance between exciting wire-ground return circuits, from *a* to *b*

$Z_{sp} = Z_s - M_s$, $Z_{rp} = Z_r - M_r$, primary leakage impedances

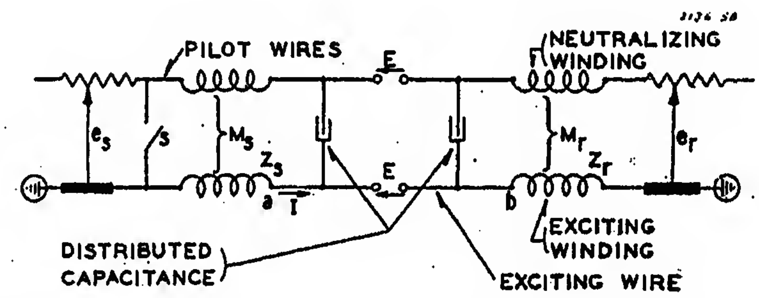
Total remnant voltage:

$$e_s - e_r = E \frac{Z_{sp} + Z_{rp} + z - m}{Z_s + Z_r - z} \tag{2}$$

Some of these items span from one potential to the other. The neutralizing transformers span from (3) to (2); that is, from the pilot wires to the remnant voltage point. The grounding capacitors span from (2) to (1); that is, from remnant voltage point to station ground. The insulating transformers span from (2) to (1).

Cable sheaths, if not connected to station ground, may usually be considered as at true ground throughout their lengths. They are usually grounded by leakage if not intentionally. Aerial cables with sheaths purposely insulated require a study of the various capacitive impedances, between wires and sheath, and sheath to ground, to determine the voltage with which their insulation is stressed. If a sheath is grounded along the line and also grounded to station ground, a heavy current will flow over it when there is a rise of station ground potential. The steepness of gradient along the cable sheath from station ground to true ground will depend on the resistance of the "pole grounds." Possible danger of burning the sheath should be checked, especially if the cable is buried under the power line so that it may carry a considerable part of the return fault current.

With given voltages, impressed on the pilot-wire circuit by longitudinal induction or a rise in station ground potential, the determination of voltage distribution as indicated above is a problem in conventional circuit theory. After determining each potential with respect to any convenient reference, such as true ground, the potential differences are obtained for verifying or designing the insulation co-



ordination. Graphic examples of this are given after operation of the neutralizing transformers is explained.

Three-Winding* Neutralizing Transformer

When used to protect against a difference in ground potential, the exciting winding of the three-winding neutralizing transformer is connected between true ground (remote pole ground) and the station ground as shown in Figure 5a. The pilot wires are connected in series with the secondary windings of the neutralizing transformer and thereby have a voltage almost equal and opposite to the station ground-potential rise impressed directly on them. Thus, with the pilot wires at true ground potential (sheath potential usually), the terminal relay equipment will be held close to station ground potential.

The connection from the exciting wind-

* Three winding is used to distinguish the type having a separate exciting winding. There may be any number of secondaries. Usually, there are two, through which a pair of pilot wires is carried.

Figure 6. Two-winding neutralizing transformer

ing to ground may be a wire carried out a few hundred feet to a pole ground. Or the cable sheath may be insulated for the last few hundred feet into the station and the exciting winding of the neutralizing transformer connected between it and station ground.

Assuming the pilot wires to be at true ground potential as indicated schematically by the dotted connection at d, Figure 5a, the remnant or unneutralized voltages between the terminal relay equipment and station ground can be expressed as a function of the station ground-potential rise, E_s, and the circuit constants shown. The voltage e_s, is the difference between the voltage drops from f to d, and a to d, due to I. Thus:

$$e_s = E_s \frac{Z_p + r}{Z + r} \qquad (1)$$

Commercial designs have been described[2] having 0.35 ampere exciting current with 4,000 volts applied to the primary winding. This results in an impedance Z = 4,000/0.35 or 11,400 ohms. The primary leakage impedance, Z_p, has been held to a value such that with a disturbing voltage, E_s, of 4,000 volts, the remnant voltage e_s, is 70 volts for $r=0$, and 81 volts for $r=35$ ohms. (r is the resistance of the exciting winding connections.)

The three-winding type of neutralizing transformer has also been used for neutralizing induced voltages.[3] In applications of this kind an exciting wire is run the full length of the pilot wires and has induced in it the same voltage as the pilot wires. However, the cost of the exciting pilot wire, which must be held to a low value of resistance, usually eliminates this scheme from consideration.

Two-Winding Neutralizing Transformer

The two-winding neutralizing transformer (or longitudinal choke) is a new form of neutralizing transformer in which the exciting current is conducted through the windings that are connected in series with the pilot wires and otherwise operates in the same manner as the three-winding neutralizing transformer. This design was introduced in 1935. The first application was for protection of extensive pilot wires along an a-c railway electrification.

The two-winding neutralizing transformer is designed to protect pilot wires and their terminal equipment from station ground potentials and longitudinally induced voltages. Its self-exciting feature is particularly valuable for applications which involve longitudinal induction, as it eliminates the need of a third pilot wire. Furthermore the device is more effective than the three-winding transformer, when used to counteract induced voltages, as the magnetizing currents flowing through the pilot circuit actually aid the neutralizing action.

By providing grounding capacitors as shown in Figure 6a, a complete excitation path is secured over the pilot wires. The resulting circuit which includes the induced voltage and the neutralizing transformers is termed a "self-exciting neutralizing-transformer circuit," since the exciting current is carried over the pilot wires which are also used for relaying.

The two windings of the neutralizing transformer are wound in the same direction on the core, so that currents which flow in the same direction in the pilot wires encounter exciting impedance, whereas relay loop currents, in opposite directions in the two pilot wires, encounter only the leakage impedance. The exciting impedance of such neutralizing transformers can readily be made as high as 100,000 ohms at 60 cycles with only 160 ohms added to the pilot-wire loop resistance. One-microfarad grounding capacitors, connected one from each wire to ground, have a parallel impedance of 1,325 ohms at 60 cycles and limit the remnant voltage to about 1.3 per cent of one half of the induced voltage. This assumes balanced conditions in which one half of the voltage is impressed across neutralizing transformers at each end of the pilot wires.

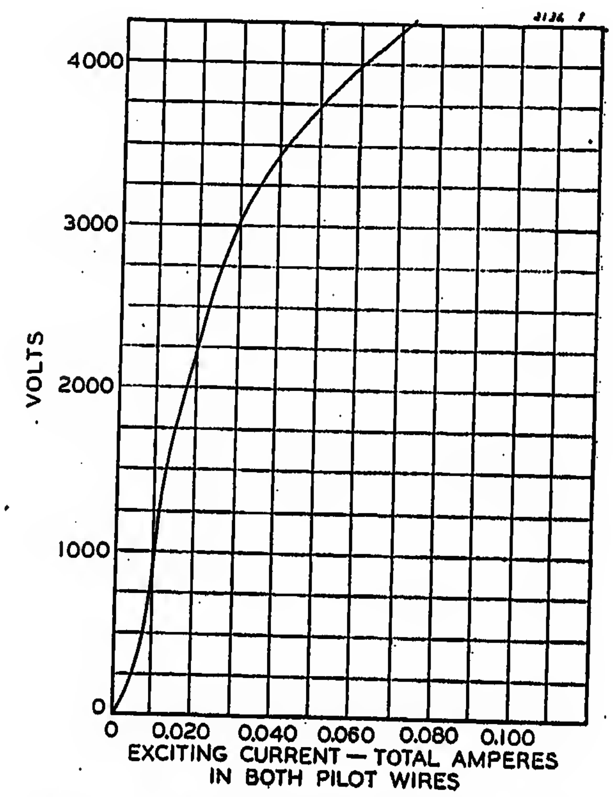

Figure 7. Saturation curve of typical two-winding neutralizing transformer (longitudinal choke coil)

Station Ground Potential

The theory of the two-winding type of neutralizing transformer, as used for neutralization of station ground potentials, may be understood from a consideration of Figure 6. The two pilot wires are considered paralleled, so that the parallel impedances are used. The remnant voltage, e_s, of the terminal relay equipment from station ground is given by

$$e_s = -IZ_c = -E_s \frac{Z_c}{Z_c + Z + Z_p} \qquad (2)$$

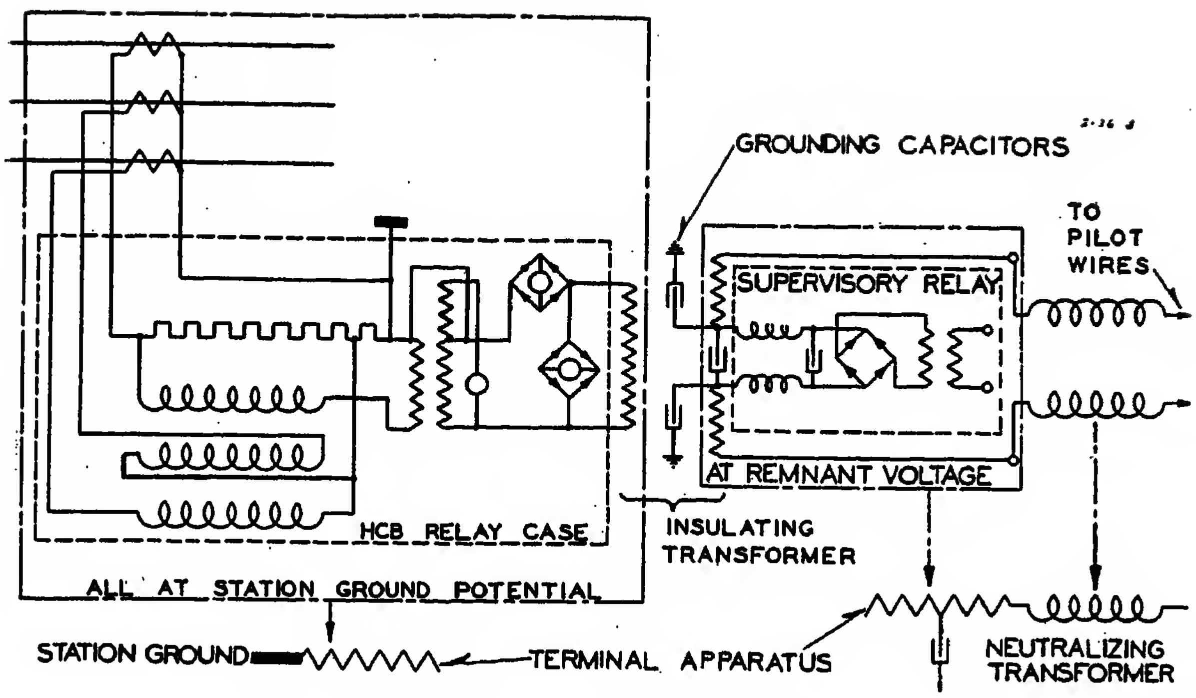

Figure 8. Actual connections

Arrows show parts included in each symbol of the potential-gradient diagrams

The voltage from the pilot wires to the cable sheath is

$$e_p = -IZ_p = -E_s \frac{Z_p}{Z_c+Z+Z_p} \tag{3}$$

In practice, the neutralizing-transformer exciting impedance Z is very large, compared with the other impedances in the circuit. Therefore, the neutralizing transformer has impressed on it approximately the full disturbing voltage, E_s. The corresponding exciting current can be determined by reference to its saturation curve, see Figure 7. The remnant voltage, e_s, is then numerically the product of the exciting current, I, and the impedance, Z_c of the grounding capacitors (see equation 2). Similarly, the voltage from pilot wires to sheath is the exciting current I multiplied by Z_p, defined in Figure 6b (see equation 3). If the distributed capacitance is small, the voltage drop from the pilot wires to the sheath may be high. This can be reduced by adding lumped capacitance ground at d or terminating impedance to ground at the other end of the line.

Figure 7 shows the excitation characteristics of a commercial design of a two-winding neutralizing transformer. At 3,000 volts the exciting current is 30 mils (15 mils in each winding), or the exciting impedance, Z is 100,000 ohms. At 4,000 volts the exciting current is 0.062 ampere. The impedance inserted in the relay loop circuit by this design is $160+j\,130$ ohms, per transformer, at 60-cycle frequency.

Longitudinal Induction

The theory of the two-winding neutralizing transformer, used for protection against longitudinally induced voltages, is given in the appendix. This treatment covers the general case in which both longitudinal induction and station ground-potentials are present. Remnant voltages for the simpler case of longitudinal induction only are obtained using the same equations with the station ground potentials set equal to zero.

The potential distribution is influenced by the relative values of terminating impedances to ground and distributed impedances to ground as well as the locations and amounts of induced voltages. These factors are taken into account in the exact theoretical treatment of the appendix. The important case in which a station ground-potential rise and longitudinal induction are both caused by the same primary fault current is fully developed, the voltage distribution being expressed by equations 5a to 9a of the appendix.

Potential Distribution for Typical Conditions With and Without Neutralizing Transformers

A reasonably accurate conception of the potentials existing in various parts of a pilot-wire circuit that is exposed to station ground potential or longitudinal induced voltage may be obtained from the typical diagrams in Figure 9. The potentials shown are based on 2,000 volts station ground potential or 4,000 volts longitudinal induction as indicated, but can be ratioed for other values of disturbing voltage. Various parts of the circuit are represented by symbols drawn in position to show the voltages to ground at which those parts operate under the abnormal conditions. In this discussion, operating voltages between wires are taken as zero, and the two wires are represented as one for determining voltages to ground. The operating voltages are usually negligible in comparison but can be superposed if appreciable.

Figure 8 illustrates which parts of a typical pilot-wire relay are included in terminal apparatus at "station ground potential," and which part operates at the "remnant voltage" to ground. The insulating transformer presents negligible impedance to pilot-wire currents in the same direction (two-winding neutralizing-transformer exciting currents) which flow to ground. It may, therefore, be considered as operating at the remnant voltage, although physically it is in the circuit between the terminating capacitances and the neutralizing transformer.

Parts (a) to (d) of Figure 9 show the distribution of 2,000 volts station ground potentials. Part (a) is without neutralizing transformers; it illustrates the distribution of voltage that is obtained when an insulating transformer is connected between the relay and pilot wires. Note that the relay is held at station ground potential, and the entire voltage difference is impressed across the transformer insulation. If a supervisory relay were connected directly to the pilot wires, with its base connected to station ground, its insulation would be stressed with the full 2,000 volts rise in ground potential.

If the cable sheath is tied to station ground, the rise in potential of the pilot wires depends on the relative lengths of pilot wires affected by sheath sections at true ground and higher potentials. For example, if one tenth of the length of cable sheath is elevated 2,000 volts and nine tenths is at true ground, the wires will rise to ten per cent of 2,000 volts, or 200 volts above true ground. If only one per cent of the sheath is elevated, the potential rise will be a corresponding proportion of the rise in the short length of sheath. A wire-to-sheath potential approaching the full station ground potential must then be provided for in the cable insulation. This illustrates that voltage stress on the cable can be reduced by insulating the cable sheath from station ground.

The use of two-winding neutralizing transformers is illustrated in parts (b) and (c). This transformer holds the relay parts that are metallically connected to the pilot wires at station ground potential, except for the small remnant voltage, caused by the neutralizing transformer exciting current passing through the capacitance to ground. These remnant voltages are usually under 100 volts. The effects of predominant and negligible pilot-wire distributed capacity are also shown in (b) and (c). The rise in pilot-wire potential indicated in (c), can be reduced by connecting small fixed capaci-

tors between the pilot wires and ground. The circuit then becomes equivalent to that shown in (b). In each case, the effect of connecting the sheath to station ground is shown. The resulting condition is tolerable, if the cable has ample insulation, and its sheath has ample current-carrying capacity. However, the sheath must be insulated from station ground if the cable is not insulated to stand 50 per cent to 100 per cent of the ground potential rise, with a suitable margin.

As shown in part (d), the three-winding neutralizing transformer produces a potential distribution under conditions of station ground voltage rise, substantially the same as for the two-winding neutralizing transformer with predominant distributed capacity.

The distribution of potentials resulting from 4,000 volts of longitudinal induction is illustrated in parts (e), (f), (g), and (h), taking into account the following variables:

With and without neutralizing transformers (two-winding type).

Pilot-wire capacitance predominant or negligible.

Different exposure conditions.

Parts (e) and (f) show that with predominant distributed capacity, introduction of neutralizing transformers leaves the pilot-wire voltages unchanged and simply lowers the potential of any relay equipment metallically joined to the pilot wires, to substantially station ground potential.

The natural distribution of pilot-wire potential determined by distributed capacitance, as explained in the appendix, can be modified by terminating capacitances to ground indicated in Figure 9(c) and (g). The distributions are shown, in part (g), for the case of distributed capacitance negligible compared with these terminating capacitors, and in part (c) for the case of distributed capacitance predominant. Other cases fall in between. The unbalanced voltage distribution which results from heavy induction near one end, when distributed capacitance is predominant, part (c), can be equalized by the addition of terminating capacitances.

As shown in parts (f) and (h), the neutralizing transformers operate to hold the relay equipment substantially at station ground potential except for the remnant voltage. Part (h) of Figure 9 also illustrates the use of a number of neutralizing transformers, connected at intervals in the pilot-wire circuit. This expedient is used to reduce voltages on the cable itself, as neutralizing transformers at the

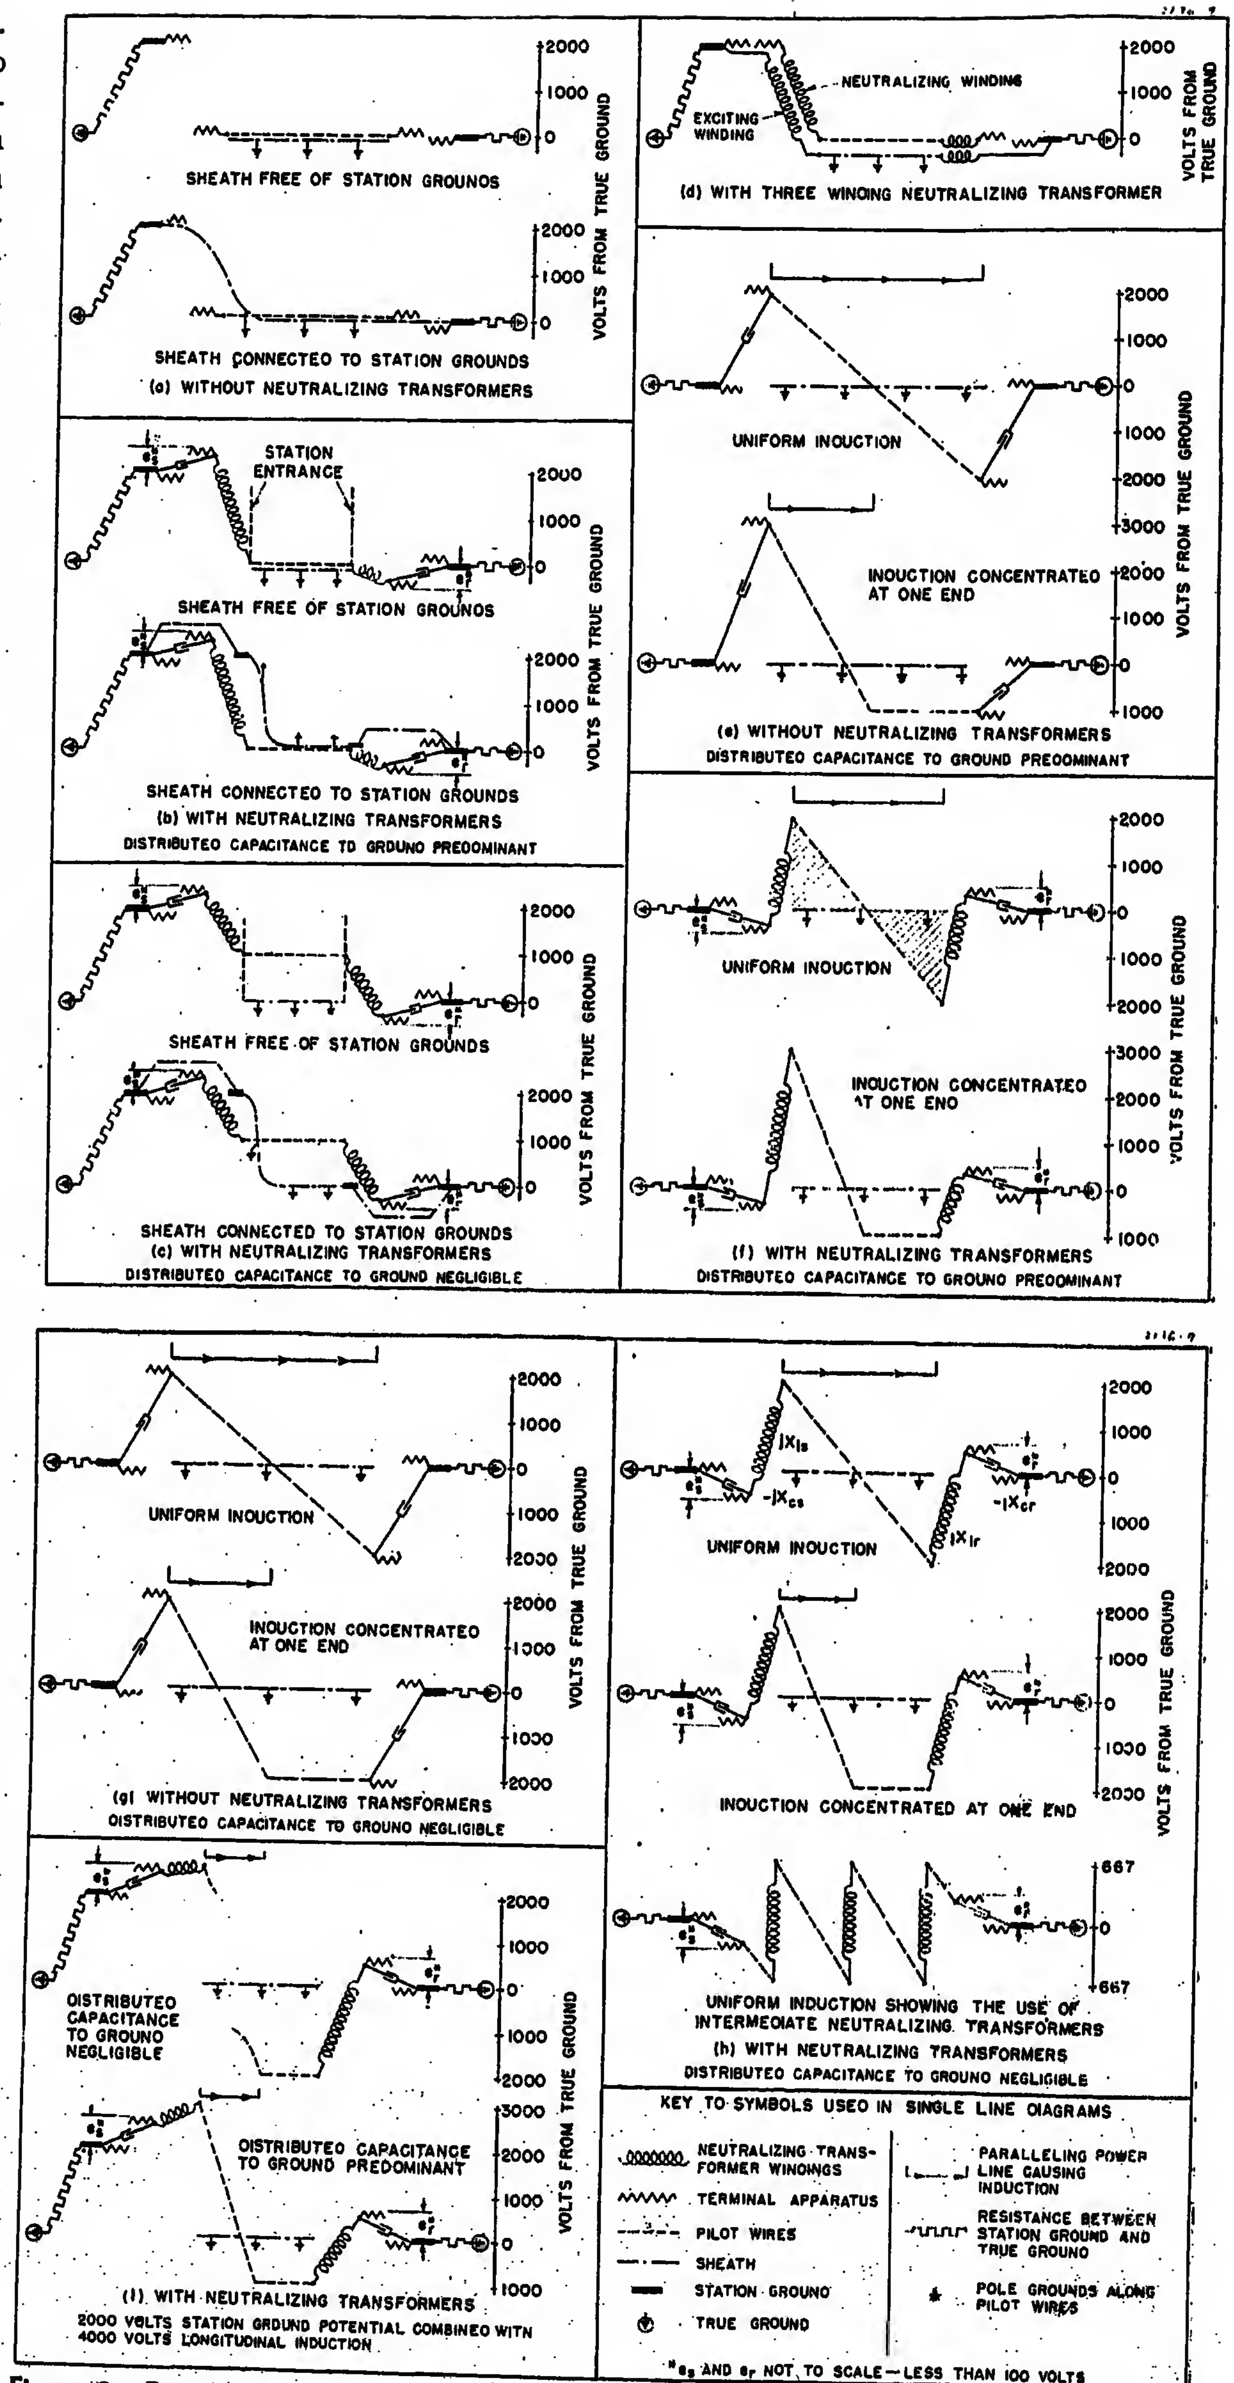

Figure 9. Distribution of wire-to-ground voltages caused by station ground potential and longitudinal induction

(a) to (d)—2,000 volts station ground potential
(e) to (h)—4,000 volts longitudinal induction
(i)—Combination of 2,000 volts station ground potential and 4,000 volts longitudinal induction

terminals provide adequate protection for the relay equipment.

Part (i) illustrates the potential gradient that is obtained when a combination of station ground potential and longitudinal induction exists. As one of these voltages is produced by resistance coupling and the other by mutual reactance coupling from the same current, the two are 90 degrees out of phase with each other. (The voltage produced by mutual coupling is ahead, if the reference directions are used as indicated in Figure 6, and the pilot wires are more closely coupled to a power phase wire than to the ground return.) As a result the voltage along the pilot wires varies not only in magnitude but also in phase position. Figure 9(i), shows the voltage magnitude to ground, of the principal parts of the circuit, but does not indicate the magnitude of voltage across the neutralizing transformers. The vectorial shift of the voltages along the pilot wires is illustrated in Figure 10.

The distribution of voltages that are imposed on pilot-wire circuits and their terminal equipments, by induction and station ground potentials, can be determined by use of the equations and diagrams presented herein. It will be noted that in many instances this can readily be accomplished by first determining the distribution of induced voltages, per Figure 6d, and then adding the rise in ground potential at right angles to it at the correct location in the circuit. The maximum stress on the pilot-wire insulation can be determined in this manner. If relay equipment is connected directly to the pilot-wire circuit, its insulation (and operating characteristics) must be able to withstand such a voltage, or neutralizing transformers must be installed to dissipate it and reduce the voltage stress at the relay to meet operating limitations. After the voltage distribution has been determined, as mentioned above, the effect of neutralizing transformers, or the use of grounding impedances, or of insulating transformers can be determined by simply subtracting the impedance drops from the voltages that are impressed on the circuit.

In general, all parallel wires that enter a cable at a given point should be protected in a similar manner to make certain that all wires within the cable are held at the same potential. A circuit of this kind should be studied, and the necessary protective measures must be taken to avoid the transfer of disturbing voltages from one set of wires to the other.

The paper has reviewed the problem of protecting pilot-wire circuits with emphasis on high-speed relay requirements and has presented mathematical and graphic aids to help the reader visualize it. It has also presented a mathematical analysis of a new tool, the two-winding neutralizing transformer, that is well suited to use in dissipating disturbing voltages that are frequently impressed on pilot-wire circuits. Use of this "tool" and the methods of analysis described should be of value to the users of pilot-wire circuits in avoiding difficulties that have been previously overlooked. The important points to be checked are the adequacy of insulation provided at different points in the circuit, and the voltage that is impressed on the lightning arresters. This latter point is of primary importance on leased circuits that are used with high-speed protective relays. The voltage distribution must be such that lightning protection is never operated by power-system disturbances.

Appendix. General Case of Longitudinal Induction and Ground Potential

In the general case where both station ground potentials and longitudinal induced voltages are present, the voltage distribution can be determined in the following manner: First determine the distribution of the induced voltage in the pilot wires to obtain the value k; this is done with the terminal equipment disconnected. Then complete the circuit to calculate the distribution of voltages in the entire circuit as will be explained.

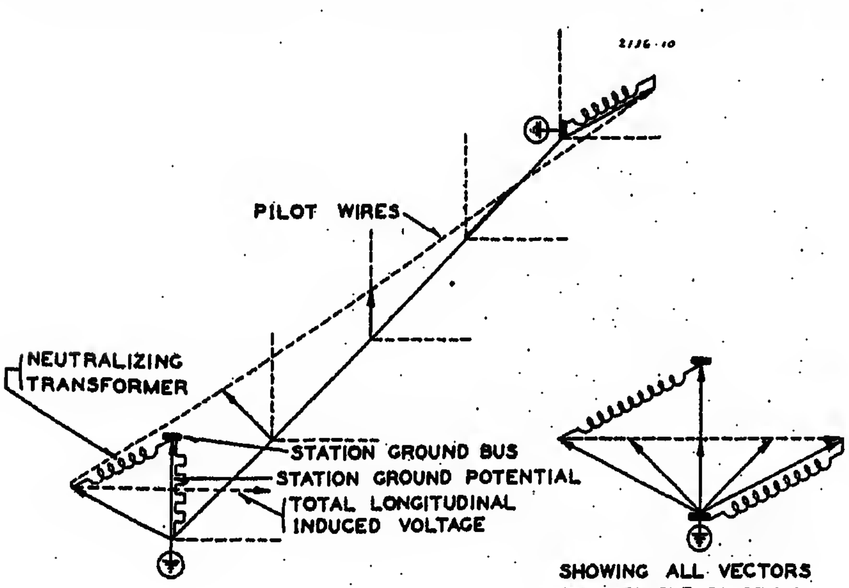

Figure 10. Vector voltage distribution along pilot wire exposed to both station ground potential and longitudinal induction

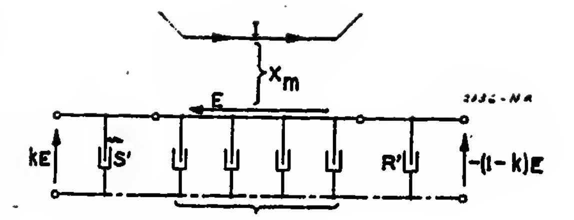
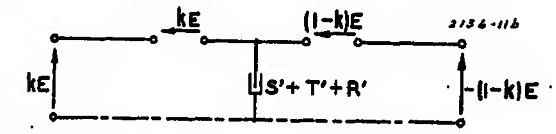


(a) Actual circuit

Uniform section of distributed capacitance and induced voltage

Total shunt capacitance in this section $= T'$

Total induced voltage $= E$



(b) Circuit equivalent to (a) as far as terminal conditions are concerned

Figure 11. Potential gradient for induction in part of a section

$$k=\frac{2R'+T'}{2(R'+T'+S')}$$

Z_{cp} = Impedance corresponding to $S'+T'+R'$

All capacitances in microfarads

As shown in Figure 6d, the pilot-wire circuit can usually be replaced by a T section composed of two parts of the induced voltage, kE and $(I-k)E$, and the total shunt capacitive impedance of the two wires to ground, Z_{cp}. This assumes that voltage drops in the series impedance of the pilot wires, caused by the shunt capacitive current, are negligible. The value of k can be determined by considering the voltage distribution in the pilot wires with the neutralizing transformers and terminal equipment disconnected. If shunt impedances are all capacitive, either distributed or lumped, the voltage distribution diagram can be constructed as shown. The positive and negative areas A are made equal, since they are proportional to the charging currents entering and leaving the pilot wires, which must be equal. This is most easily visualized by referring to Figure 6d. Note that the abscissa is capacitance, rather than distance to allow for cable or open wire, and lumped capacitance effects. Thus the potential distribution diagram can be readily drawn from the known capacitances and induced voltages by making the areas equal.

One of the most common cases is shown in Figure 11. Uniform induction, of total voltage E, occurs over a section having uniformly distributed capacitance, totaling T' microfarads. The sum of remaining distributed capacitance plus lumped capacitance at one end is S' and at the other end, R'. For this case

$$k=\frac{2R'+T'}{2(R'+T'+S')} \tag{4}$$

After the potential distribution in the pilot wire above has been determined, that is, the value of k fixed, the equivalent diagram can be connected to the terminal equipment as in Figure 6c. A vector solution of the resulting two-mesh network gives the various voltages and exciting currents.

120-Kv Compression-Type Cable

R. W. ATKINSON
FELLOW AIEE

THE oil-filled type of high-voltage paper-insulated cable has been used on all extra high-voltage underground installations now in service in this country. While the major portion of these installations operates at oil pressures under 30 pounds per square inch, several of the shorter ones utilize oil pressures up to 200 pounds per square inch ("oilostatic" type). Although an alternate system[1] in which a high gas pressure is applied externally to the lead sheath has been in commercial service abroad since 1932, it was not until recently that this type of cable, known as compression cable, received serious study here. In 1939 the Detroit Edison Company found that a system employing a welded steel pipe line offered a number of advantages over the conventional duct installation under the conditions existing over the route of a projected 120-kv underground circuit. For this reason the companies with which the authors are associated initiated an intensive laboratory and field investigation of the technical characteristics of several systems employing a steel pipe. The present paper describes some of the more interesting results of the technical investigation on the compression cable system.

Essentially the compression-cable system comprises a cable that is in most respects an ordinary solid-type cable encased in a pressure chamber in which a gas pressure of approximately 200 pounds per square inch is applied externally to the lead sheath. In any high stress design it is necessary to eliminate entirely or nullify effectively the two important inherent defects of ordinary solid-type cable:

1. The expansion and contraction of the impregnating compound with the load cycle must be provided for.

2. The small but inevitable gas occlusions within the insulation must be rendered innocuous.

In the low-pressure oil-filled cable the first requirement is taken care of by incorporating an oil-flow channel or channels within the cable and by locating along the route reservoirs having expansible cells and an external gas supply to maintain positive pressure. The second prerequisite is met by employing a design which allows more complete degassing of the oil and saturation of the paper than obtained in ordinary solid-type cable. Several investigators have patented designs in which impermeable expansible members and the associated gas supply are incorporated in the conductor or sheath of the cable itself. Because of economic considerations none of these latter designs has attained commercial recognition. In the compression cable system the cable is made noncircular so that the lead sheath by change of shape may serve as an impermeable expansible member, the action of which is made reversible by external gas pressure. Thus the cable becomes self-compensating in that on increasing load the volumetric increase is accommodated by an increase in the cross-sectional area, while on decreasing load the external gas pressure causes the reverse action to take place, thereby preventing void formation as a result of load changes.

In actual practice the compression cable is made oval in cross section so that the shape is free to change in such a direction as to alter the minor axis at the expense of the major axis and hence alter the cross-sectional area without necessitating any large change in the periphery of the cable. A thin metal binder tape with paper tape over and under it is applied over the lead sheath in order to insure uniform diaphragm action along the sheath. The external gas pressure is secured by placing the cable in a welded steel pipe line filled with nitrogen gas under pressure. By actual field and laboratory experience it has been found that a gas pressure of about 200 pounds per square inch is adequate to maintain a positive internal oil pressure sufficiently high to prevent ionization in those voids

Paper 42-133, recommended by the AIEE committee on power transmission and distribution for presentation at the AIEE summer convention, Chicago, Ill., June 22–26, 1942. Manuscript submitted April 11, 1942; made available for printing May 20, 1942.

I. T. FAUCETT is chief engineer, General Cable Corporation, New York, N. Y.; L. I. KOMIVES is engineer, underground lines department, and H. W. COLLINS is assistant to the superintendent of the electrical system, both with Detroit Edison Company, Detroit, Mich.; and R. W. ATKINSON is director of the high-voltage research department, General Cable Corporation, Bayonne, N. J.

The authors are indebted to many of their engineering associates who have contributed to this work. They wish especially to thank S. M. Dean, W. S. Brown, F. G. Cox, R. C. Fellows, H. C. Frank, H. G. Hall, E. Johansson, L. Meyerhoff, E. Richman, C. B. Sharp, and G. J. Shurts.

These are

$$I_s=\frac{-E_rZ_{cp}+Z_{cp}(1-k)E+(Z_{cr}+Z_r+Z_{cp})(kE+E_s)}{(Z_{cs}+Z_s+Z_{cp})(Z_{cr}+Z_{cp}+Z_r)-Z_{cp}^2} \quad (5)$$

$$e_s=Z_{cs}I_s \quad (6)$$

$$e_r=e_s-E-E_s+E_r \quad (7)$$

$$E_{sp}=-E_s+I_s(Z_s+Z_{cs}) \quad (8)$$

$$E_{rp}=E_{sp}-E \quad (9)$$

E_r and E_s = station ground potentials at r and s

E = voltage induced in the pilot wires

Frequently, the shunt capacitance to ground of the pilot wire will be so large that the potential distribution of the pilot wires will be relatively unaffected by the connection of the neutralizing transformers and terminating capacitors, Z_{cs} and Z_{cr}. Test of this condition is whether the neutralizing transformer impedance (approximately 100,000 ohms for a commercial design) is large compared with the capacitive reactance to ground (sheath) of the pilot wires. In this case corresponding to $Z_{cp}=0$, the disturbing voltages can be taken as E_s+kE at the "s" end and $(1-k)E$ at the "r" end. The voltages e_s and e_r can then be determined by multiplying Z_{cs} and Z_{cr} respectively by the neutralizing transformer exciting current (Figure 7) corresponding to these disturbing voltages.

A practical case of considerable importance is that of station ground potential at only one end, combined with longitudinal induction from the same power current. For this case, represented in Figure 6c by $E_r=0$, the longitudinally induced voltage E is 90 degrees ahead of the station ground potential E_s. Thus taking E_s as reference, ($\bar{E}_s=\bar{E}_s$) equations 5 to 9 reduce to 5a, to 9a, as shown below:

When $E_r=0$ E_s = reference = $\bar{E}_s$ $E=90°$ ahead $=j\bar{E}$

Substituting these quantities in equations 5 to 9.

$$I_s=\frac{jZ_{cp}(1-k)\bar{E}+(Z_{cr}+Z_r+Z_{cp})(jk\bar{E}+\bar{E}_s)}{(Z_{cp}+Z_s+Z_{cp})(Z_{cr}+Z_{cp}+Z_r)-Z_{cp}^2} \quad (5a)$$

$$e_s=Z_{cs}I_s \quad (6a)$$

$$e_r=e_s-j\bar{E}-\bar{E}_s \quad (7a)$$

$$E_{sp}=\bar{E}_s+I_s(Z_s+Z_{cs}) \quad (8a)$$

$$E_{rp}=E_{sp}-j\bar{E} \quad (9a)$$

which are inherent in solid-type cable when operated in the usual manner. In consequence of the application of this principle of using high gas pressure in conjunction with an oval-shaped cable and the lead-sheath separator, it is possible to operate ordinary solid-type insulation at voltage stresses and conductor temperatures comparable with those used on the oil-filled type of cable.

Experience Abroad

The first commercial circuit of compression cable was installed in England in 1932. The cable used in this initial 66-kv installation was a three-conductor type *HSO* design, that is, a conventional three-conductor type *H* cable with round conductors and binder tape and a triangular-shaped sheath, the latter being obtained by omitting the major portion of the filler material. In order to distribute the diaphragm action as uniformly as possible over the flat sides of the triangular-shaped sheath, a metal binder tape with an asphalted paper tape over and under it, was applied over the sheath. A rectangular steel wire armor applied with a long lay completed the makeup. The armor wires were considered necessary in order to permit the pulling in of a long length of cable without injury. It is the practice abroad to allow these armor wires to take the entire strain of the pull.

While from an electrical point of view this installation has operated satisfactorily since being placed in service, yet on the basis of subsequent experience and laboratory tests the use of the type *HSO* construction has been discontinued abroad and another construction known as type *HSL* has been adopted, because it is easier to manufacture and lends itself better to diaphragm action of the lead sheath. In the latter design three oval-shaped conductors, each separately insulated, leaded and reinforced with several metal tapes, are cabled together with a short lay and armored with steel tape.

In addition to the two designs mentioned, both of which are installed in a steel pipe, a third type known as the self-contained compression cable has been developed abroad. In this design the function of the steel pipe is accomplished by an outer lead sheath which is separated from the diaphragm sheath by a spacer wire to provide a gas channel and is suitably reinforced to withstand high gas pressure. It was at first considered that this design might find some application for duct systems in this country. However, to protect the metallic reinforcing tapes against mechanical damage and corrosion, a third lead sheath would be desirable. With the large conductor sizes commonly employed here, the resulting sheath losses, which cannot easily be prevented, would be excessive. In view of these facts, this type cannot be justified economically.

At the end of 1940 there were over 55 conductor miles of compression cable in service abroad operating at voltages ranging from 50 to 120 kv. Operating experience on these installations has been entirely satisfactory from an electrical standpoint. Electrolytic corrosion of the pipe was experienced on the first installation in England as the result of poor pipe coating, and mechanical trouble near the joint wipes was encountered on a 50-kv installation in Copenhagen because of inadequate provisions for the differential longitudinal movement between cable and pipe.

Because of the difficulty of obtaining precise information on all phases of the foreign installations, and the hazard involved in extrapolating foreign experience to relatively large loads and consequently large conductor sizes normally used in this country, it seemed advisable to recheck fully the mechanical features of the system in the laboratory and in the field by means of an experimental installation.

Preliminary Studies

Diaphragm Action

It was first essential to determine whether the lead sheath could withstand indefinitely the diaphragm action resulting from temperature changes occurring during normal operation of cable. Accordingly extensive laboratory tests were made on pure lead sheath simulating the normal conditions of operation.

It is reasonable to assume that the maximum daily temperature change would be approximately 20 degrees centigrade, which would correspond to a volume change of one-half of one per cent. This about equals the volume difference between an oval-shaped sheath in which the ratio of the minor to major axis is 0.9 and a circular sheath of the same perimeter. Assuming the maximum seasonal change to be 80 degrees centigrade, a volume change of two per cent would occur. To obtain the desired information on the mechanical performance of the lead sheath it was necessary to subject the samples to changes in volume corresponding to both these daily and annual changes. The two per cent volume change would occur once for every 365 of the one-half of one per cent volume change cycles. The test program adopted for most of the measurements consisted in subjecting the samples to one two per cent volume change and 300 one-half of one per cent volume changes in a 24-hour period. This accelerated laboratory test program subjected samples in a single day to the equivalent of approximately one year's diaphram action under normal operation.

Samples of compression cable 32 inches long were used for the tests. The diaphragm action or change of volume was

Table I. Tests of Diaphragm Action of Lead Sheath

Sample Number	External Pressure Medium	Internal Pressure Medium	Type of Cycle	Temp.	Lead Thick. Mils	Origin of Cracks	No. of Cycles to Failure

A—Oil initially degassed, but becoming slowly contaminated with air.

B—Degassed oil protected by Sylphon diaphragms from air contamination.

C—Compressed air.

D—Nitrogen (water-pumped).

produced by causing pressure differentials between the inside and outside of the cable sheath. At the start of the tests oil, not highly degassed, was used as a pressure medium on the inside of the sheath and compressed air was used directly on the outside. The first eight samples tested on the cycle described gave a life ranging from 4,100 to 5,800 cycles (number of one-half of one per cent volume cycles) at room temperature. Examination of these samples after failure showed evidence that the incipient cracks which occurred had originated on the outside surface of the sheath. Since that surface was in direct contact with the compressed air it seemed likely that oxidation may have influenced the results. Subsequent tests were made in which carefully degassed oil was used as an external pressure medium. This change immediately resulted in a life ranging from 11,500 to 13,000 cycles. Further precautions to insure carefully degassed oil on the inside as well as the outside of the sheath resulted in a life ranging from 15,240 to 24,000 cycles, that is, a life approximately four times as great as that obtained when no precautions against oxidation of the sheath had been taken.

Table I gives the results of laboratory tests on five different kinds of samples (*M, N, O, P, Q*) each representing some change in either sheath thickness, tension of paper tapes during manufacture, or in degree of looseness of armor tapes. In general these structural differences had no significant effect on the life of the sheath.

Samples tested with air as a pressure medium show that thinner sheaths and higher temperatures decrease the ability to withstand diaphragm action. This may be attributed to the effect of oxidation.

The test conditions differed from service conditions in two important respects, namely:

(*a*). That each cycle is carried out in about $^1/_{300}$ the time that would occur in practice.

(*b*). That the volume ranges in the test cycles correspond to load conditions which are possible in service but are not normal for most installations.

In both of these respects, the test conditions are the more severe. The stresses required to produce the same amount of deformation in the sheath are very much less for slowly applied deformation. For a given deformation where the lead is not exposed to oxidation as under service conditions, a greater number of cycles is required to produce failure when the period is long than when it is short. In view of this and the fact that the number of full volume daily cycles per year will generally be less than 300, the approximate 50 years represented by 15,000 cycles is a conservative estimate for the life of the lead sheath.

Longitudinal Movement
